observable, nor can the observed spot volatility simply be substituted for it (the spot market itself also contains a noise component of about 40%); empirically, it can only be approximately identified with the help of the natural experiments discussed below [46] and the permanent/transitory variance decomposition [10], so the credibility of this benchmark is limited by the credibility of the spot-noise decomposition. Unlike the stock excess volatility Shiller found, which stems mainly from investor sentiment and discount-rate volatility, the excess volatility of perpetual futures is driven to a large extent by the mechanism-induced design and liquidity frictions analyzed in this chapter, which is an important feature distinguishing the crypto derivatives market from traditional asset markets (this chapter does not claim that the excess volatility of perpetuals can be explained by Shiller's discount-rate channel; it borrows only his measurement structure of "actual volatility exceeding the volatility that fundamentals should support"). In a fully efficient market, the price change of a derivative should reflect only the change in the discounted value of the underlying asset's future cash flows or updates to macro fundamental information. In crypto markets, however, the price-discovery process is often accompanied by significant microstructure noise. As cited in Section 22.6.2, the signal-to-noise ratio of the crypto market is significantly lower than that of traditional stock markets such as the NYSE and NASDAQ [11]. This high proportion of noise trading means that most price volatility is driven not by fundamental information but by the trading behavior of market participants itself.

The core challenge in measuring the excess volatility of perpetual futures is how to control for information differences. Because perpetual futures and the spot market share the same underlying asset, their price-discovery processes are highly intertwined, and a simple subtraction of volatilities cannot accurately isolate the common volatility driven by information flow. To isolate pure excess volatility, financial economists usually adopt a natural-experiment design. For example, by observing the changes in market structure before and after the approval of U.S. spot Bitcoin ETFs, researchers found that spot-market volatility declined significantly after the introduction of a more information-efficient investment channel, which supports the stabilization hypothesis that over-speculation in the derivatives market causes the spot market to bear additional volatility [46].

Another measurement framework separates the permanent component from the transitory component through variance decomposition of high-frequency data. The permanent component represents the information-driven price random walk, while the transitory component captures the mean-reverting volatility caused by liquidity shocks and market frictions. As cited in Section 22.6.2, the share of the noise component in the total variance of crypto prices is significantly higher than in traditional stock and foreign-exchange markets [10]. This systematically high noise share provides a benchmark for quantifying the microstructure frictions unique to perpetual futures.

22.7.2 Source attribution

The excess volatility of perpetual futures is not caused by a single factor but is the joint result of its unique market-microstructure features. One categorical point must be clarified first: by definition, excess volatility has already removed the informational

component common to perpetuals and spot (the two cancel each other out in the subtraction), so the source decomposition in this section focuses on three sources unique to perpetuals—mechanism-induced, liquidity, and transmitted. The "informational" item appearing below and in Figure 22-15 refers specifically to the information-overshoot differential that perpetuals produce relative to spot because of high leverage (its amplification mechanism is classified under mechanism-induced volatility), not to informational volatility itself. Figure 22-15 illustratively presents the relative contribution of these sources to the excess volatility of perpetual futures.

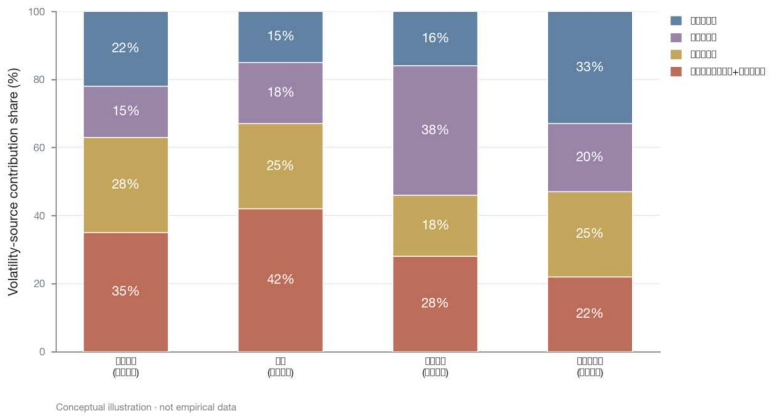

Figure 22-15. Source-attribution decomposition of the excess volatility of perpetual futures (drawn by the author: the relative share of each source is an illustrative estimate based on the logic of event-window/variance-ratio decomposition and the four-source conceptual framework; the four-source decomposition is a first-order approximation and liquidity is a residual category, see Section 22.1.3; not a precise measurement based on a single empirical sample)

As shown in Figure 22-15 (the proportions in the figure are an illustrative ordering, not a precise statistical decomposition), mechanism-induced volatility usually accounts for a larger share of the excess volatility (its core being the periodic noise of liquidation cascades and funding-rate settlement), followed by liquidity volatility, with transmitted volatility being especially prominent in crisis events; the information-overshoot differential, though a relatively small share, nevertheless shows by its existence that even a *good* price-discovery process generates some excess volatility through overshoot in a high-leverage environment.

Based on the analysis in Sections 22.4 and 22.3, the contribution of each source to excess volatility can be summarized as follows (the following is a conceptual attribution ordering based on mechanism analysis, not a precise measurement of variance shares). Mechanism-induced volatility is very likely the main contributor to excess volatility. As argued in Sections 22.4.1 and 22.4.2, liquidation cascades and the funding-rate settlement cycle are its core driving forces. Empirical evidence further shows that during the every-8-hour funding-rate settlement window of perpetual futures, adverse-selection risk in the spot market also increases significantly, causing quote spreads to widen and market depth to deteriorate [20], which means that the impact of mechanism-induced volatility has already spilled over into the microstructure of the spot market.

Liquidity volatility is another main contributor to excess volatility, rooted in the frag-

mentation of crypto-market depth and the constraints of market makers' inventory management. On high-frequency time scales, the temporary price deviation triggered by a large order and its subsequent partial reversal are a typical manifestation of liquidity friction [47]. Transmitted volatility contributes prominently in crisis events, as the extreme volatility of large-cap assets is rapidly transmitted to less liquid altcoin markets [48]. Although informational volatility is theoretically an efficient price-discovery process, because the high leverage of perpetual futures naturally attracts informed traders, the process of information being incorporated into prices is often accompanied by overshoot, and this overshoot itself also constitutes a component of excess volatility.

22.7.3 The heterogeneity of excess volatility

Excess volatility exhibits significant heterogeneity across different types of crypto assets and different stages of market development. From the asset dimension, Bitcoin's excess volatility is systematically lower than that of Ethereum and other mid-cap altcoins. This difference is mainly attributable to the fact that the Bitcoin spot market has the deepest liquidity and the broadest institutional participation, and its perpetual futures market has the highest arbitrage efficiency. By comparison, the altcoin spot market has poorer liquidity and lacks an effective short-selling mechanism, causing its perpetual futures to often accumulate a large basis in one-sided markets, which in turn triggers more violent funding-rate arbitrage volatility and liquidation shocks. Figure 22-16 tracks the evolution over time of the excess volatility of different asset classes.

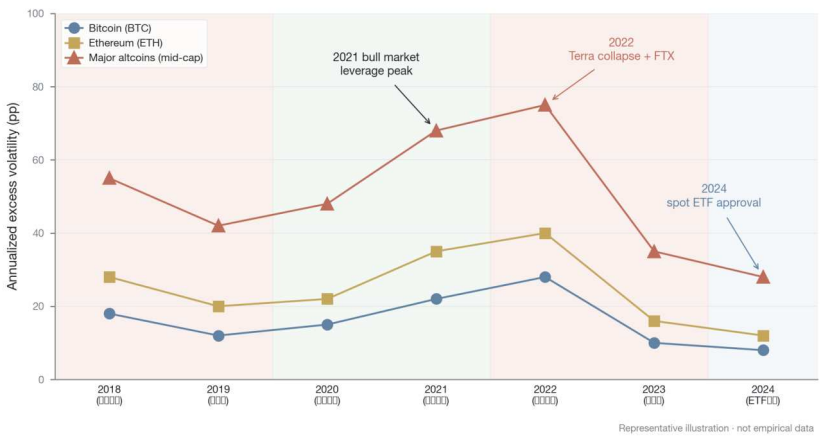

Figure 22-16. Time evolution of the excess volatility of perpetual futures across asset classes (representative illustration: the evolution trend, across the market cycle, of the annualized excess volatility of the perpetual futures of BTC, ETH, and altcoins ranked 10–30 by market capitalization relative to contemporaneous spot; a trend illustration, not measured monthly RV differences)

As shown in Figure 22-16, the excess volatility of altcoins is consistently higher than that of Bitcoin and Ethereum, and jumps by a larger amount when volatility intensifies; Bitcoin, by contrast, is relatively moderate and stable, reflecting its mature market-making ecosystem and efficient cross-market arbitrage. The long-term downward trend of the three curves suggests that the crypto derivatives market is gradually moving toward institutional maturity.

Examined from the time dimension, excess volatility exhibits a strong procyclical feature. In the bull-market phase, driven by retail FOMO and strong demand for leverage, market-wide open interest and leverage rise sharply. This high-leverage environment greatly amplifies the sensitivity of prices to small shocks, making excess volatility during a bull market significantly higher than during a bear or range-bound market. When the observation horizon is extended to the 10-year period from 2015 to 2025, however, one finds that the price-formation mechanism of the crypto market is undergoing a structural transformation. Since 2017, the noise component of the market's total variance has shown an overall downward trend, but with cyclical rebounds during speculative frenzies—for example, temporary jumps in the noise share can be observed during the 2020 DeFi boom and the 2024 memecoin wave. At the same time, the component reflecting overall market information has risen steadily from a long-term perspective.

This long-term downward trend reflects the gradual maturation of the crypto market. As market regulation has tightened, derivatives infrastructure has matured, and institutional investors have entered in depth, the market's pricing efficiency has improved substantially. For example, empirical analysis of successive Bitcoin halving events shows that, as the market becomes more standardized, the abnormal returns and excess volatility around halving events are both declining significantly [49]. The abundance of institutional arbitrage capital allows the calendar and cross-market basis to be closed more quickly, thereby suppressing the extreme price volatility triggered by local liquidity exhaustion.

22.7.4 Welfare implications

Quantifying excess volatility ultimately requires answering its welfare-distribution impact on market participants. The additional volatility created by perpetual futures is not evenly distributed among all participants but profoundly reshapes the market's wealth-transfer pattern. For profit-maximizing informed traders and high-frequency arbitrage institutions, high volatility is directly equivalent to high-frequency trading opportunities and rich arbitrage space. Using advanced algorithms and low-latency infrastructure, they extract profits from the periodic swings of the funding rate and the instantaneous mispricing triggered by liquidation events.

Market makers' attitude toward excess volatility, however, is more complex. Moderate volatility can bring considerable bid-ask spread income, but when volatility breaks through a certain threshold, the inventory risk faced by market makers rises sharply. Empirical data from the options market show that when market makers' aggregate gamma inventory is imbalanced, they significantly widen quote spreads to hedge risk, causing overall market liquidity to dry up [50]. This liquidity retreat often occurs precisely when the market most needs depth, further intensifying the spiraling price decline. Figure 22-17 uses a tiered framework diagram to summarize the differentiated welfare impact of excess volatility on different groups of market participants.

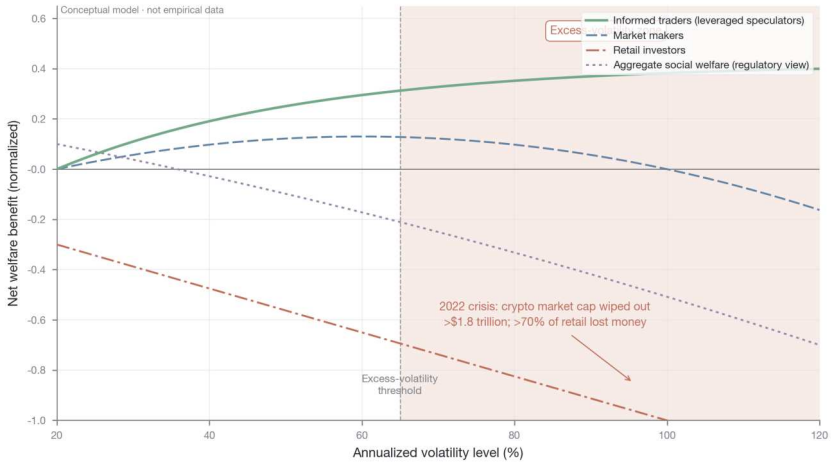

Figure 22-17. The welfare impact of excess volatility on different market participants (Data source: drawn by the author, supplemented with data on retail loss rates from Cornelli et al. (2023) [51])

As shown in Figure 22-17, the welfare effect of excess volatility is markedly asymmetric: informed traders and high-frequency arbitrage institutions sit at the positive end, benefiting from higher volatility and more frequent mispricing opportunities; market makers are in the middle, with moderate volatility bringing spread income but extreme volatility bringing inventory losses; retail investors are at the negative end, lacking an informational advantage and risk-control tools, more easily triggering forced liquidation and thereby becoming the bearers of a systemic wealth transfer.

Near the positive end of the welfare distribution, there is also a class of size-driven participants who win by position size rather than analytical capability—namely, large holders. Although these participants do not rely on an informational or analytical advantage, their large positions give them the ability to influence the timing of a liquidation cascade through strategic selling or accumulation. In excess volatility, large holders play a dual role: they may profit by intensifying mechanism-induced volatility through selling, or they may become a key force for market stability when liquidity is exhausted. This internal heterogeneity suggests that the three-way framework of Figure 22-17 still admits further stratification at the informed-trader end.

Retail investors are the main losers in excess volatility. Lacking sophisticated risk-management tools and a deep understanding of market microstructure, retail investors are extremely prone to triggering forced liquidation during excess volatility. A BIS research report reveals this striking wealth transfer: during the crypto-market crisis of 2022 (during which market-wide capitalization shrank by more than $1.8 trillion), large investors successfully reduced their holdings before the crisis erupted, while a large number of retail investors added to positions against the trend during the decline, ultimately causing most crypto-app users to suffer substantial losses [51]. This systematic transfer of wealth to institutions indicates that the high-leverage mechanism of perpetual futures has a significant negative welfare effect in an environment lacking investor protection.

From the macro perspective of regulators, persistent excess volatility is not only a

signal of market manipulation and institutional deficiency but also a manifestation of financial-resource misallocation. If the price movements of a market are driven mainly by endogenous mechanism friction and speculative noise rather than reflecting fundamental value discovery, then that market cannot effectively perform the core function of capital allocation. How to optimize the design of the liquidation mechanism—for example, by introducing auction-based liquidation to reduce price impact [31]—and how to regulate leverage caps will therefore be key challenges for the crypto derivatives market as it moves toward maturity and ultimately integrates into the mainstream financial system.

22.8 Chapter summary

Price volatility in perpetual futures markets is not a homogeneous random-walk process but a complex product jointly shaped by four mechanisms of fundamentally different natures. Informational volatility reflects how the market prices new fundamentals, macro events, or on-chain data, and is an indispensable price-discovery mechanism of a healthy market. Liquidity volatility arises from temporary price shocks when order-book depth is insufficient and is a friction cost of market microstructure. Mechanism-induced volatility is driven entirely by the institutional design unique to perpetual futures, including the forced liquidations triggered by liquidation cascades and the predictable pulses brought by the funding-rate settlement cycle. Transmitted volatility reveals the linkage across assets and markets, allowing an isolated event to spread globally through arbitrage channels and margin-cross effects.

The relative shares of these four sources under different market regimes constitute the dynamic switching mechanism of the volatility budget. In a normal market, informational volatility dominates, and price movements mainly reflect the genuine arrival of information. When the market faces stress or falls into crisis, however, sharp liquidity contraction and mechanism-induced liquidation rapidly take over the volatility budget. At this point, most of the price movement observed in the market no longer contains new information but is pure structural noise. This exit of informational volatility and sharp expansion of frictional volatility under extreme conditions is central to understanding the fragility of the crypto market.

A direct corollary of the four-source decomposition framework is that perpetual futures markets exhibit significant excess volatility. Comparison with the spot market and traditional financial derivatives shows that the total volatility of perpetual futures is systematically higher than the level its information content should support. This excess portion is contributed mainly by liquidity frictions and mechanism-induced deficiencies and is a hidden cost that the current institutional design imposes on all market participants. The existence of excess volatility not only increases market makers' inventory risk but also causes retail traders to trigger stop-losses more frequently, systematically harming market welfare. More critically, because mechanism-induced volatility such as liquidation cascades and funding-rate settlement is largely endogenous to the rules, this portion of excess volatility can in principle be substantially reduced through institutional optimization (such as introducing gradual liquidation or a continuous funding rate); but because there is a fundamental trade-off between liquidation efficiency and

system solvency, eliminating mechanism-induced volatility entirely is neither realistic nor desirable.

Decomposing the sources of volatility not only clarifies the multiple causes behind a single price movement but also lays the foundation for understanding the evolution of volatility over time. The four volatility sources do not occur in isolation along the time dimension but reinforce one another through systematic interaction effects. When an initial information shock triggers a price adjustment, the ensuing adverse-selection risk causes market makers to retreat, thereby activating liquidity volatility. The enlarged temporary price shock further touches the bankruptcy price of leveraged traders, setting off a liquidation cascade and causing mechanism-induced volatility to rise sharply. Ultimately, this extreme local volatility spills outward through cross-asset arbitrage and cross-margin mechanisms, forming transmitted volatility, which in turn further intensifies the global liquidity contraction.

This nonlinear positive-feedback loop—triggered by information, amplified by liquidity, detonated by mechanisms, and finally transmitted market-wide—explains why high volatility is often not a fleeting, isolated event. Once volatility breaks through a critical threshold, the mutual reinforcement among the sources makes it difficult for the system to return to calm in the short run. This leads to the next core topic: now that we have clarified the constituent elements of volatility and their interaction mechanisms, what macro features does this positive-feedback process exhibit over time? Why does volatility always exhibit strong time-variation and autocorrelation in the market? Chapter 23 will formally examine the dynamic mechanism of this volatility-clustering phenomenon, analyzing how slow variables, feedback loops, and state machines jointly determine the market's switching between low- and high-volatility states.

The Microstructural Mechanisms of Volatility Clustering

The volatility of Bitcoin perpetual futures follows a pattern no statistician can ignore: high volatility tends to follow high volatility, and low volatility tends to follow low volatility. In cryptocurrency markets, this volatility clustering is more pronounced and more persistent than in traditional financial assets. Empirical research shows that the probability of volatility clustering in crypto assets—high volatility persistently followed by high volatility—is significantly higher than in traditional financial assets [1]. This characteristic implies that volatility is not pure white noise but possesses deep long-memory properties. Generalized autoregressive conditional heteroskedasticity (GARCH) models and their variants (detailed in Section 23.1.1) can capture this clustering at the statistical level [2]. However, the successful fit of a statistical model is merely a mathematical description of the phenomenon; it does not answer a more fundamental economic question: why does the current conditional variance depend on past shocks? What exactly is the microstructural mechanism that drives this volatility memory and clustering?

This question marks the starting point for a deeper investigation into volatility dynamics. Statistical description tells us that high volatility is more likely to follow high volatility, but understanding and predicting market behavior requires uncovering the causal chain behind the data. In perpetual futures markets, volatility is not determined independently by a single random event; rather, it is shaped jointly by a series of interwoven market frictions, institutional designs, and participant behaviors. When an exogenous information shock breaks the market's calm, it alters not only the current price but also the market's liquidity depth, the level of systemic leverage, and market makers' risk appetite. Changes in these variables set new initial conditions for the next period's price movement, so that a new shock of the same magnitude can produce a volatility response far exceeding the norm under the new market state. The microstructural mechanism of volatility clustering therefore lies in how the market state, evolving on its own across different time scales, amplifies external shocks.

To explain this process systematically, this chapter constructs a three-layer explanatory framework composed of slow variables, feedback loops, and a state machine. At the lowest layer, the macroeconomic environment, the level of systemic leverage, and liquidity depth act as slow variables that evolve gradually over longer time scales, setting the baseline for market fragility. These slow variables do not directly generate violent

price swings, but they determine the system's capacity to absorb external shocks. At the intermediate layer, strong positive feedback loops form between volatility and liquidity, between volatility and leverage, and between volatility and participant behavior. Once the slow variables accumulate to a critical point, a minor triggering event can activate these feedback loops, causing shocks to be continuously amplified rather than dampened within the system. At the top layer, the interaction of these mechanisms manifests as nonlinear jumps of the market among three discrete states: calm, stressed, and crisis. These three layers of mechanism may exist in any leveraged market, but the institutional design specific to perpetual futures—the buffer-free transmission of liquidation cascades, the pulse-superposition effect of funding rates, and the around-the-clock trading environment with no market close—imposes systematic amplification on all three layers, explaining why the volatility clustering effect in crypto markets far exceeds that of traditional assets. This chapter also reveals that the accumulation rate of systemic risk often peaks during low-volatility periods, and it ties all the theoretical components together through a complete volatility life-cycle case study.

Dissecting these three layers of mechanism one by one moves the analysis beyond a purely statistical view of volatility toward one grounded in market microstructure and dynamics. Grasping how slow variables gradually accumulate fragility, how feedback loops amplify shocks, and how the state machine drives regime transitions not only explains why high-volatility events cluster in the time series; it also provides a solid theoretical foundation and a structured framework for building forward-looking volatility forecasting models and dynamic risk management strategies in the next chapter.

23.1 The empirical facts of volatility clustering

Financial asset time series commonly exhibit a statistical feature known as *volatility clustering*: large price movements tend to be followed by large price movements, while small price movements tend to be followed by small price movements. In crypto assets, and especially in perpetual futures markets, this clustering effect is particularly severe. Using empirical data and econometric models, this section establishes the empirical facts of volatility clustering in perpetual futures markets and compares them quantitatively with traditional financial markets. It aims not only to describe the phenomenon precisely but also to motivate the inquiry into the underlying microstructural mechanisms that follows.

23.1.1 Definition and measurement

The essence of volatility clustering is the persistence over time of the variance of asset returns. Operationally, this persistence is most often measured through the GARCH model. Since Engle (1982) introduced the autoregressive conditional heteroskedasticity (ARCH) model and Bollerslev (1986) generalized it into the GARCH form, this framework has become the standard tool for characterizing volatility clustering in financial time series [3][4]. The model assumes that the current conditional variance depends not only on past squared returns (i.e., external shocks) but also on past conditional variances. The standard form of the GARCH(1,1) variance equation is:

$$\sigma_t^2 = \omega + \alpha\epsilon_{t-1}^2 + \beta\sigma_{t-1}^2$$

where σ_t^2 is the conditional variance in period t, $\omega > 0$ is a constant term (which determines the long-run variance level), ϵ_{t-1} is the return residual from the previous period (i.e., the external shock), $\alpha \geq 0$ measures the immediate impact of new information shocks on volatility, and $\beta \geq 0$ measures the memory effect of historical volatility on current volatility. Their sum, $\alpha + \beta$, is called the volatility persistence parameter; the closer its value is to 1, the stronger the volatility clustering effect—that is, the longer high-volatility or low-volatility states persist [5] (when $\alpha + \beta < 1$, the process is covariance-stationary, and the half-life of a shock is $\ln 0.5 / \ln(\alpha + \beta)$).

In most traditional financial assets, this persistence parameter typically falls within the range of 0.95 to 0.99. This means that a major market shock triggers not only violent volatility on the day itself but also an effect that persists, in diminishing fashion, over the following weeks or even months. This slowly decaying process constitutes the volatility half-life—the time required for a shock's impact to halve. For assets with a high persistence parameter, the volatility half-life can extend to several weeks. Beyond parameter estimation, volatility clustering can also be observed directly through the autocorrelation function of realized volatility. In an idealized random-walk market that lacks any clustering effect, the autocorrelation coefficients of realized volatility should decay rapidly to zero; in real markets, however, these coefficients often remain significantly positive across many lag orders, confirming the self-perpetuating character of volatility states.

Figure 23-1 uses a GARCH(1,1) model to simulate the conditional volatility of BTC perpetual futures across a typical market cycle.

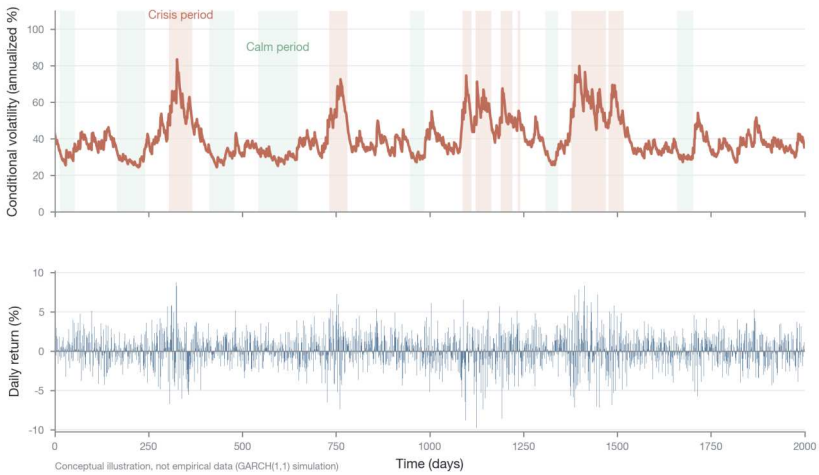

Figure 23-1. The clustering pattern of BTC perpetual futures volatility (Simulated by the author using a GARCH(1,1) model; parameters: ω=0.00001, α=0.08, β=0.90, sample length 2,000 days; illustrative simulation, not empirical data)

In Figure 23-1, volatility is not uniformly distributed but exhibits a clearly clustered structure: each high-volatility cluster contains multiple consecutive days of extreme

movement. When the market moves from a calm period into a stressed or crisis period, the volatility baseline rises markedly and sustains itself for a considerable time, until the intrinsic constraints of market mechanisms gradually exhaust it. This clustered distribution is precisely the intuitive manifestation of $\alpha + \beta$ approaching 1 in the GARCH model: past shocks, through the path dependence of the conditional variance, continuously transmit energy along the time series.

23.1.2 Cross-market quantitative comparison

Comparing crypto-asset perpetual futures with traditional financial markets more clearly delineates the distinctiveness of their volatility clustering. Empirical research shows that the returns of major crypto assets such as BTC and ETH not only exhibit the leptokurtic, fat-tailed features similar to those of traditional markets, but that the intensity of their volatility clustering is significantly higher than that of traditional assets across multiple dimensions [6]. This difference does not stem simply from the innate "high volatility" of crypto assets; rather, it is deeply rooted in their specific market microstructure and derivatives design.

To quantify the specific magnitude of this difference, Table 23-1 systematically compares BTC perpetual futures, BTC spot, and S&P 500 index futures across five dimensions: the persistence parameter, the autocorrelation coefficient, the half-life, the duration of clustering episodes, and average volatility.

Metric	BTC perpetual futures	CME BTC futures	BTC spot	S&P 500 futures
GARCH(1,1) $\alpha+\beta$	0.97–0.99	0.95–0.97	0.95–0.98	0.95–0.98
Daily autocorrelation of realized volatility	0.65–0.80	0.60–0.74	0.58–0.72	0.55–0.70
Volatility half-life (days)	15–40	12–28	12–30	10–25
Duration of extreme volatility clusters (days)	5–15	4–10	4–10	3–8
Average daily volatility (%)	3.5–5.2	3.3–4.9	3.2–4.8	1.2–1.8

Table 23-1. Cross-market quantitative comparison of volatility clustering intensity (Data source: the author's directional estimates synthesized from multiple sources; the specific ranges are not reported cell-by-cell from a single source [6][1])

The quantitative comparison reveals several key facts. The most diagnostically valuable contrast in the table is not the difference between BTC perpetual futures and the S&P 500 (the two differ fundamentally in the risk premium and volatility level of the underlying asset), but the difference between BTC perpetual futures and CME BTC futures, because the two share the same underlying asset yet differ significantly in institutional design (CME uses a traditional margin-call mechanism, imposes trading-session limits, and sets lower leverage caps). BTC perpetual futures are systematically higher than

CME BTC futures in both the persistence parameter and the half-life, a difference that points more cleanly to the institutional amplification effect of perpetual futures than to the volatility characteristics of the underlying asset itself. The $\alpha+\beta$ ranges of BTC perpetual futures and BTC spot do overlap (0.97–0.99 versus 0.95–0.98), so this difference may not be statistically significant, and the magnitude of the institutional amplification effect requires rigorous testing on larger samples. The high persistence of BTC perpetual futures may also be driven partly by macro factors, such as the volatility cycles of the VIX and the U.S. dollar index, rather than being entirely endogenous to the perpetual futures mechanism, and this motivates the slow-variable analysis in Section 23.2. The duration of extreme volatility clusters in perpetual futures is significantly longer than in traditional markets or CME BTC futures, and this prolonged high-pressure state places extremely high demands on market makers' inventory management and risk control.

23.1.3 Nonlinear clustering features

Traditional autoregressive models tend to depict volatility clustering as a smooth, symmetric, slowly decaying process. In perpetual futures markets, however, the clustering phenomenon exhibits more complex nonlinear features. Cont (2007) [7], using an agent-based simulation model, showed that when trend followers and fundamental traders interact dynamically in the market, volatility clustering can arise spontaneously as an emergent property, without any exogenous GARCH structure. The analysis in this chapter is complementary to Cont's agent-based model: Cont's model focuses on how information diffusion and strategy imitation generate clustering in the cross-section, whereas this chapter's three-layer framework focuses on how leverage, liquidity, and liquidation mechanisms sustain and amplify clustering along the time series. Together they point to the multi-source origins of volatility clustering. These nonlinear features challenge simple statistical descriptions and call for a more refined mechanistic analysis.

Tail clustering is a prominent nonlinear feature of crypto-asset markets. Extreme volatility events—that is, observations in the tails of the return distribution—rarely occur in isolation; instead, they tend to erupt in bursts within a short period. This phenomenon is already evident in the distribution of extreme funding-rate values, and along the volatility dimension it manifests as a single 5-standard-deviation shock often rapidly inducing several subsequent shocks of 3 to 4 standard deviations [8]. Such bursts of extreme events indicate that the market's risk-absorption capacity is structurally damaged after the first shock, so that subsequent minor disturbances can also trigger violent price responses.

Jump clustering describes the discontinuous transition of volatility states. In perpetual futures, the rise in volatility is often not gradual but accompanied by jump-like discontinuities in price. After the market experiences a liquidation cascade triggered by leverage unwinding, the probability of a second or even third cascade occurring within a short period rises sharply and nonlinearly. This clustering of jumps reflects the asymmetric dynamics of market liquidity in a crisis state: sudden evaporation and slow recovery.

Directional clustering reveals the asymmetry of volatility clustering. Empirical data

show that volatility clustering triggered by price declines significantly exceeds clustering triggered by price increases in both intensity and duration. The root of this asymmetry is that the positive feedback loop of the liquidation mechanism is stronger in a declining market: falling prices erode long-position margin, triggering forced liquidations; liquidation orders act as market sell orders that push prices down further, forming a self-reinforcing downward spiral. By comparison, although short liquidations also occur in a rising market, their systemic positive feedback is typically weaker. This asymmetry stems from three structural factors. First, the share of long open interest in perpetual futures markets is typically higher than that of shorts, so the stock of positions available for liquidation is larger on the downside. Second, long liquidations destroy buy-side purchasing power at the system level (margin is confiscated), whereas the purchasing power released by short liquidations is dispersed across different accounts and is not necessarily reinvested in the market. Third, market makers withdraw liquidity more rapidly in response to downside volatility than to upside volatility, because downside risk typically poses a more direct threat to market makers' inventory.

These empirical facts—tail clustering, jump clustering, and directional clustering—demonstrate that although statistical models can precisely fit the persistence of volatility, they cannot answer the mechanistic question of why the conditional variance depends on past shocks. Moving from "description" to "explanation" requires introducing the causal chain of market microstructure and participant behavior. The next section begins with the outermost slow variables and gradually constructs this causal chain.

23.2 Slow variables and the fragility baseline

Beneath the surface appearance of volatility clustering lie complex microstructural dynamics. The framework faces an endogeneity problem at the outset: volatility is both the explained variable and a determinant of the state of the slow variables, since a low-volatility environment itself drives leverage accumulation. This circularity is a common challenge in the analysis of financial systems and can be partly mitigated by introducing indicators exogenous to volatility (such as the ratio of open interest to market capitalization or the number of active on-chain addresses). To understand why high-volatility periods tend to persist, one must decompose the factors that drive market volatility across different time scales. In this analytical framework, the most fundamental level consists of macro and systemic factors that change relatively slowly. These factors, termed "slow variables," do not directly generate instantaneous price jumps, but they constitute the underlying environment in which the market operates and determine how sensitive the market is to external shocks. The mechanism through which slow variables operate is to set the activation threshold of the feedback loops: within a safe range, even a large information shock can be smoothly absorbed by the market; within a dangerous range, a minor disturbance may trigger a violent liquidation cascade and liquidity exhaustion.

23.2.1 The macroeconomic environment

The macroeconomic environment is the outermost slow variable that determines the overall tone of crypto-asset markets. As a typical high-beta asset, Bitcoin and other

cryptocurrencies exhibit extremely high sensitivity of their volatility to changes in global liquidity conditions and investor risk appetite [9]. The interest rate cycle plays a central role in this transmission mechanism. When a central bank is in a rate-hiking cycle or maintains a high-interest-rate environment, the rise in risk-free yields inevitably depresses global investors' overall risk appetite. Against this macroeconomic backdrop, capital tends to withdraw from the high-risk, high-volatility crypto market, thinning overall market liquidity. A systemic decline in liquidity means that, under an order-flow shock of the same magnitude, asset prices deviate more sharply, thereby raising the baseline volatility level at the macro level [10]. The transmission strength of the interest rate channel to the crypto market is time-varying, however, and may be weaker than commonly assumed. During 2023–2024, BTC still rose sharply even as the Federal Reserve maintained the highest interest rate level in two decades. This counterexample suggests that crypto-native factors, such as ETF inflows and the halving narrative, can override interest rate transmission in particular periods. The macro variable that more directly affects crypto-market liquidity may be the total amount of USD liquidity—including the size of the Federal Reserve's balance sheet and the global M2 supply—rather than the policy rate level itself.

Beyond traditional macroeconomic indicators, the narrative cycles unique to the crypto market constitute another dimension of slow variable. In stages dominated by a bull-market narrative, optimistic market sentiment prompts traders to make widespread use of leverage. Although this sentiment-driven leverage accumulation manifests initially as steady price increases and positive volatility, it in fact accumulates structural fragility within the system. Conversely, in a bear-market narrative, persistent negative expectations lead market makers and arbitrage capital to scale back their operations, and market depth and resilience decline markedly. At this point, any negative news is more likely to trigger a disproportionate price decline in an environment lacking buy-side support, manifesting as strong negative volatility clustering [11].

Macroeconomic uncertainty—such as geopolitical conflict or a sudden shift in inflation expectations—further reinforces this slow-variable effect. When macroeconomic uncertainty rises, cross-market arbitrageurs and macro hedge funds typically reduce their risk exposure in the crypto market. This precautionary withdrawal of capital not only reduces the market's effective liquidity but also raises the risk aversion of all participants. Thus, although changes in the macroeconomic environment unfold slowly on a monthly or quarterly scale, they set the baseline for the low-frequency component of volatility and determine the market's initial resistance when facing sudden events.

23.2.2 The level of systemic leverage

In crypto derivatives markets, the level of systemic leverage is the key internal slow variable that determines the intensity of volatility clustering. As the earlier analysis of leverage endogeneity noted, the evolution of leverage over the market cycle is not random but follows a self-reinforcing logic. During a calm period of persistently rising prices, the margin value of existing positions increases accordingly, so the effective leverage ratio naturally declines. This superficial sense of safety prompts traders to establish new leveraged positions or to raise the leverage multiples of existing ones, so

that a massive volume of open interest slowly accumulates at the system level.

Figure 23-2 illustrates the nonlinear relationship between the level of systemic leverage and volatility amplification. Leverage does not directly generate volatility; its core role is to define the trigger distance of a liquidation cascade.

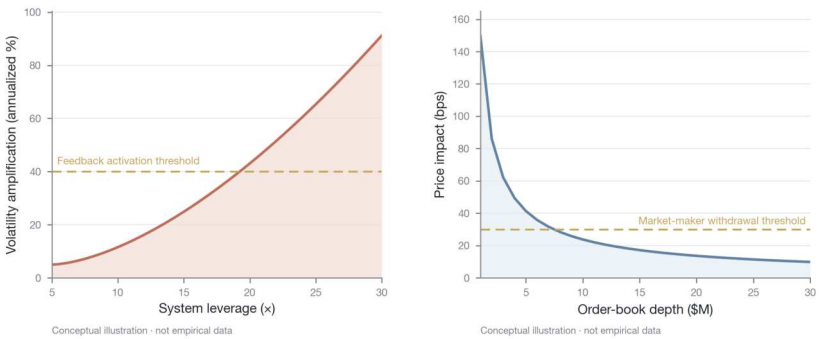

Figure 23-2. How slow variables set the activation threshold of feedback loops (Drawn by the author based on this chapter's analytical framework; conceptual illustration, not empirical data)

In a high-leverage environment, an initial price decline of merely 2% can reach the liquidation lines of a large number of highly leveraged long positions. Once the liquidation engine is activated, forced market sell orders indiscriminately hit the order book, driving prices down further and, in turn, triggering the liquidation of more positions that were originally in the safe zone [12]. This low trigger threshold, set by the accumulation of leverage, explains why, in certain market states, a trivial piece of external news can trigger volatility as high as 10% or even more extreme. The persistent climb of leverage during a bull market shortens the liquidation trigger distance, so that a minor price disturbance can set off the positive feedback loop of volatility clustering.

23.2.3 Liquidity depth

If the level of leverage determines the scale of potential selling pressure, then liquidity depth determines the market's capacity to absorb it. In the crypto market, the baseline level of liquidity is not constant but is constrained by the capital-deployment cycles of professional market makers, constituting a core slow variable. Market makers' capital-allocation decisions are typically based on a long-term risk-return assessment, including funding costs, investment in technical infrastructure, and expectations about overall market trading activity. This adjustment of capital deployment is a slow process, so the market's apparent depth remains relatively stable over weeks or even months.

Changes in liquidity depth directly alter the price impact function. At year-end, during holidays, or in prolonged market downturns, market makers tend to systematically reduce their capital deployment across exchanges, thinning the order book. Against this slow-variable backdrop of scarce liquidity, even routine-scale institutional rebalancing or a moderate information shock can produce far greater price slippage than usual, owing to the lack of sufficient counterparties, which manifests statistically as a rise in volatility [13].

A particularly destabilizing interaction also exists between liquidity depth and the level of systemic leverage. Figure 23-3 reveals how this interaction shapes the market's most fragile state: when high leverage (enormous potential liquidation selling pressure) and thin liquidity (extremely weak absorptive capacity) appear simultaneously, the market enters a highly unstable danger zone in which liquidation orders are more easily triggered and encounter enormous slippage during execution, accelerating the spread of the liquidation cascade [14].

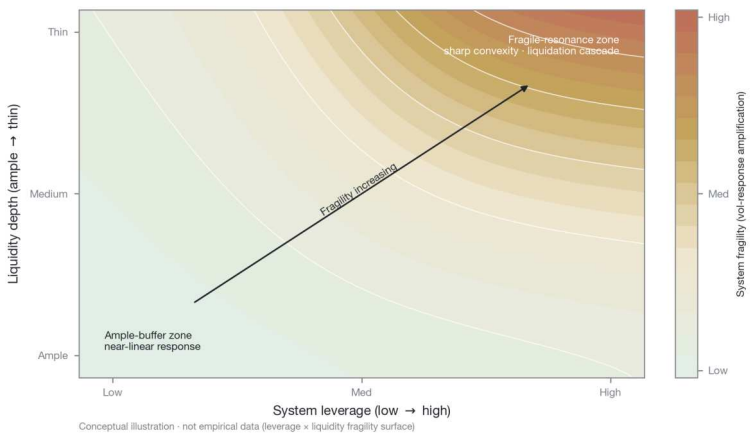

Figure 23-3. The two-dimensional fragility surface of the interaction between leverage level and liquidity depth: in the lower-left region (low leverage, ample liquidity) the volatility response is approximately linear, whereas in the upper-right region (high leverage, thin liquidity) the convexity increases sharply (Drawn by the author based on market microstructure theory; conceptual illustration, not empirical data)

The core message of Figure 23-3 is that systemic fragility is not determined linearly by any single slow variable but is driven nonlinearly by the interaction term between leverage level and liquidity depth. This interaction is closer to a threshold interaction than to simple multiplication: when the systemic leverage ratio is below a certain critical level, the effect of liquidity depth on fragility is approximately linear and mild; once the leverage ratio crosses that threshold, the sensitivity of fragility to liquidity increases convexly and sharply, because high leverage shortens the liquidation trigger distance, so that a liquidity gap of the same magnitude causes disproportionate price displacement and liquidation volume. This feature explains why monitoring risk indicators along a single dimension is often insufficient to capture the system's true fragility.

23.2.4 The pre-programming of fragility

Taking the macroeconomic environment, leverage level, and liquidity depth together yields a core insight about volatility clustering: slow variables do not directly generate short-term violent volatility; their mechanism is to "pre-program" the market's fragility, thereby determining how low the threshold for activating the feedback loops is. This mechanism can be described as a state-dependent nonlinear response.

During periods when the slow variables are in the safe range—that is, when the macroe-

conomic environment is accommodative, systemic leverage is moderate, and market-maker liquidity is ample—the market possesses a strong shock-absorbing capacity. At such times, even when major negative news breaks or a large-scale selling shock hits, ample liquidity can smoothly absorb these orders, and the low leverage ratio ensures that a short-term price decline does not trigger a chain of forced liquidations. In this state, the volatility induced by a shock is isolated, its energy decays rapidly, and volatility does not exhibit pronounced clustering.

However, as the slow variables gradually shift into the danger range, the market microstructure undergoes a qualitative change. Using the joint time series of the level of systemic leverage and conditional volatility, Figure 23-4 depicts the complete cycle in which the "fragility gap" widens continuously during the calm period and is then violently released once triggered.

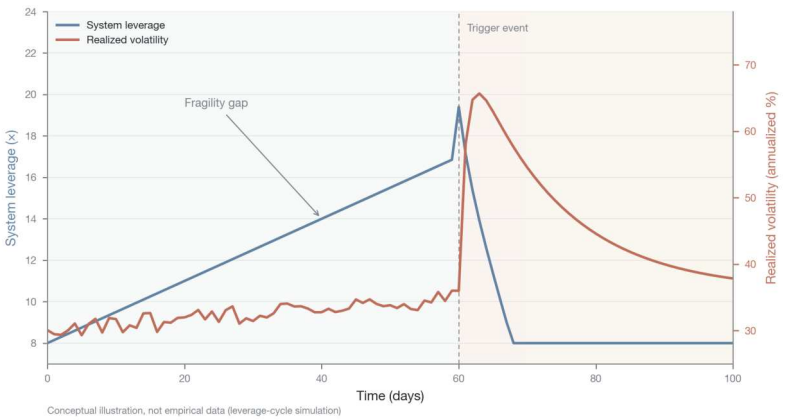

Figure 23-4. The time-series relationship between the level of systemic leverage and volatility (Simulated by the author based on leverage-cycle theory; core parameters: α=0.08, β=0.90, with systemic leverage in the figure ranging roughly from 8× to 19×; illustrative simulation, not empirical data)

In this highly fragile state, what triggers a crisis is often not a large-scale black-swan event but merely a routine information shock or a market order slightly larger than usual. This minor disturbance is enough to break through the feedback-activation threshold that the slow variables have already driven to an extremely low level, triggering the liquidation engine and driving market makers to retreat. Once the self-reinforcing cycle of liquidity withdrawal and liquidation selling begins to operate, volatility no longer depends on the input of external information but is self-perpetuated and amplified by the market's internal microstructural mechanisms. Volatility clustering is therefore not a purely random phenomenon but the inevitable result of slow variables gradually accumulating fragility along the time dimension and finally releasing it violently through feedback loops under a minor trigger. The specific path by which slow variables evolve toward the danger range during low-volatility periods is analyzed in detail in Section 23.6.

23.3 Positive feedback loops and shock amplification

After slow variables have set the market's fragility baseline, the key factor determining whether volatility clustering actually occurs is the activation of positive feedback loops. This section analyzes three positive feedback channels—between volatility and liquidity, between volatility and leverage, and between volatility and market behavior—to explain how an initial shock produces persistent volatility clustering along the time series through microstructural transmission.

23.3.1 The intertemporal transmission of shocks

The analysis in Chapter 22 identified four main sources of volatility: information shocks, liquidity frictions, microstructural mechanisms, and behavioral biases. This cross-sectional perspective explains, at any given moment, which factors jointly push up market price volatility. However, to understand why volatility exhibits pronounced clustering along the time series, one must shift the analytical perspective from a static decomposition of sources to a dynamic time-series evolution. The core of volatility clustering is that an initial external shock not only has an impact in the current period but also, through the market's internal transmission mechanisms, alters the market state of the next period, so that a subsequent shock of the same magnitude can trigger larger price movements.

This time-series self-amplification mechanism constitutes the microfoundation of volatility memory. When an information shock in period t causes violent price movement, market makers contract their liquidity supply because of the rise in inventory risk and adverse-selection risk (the mechanism is detailed in Section 23.3.2), pushing the market liquidity of period t+1 below the normal level. In a liquidity-scarce environment, even if only routine-scale order flow appears in period t+1, it produces a far larger price impact than usual owing to insufficient market depth, thereby realizing higher volatility [15]. This transmission chain clearly explains the microeconomic meaning of the β coefficient in the GARCH model: the conditional variance depends on past shocks because past shocks, by altering the behavior of market participants and the state of the system, substantially reduce the market's capacity to absorb new shocks.

23.3.2 The liquidity loop

Among all the mechanisms that amplify volatility, the feedback loop between volatility and liquidity has the shortest transmission path. This loop is essentially the manifestation, along the volatility dimension, of the reflexivity triangle discussed in Chapter 20. The classic model of Kyle (1985) [16] defines the price impact coefficient λ as the marginal effect of order flow on price, while the illiquidity measure proposed by Amihud (2002) [17]—the ratio of the absolute value of daily returns to trading value—provides a standardized measure for cross-market liquidity comparison. Both classic indicators require a revised reading in crypto perpetual futures markets, however. The Kyle lambda derives from an equilibrium model of a single risk-neutral market maker facing informed traders, which differs structurally from the crypto environment of multiple competing market makers who can cancel orders at any time; and the Amihud ratio is

highly sensitive to the choice of aggregation window (hourly, daily, weekly) in a 24/7 continuous-trading market. In practice, the decay rate of order-book weighted depth—for example, how the ratio of depth in the $\pm 0.5\%$ and $\pm 2\%$ price ranges changes with volatility—may be a liquidity measure more native to perpetual futures. Nevertheless, the core mechanism that the Kyle lambda captures—that the marginal price impact of order flow rises nonlinearly as liquidity declines—still holds in the crypto market. When market volatility rises, λ rises nonlinearly, and the cost structure faced by market makers changes nonlinearly. According to inventory models and information-asymmetry theory, market makers' cost function exhibits pronounced convexity when volatility rises [18]. Market makers' liquidity withdrawal unfolds along two causal paths. First, market makers actively widen their quotes and withdraw quoted depth because of the rise in inventory risk and adverse-selection risk; this is a rational response based on a risk-return trade-off. Second, market makers are forced to reduce their exposure because their own margin constraints tighten, and in extreme cases this even triggers the liquidation of the market makers' own positions. In crypto perpetual markets, because market makers bear no obligation to remain present, the response along the first path is extremely fast (millisecond-level order cancellation) and is usually the primary driver of liquidity evaporation. The common result of both paths is that market makers sharply reduce quoted depth across all levels of the order book.

The withdrawal of liquidity has a direct and significant effect on market microstructure. As the order book thins, the price impact coefficient faced by a market order of the same magnitude increases severalfold. During extreme volatility, the bid-ask spread can rapidly widen from a normal 3 basis points to more than 30 basis points, and the market impact coefficient can even be amplified tenfold [19][20]. This large price jump caused by liquidity exhaustion is statistically recorded as a further rise in realized volatility. This rise in secondary volatility contains no new fundamental information; it is purely a mechanical result of the deterioration in market microstructure and the decline in liquidity-bearing capacity. Because the process by which market makers reassess risk and restore liquidity supply is typically slow and cautious, this liquidity-scarce state persists, so the volatility amplification effect continues along the time series and ultimately manifests as the volatility clustering we observe in the data.

The foregoing analysis of the liquidity loop implicitly assumes a single exchange and a single asset, but the actual transmission network is far more complex. BTC perpetual futures trade simultaneously on more than a dozen exchanges, each of which uses a composite index incorporating prices from other platforms as its mark price. When a liquidation cascade on one exchange causes a sharp price drop, its price deviation is transmitted through the index price to other platforms, triggering their liquidations even if their own order books have not been directly hit. Under a unified margin account, losses on a BTC perpetual position can also directly cause margin shortfalls for positions in ETH, SOL, and other instruments within the same account, forcing traders to close out non-BTC instruments to raise liquidity. The cross-market liquidity spiral described by Brunnermeier and Pedersen (2009) [21] is therefore especially pronounced in crypto derivatives markets: during the May 2021 event, the daily correlation between BTC and ETH rose markedly (climbing above 0.9 in the crisis period), a direct manifestation of this cross-instrument contagion.

The liquidity loop does not operate in isolation but is nested with the leverage loop and the behavioral loop. Figure 23-5 integrates these three feedback channels into a unified conceptual network, showing how an initial shock is transmitted simultaneously along multiple paths and reinforced at each node.

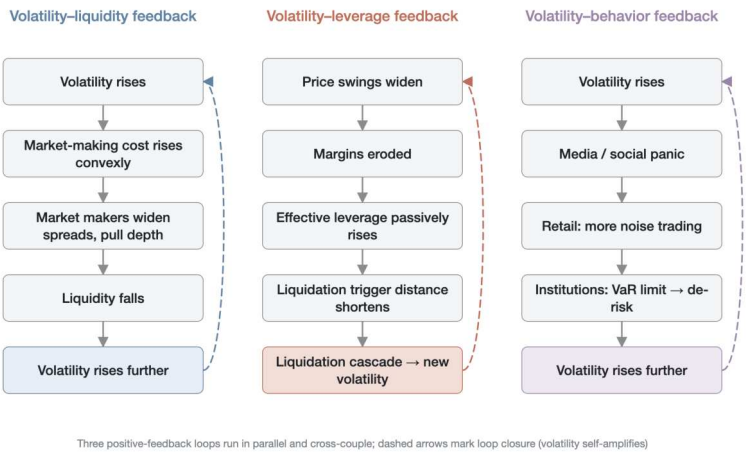

Figure 23-5. Conceptual diagram of volatility feedback loops (Drawn by the author based on this chapter's analytical framework; conceptual mechanism illustration, not empirical data)

The key feature of Figure 23-5 is that multiple cross-coupling points exist among the three loops. The withdrawal of liquidity simultaneously lowers the execution quality of liquidation orders (coupling with the leverage loop) and intensifies the visual impact of price jumps (coupling with the behavioral loop), while the panic selling of retail investors in the behavioral loop further consumes the already-thin liquidity. This multi-channel, cross-coupled network structure makes the volatility amplification effect far greater than any single loop can explain. The following two subsections analyze the independent transmission mechanisms of the leverage loop and the behavioral loop respectively.

23.3.3 The leverage loop

The liquidity feedback loop explains the slow decay of volatility, whereas the leverage feedback loop explains the violent short-term eruption of volatility. In perpetual futures markets, high leverage is not merely a tool of capital efficiency but a core source of systemic fragility. When an initial rise in volatility causes a large deviation in the asset price, the margin balances of traders holding highly leveraged positions are rapidly eroded. As net value declines, the effective leverage ratio of these positions rises passively, bringing them ever closer to the threshold that triggers forced liquidation [22].

This passive rise in effective leverage significantly increases the probability of liquidation across the entire system. Once the price reaches a key liquidation line, the exchange's liquidation engine automatically takes over the position and sends a large volume of market orders to the book. This forced, extremely price-insensitive order flow floods into an already fragile order book, instantly breaking through multiple layers of liquidity and driving a further plunge or spike in price. This violent price movement driven by

liquidation generates additional volatility, which in turn triggers deeper liquidations, forming the classic liquidation cascade [14]. This is a positive feedback mechanism whose operation requires no external information input and is driven entirely by the internal leverage-clearing demand of the system. Exchanges have designed multiple circuit-breaker mechanisms to curb this cascade, including tiered margin systems (large accounts face higher margin rates to suppress concentration), auto-deleveraging (ADL) mechanisms (which preferentially offset profitable counterparties rather than dumping everything at market price), and insurance funds (which absorb bankruptcy losses to avoid socialized loss allocation). In extreme conditions, however, these mechanisms often fail to curb the cascade effectively—because the insurance fund is exhausted within minutes, auto-deleveraging triggers panicked withdrawal by counterparties, and tiered margin adjusts with a lag amid successive price gaps—so that positive feedback ultimately still dominates market dynamics. This feedback loop does not terminate naturally until all these circuit-breaker mechanisms have failed, or until leverage has been fully released and fragile positions have been completely unwound. Because a large-scale deleveraging process often requires several consecutive days of liquidation activity to complete, and each day's liquidations create new volatility in the market, the duration of deleveraging overlaps highly, along the time series, with the period of extreme volatility clustering.

23.3.4 The behavioral loop

In crypto-asset markets, the high share of retail investors gives the emotional contagion and herd behavior studied in behavioral finance a more prominent role in volatility transmission. When market volatility rises sharply, it is often accompanied by a surge in media coverage and the rapid spread of panic on social networks. This deterioration of the information environment triggers investors' loss aversion and herd mentality, leading large numbers of noise traders lacking fundamental support to flood into the market and engage in panic selling or momentum chasing [23]. This irrational trading behavior not only fails to provide liquidity but consumes precious market depth, further pushing up the market's realized volatility. At the same time, not all retail investors choose to sell in a decline. "Buying the dip" is a deeply entrenched behavioral pattern in the crypto community, and some traders add leverage to buy in as prices fall. Research shows that the loss aversion and aggressive trading behavior of Bitcoin derivatives traders under liquidation risk systematically amplify the tail losses of hedged portfolios in extreme markets [24]. Such behavior can slow the pace of the rise in volatility in the short term, but it ultimately converts these newly established highly leveraged positions into fuel for the next wave of liquidations, making the delayed cascade larger in scale.

At the institutional-investor level, behavioral feedback takes a more institutionalized and mechanical form: the value-at-risk (VaR) spiral. Most institutional investors and market makers are subject to strict VaR risk-control models. When market volatility rises, the VaR value computed from historical data soars accordingly, causing the institution's risk exposure to rapidly approach or breach its internally set risk limit. To meet compliance requirements and internal risk-control standards, these institutions are forced to cut their risk exposure simultaneously—that is, to sell risk assets—precisely when market liquidity is worst. This procyclical de-risking behavior generates enormous

selling pressure, directly causing further price declines and a continued rise in volatility, which in turn triggers a new round of VaR breaches and forced liquidations [21]. In practice, only a few leading market makers and hedge funds in the crypto market are truly bound by strict VaR models. A larger share of trading volume comes from retail and semi-professional traders who use simple stop-losses or fixed position limits, and whose de-risking is driven more by a pain threshold than by a model. Nevertheless, whether it is retail panic selling or institutional mechanical de-risking, both reinforce the self-propagation of volatility along different dimensions.

23.3.5 Activation and termination conditions

Feedback loops are not activated in every market state; their activation threshold is determined by the slow-variable dynamics of the first layer of explanation (Section 23.2.4). When the slow variables are in the safe range, the threshold is high, and the market can absorb a large information shock without triggering systemic positive feedback; once a high leverage ratio or excessive liquidity concentration has caused fragility to accumulate sufficiently, the threshold drops markedly, and a routine-scale shock is enough to trigger the feedback loops.

Once a feedback loop is activated, its termination exhibits pronounced lag and asymmetry: the end of volatility clustering depends on the exhaustion of the momentum internal to the feedback mechanism, and this exhaustion is far slower than the activation (the bidirectional micro-mechanisms of entering and exiting the high-volatility regime are detailed in Section 23.4.3). The leverage loop must wait for large-scale liquidations to complete and the systemic leverage ratio to fall substantially; the liquidity loop must wait for market makers to return cautiously at a higher risk premium; and the termination of the behavioral loop lags especially. This lag arises not because the same participants gradually become desensitized, but because the price-sensitive seller cohort has already been flushed out during the earlier liquidations and panic. The remaining holders either have already accepted their paper losses (refusing to realize losses under the disposition effect) or are new entrants who built positions at lower prices, so the composition of the market crowd has undergone a structural change. Because capital rebuilding, confidence recovery, and the resetting of risk-control parameters all take time, the termination of a feedback loop is far more protracted than its activation. This explains the sharp-rise, slow-decay asymmetric shape of volatility clusters in real data. This asymmetry also reveals a structural blind spot of the standard GARCH model: its β coefficient imposes a symmetric decay structure on upward and downward shocks, which systematically underestimates the speed of the transition from calm to crisis while overestimating the speed of recovery from crisis to calm. Asymmetric GARCH variants—such as the GJR-GARCH proposed by Glosten, Jagannathan, and Runkle (1993) or the EGARCH—can better capture this dynamic [25], which will be discussed further in the selection of volatility forecasting models in Chapter 24.

23.4 The state machine and volatility regime transitions

The interaction between slow variables and feedback loops makes volatility change not continuously and smoothly but with discrete state jumps. Although continuous

GARCH-type models can fit the persistence of volatility, they cannot capture the market's abrupt shifts between calm and crisis. This section introduces a Markov regime-switching model that abstracts the volatility dynamics of perpetual futures markets into nonlinear transitions among three discrete states—calm, stressed, and crisis—and analyzes the asymmetry of state transitions and their interaction with slow variables.

23.4.1 The model framework

In traditional financial econometrics, volatility clustering is usually modeled as a continuously evolving process. The GARCH model and its variants form the foundation of this analytical paradigm, whose core assumption is that the conditional variance at the current moment is a continuous function of past return shocks and past variances. Within this framework, volatility slides smoothly between "high" and "low," and its response to new information takes the form of a gradual adjustment of variance. However, the empirical data of cryptocurrency perpetual futures markets reveal a markedly different dynamic character: changes in volatility are often not continuous but exhibit pronounced jumpiness and state-like behavior. The market may hold a low annualized volatility of 30% for weeks, then jump above 120% within hours on a single liquidation event, *sit* at this high level for several days, and then switch states again. This multimodal feature in the frequency distribution suggests that a single continuous process is insufficient to capture the abrupt changes in market microstructure; volatility in fact switches among several discrete regimes [7].

To describe this nonlinear regime switching precisely, the Markov regime-switching model provides a rigorous statistical framework. Hamilton (1989) [26] first introduced the Markov chain into the analysis of macroeconomic time series, proposing that the generating process of an observed variable depends on an unobservable discrete state variable. When this idea is extended to volatility modeling, it forms the Markov regime-switching conditional-heteroskedasticity model [27][28]. In this model, the market is assumed to be in one of a finite number of discrete states, each with its own mean, variance characteristics, and mechanism for responding to shocks. Let the unobservable state variable $S_t \in \{1, 2, 3\}$ correspond to the three states of calm, stressed, and crisis, respectively, with transitions among states governed by a 3×3 transition probability matrix $\mathbf{P}$:

$$\mathbf{P} = \begin{pmatrix} p_{11} & p_{12} & p_{13} \\ p_{21} & p_{22} & p_{23} \\ p_{31} & p_{32} & p_{33} \end{pmatrix}$$

where $p_{ij} = \Pr(S_t = j \mid S_{t-1} = i)$, and the elements of each row sum to 1. The conditional return distribution in each state follows a normal distribution with different parameters:

$$r_t \mid S_t = k \sim \mathcal{N}(\mu_k, \sigma_k^2), \quad k = 1, 2, 3$$

where $\sigma_1^2 < \sigma_2^2 < \sigma_3^2$, corresponding to the increasing conditional variances in the calm, stressed, and crisis states. Throughout this chapter, the volatility metric is realized volatility (returns aggregated intraday at a 5-minute frequency), annualized

by the crypto-market convention of continuous trading 365 days a year—that is, the daily volatility is multiplied by $\sqrt{365}$—rather than the traditional-market convention of $\sqrt{252}$. The current state depends only on the previous state, which is precisely the core embodiment of the Markov property. By introducing discrete states, the model can explain why in some periods the market has an extremely high capacity to absorb shocks, while in other periods a shock of the same magnitude triggers a violent surge in volatility.

Applying the Markov regime-switching model to perpetual futures markets rests intuitively on the nonlinear mapping between the continuous change of slow variables and the threshold activation of feedback loops. Slow variables such as macro liquidity depth and the systemic leverage ratio undergo slow and continuous evolution in daily trading, and these changes do not by themselves directly manifest as a rise in volatility. However, the feedback loops in the microstructure—particularly the liquidation cascade and the market-maker order-cancellation mechanism—have a distinct threshold-trigger character. When the accumulation of slow variables pushes systemic fragility past a certain critical point, an ordinary information shock that could originally have been smoothly absorbed instantly activates the positive feedback loop. Once the feedback loop is activated, the market microstructure undergoes a qualitative change, and the system "jumps" from one state into an entirely new one. In the new state, high-frequency liquidation events and widened bid-ask spreads reinforce each other, allowing the market to sustain itself within this high-volatility regime until the internal imbalance is fully digested. This discrete jump, driven by continuous slow variables and triggered via a threshold mechanism, constitutes the third layer of explanation for understanding volatility clustering in perpetual futures.

23.4.2 The transition matrix

Based on empirical estimation with a hidden Markov model (HMM), the volatility dynamics of perpetual futures markets can be abstracted into a three-state Markov machine: the calm state, the stressed state, and the crisis state. The three-state division is a deliberate simplification of the actual market continuum. The internal risk-control systems of major exchanges typically use a finer-grained classification of five to six market states (including intermediate states such as early warning and price-protection triggering); this chapter adopts three states to strike a balance between analytical simplicity and the ability to capture the phenomenon. These three states differ significantly not only in their statistical distributions but also in the relative weights of their underlying microscopic drivers. The calm state is the market's norm, occupying roughly 65% to 75% of trading time. In this state, annualized volatility typically remains in the range of 20% to 40%, and the return distribution is approximately normal with thin tails. The microstructure is characterized by extremely narrow bid-ask spreads, liquidation volume at a trough, and smoothly functioning cross-exchange arbitrage. At this point, volatility is driven mainly by exogenous information shocks, with information sources accounting for more than 60% of total volatility, and traditional continuous volatility models have good predictive power in this regime.

When market fragility accumulates and a specific shock strikes, the system jumps to

the stressed state, which accounts for about 20% to 30% of the time. The stressed state is typically characterized by annualized volatility rising to 50% to 80%, with the return distribution beginning to show pronounced fat tails and skewness. At the microscopic level, market makers perceive increased risk and begin to passively widen spreads and reduce order-book depth; at the same time, some highly leveraged positions approach the liquidation line, causing liquidation volume to rise initially. In this regime, the contributions of liquidity sources and mechanistic sources (such as funding-rate pulses) to volatility increase significantly, together accounting for 40% to 60%. If the shock is not relieved and liquidation volume breaks through a critical threshold, the market moves further into the crisis state. Although the crisis state accounts for only 3% to 8% of total time, its annualized volatility often soars above 100% to 200%, accompanied by extreme fat tails and frequent price jumps. At this point, the liquidation cascade erupts fully, liquidity is nearly exhausted, mechanistic sources completely dominate market dynamics, and the relative importance of information shocks falls to its lowest level.

Figure 23-6 integrates these three states and their transition logic into a complete state-machine schematic.

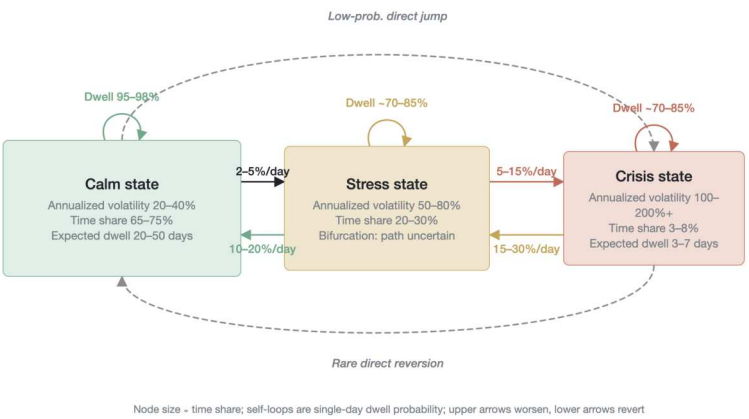

Figure 23-6. Schematic of the volatility state-transition machine for perpetual futures (Drawn by the author based on a Markov regime-switching model [26]; the transition probabilities and time shares are the author's HMM estimates on daily data for Binance BTC-USDT perpetual futures from 2019 to 2024, with wide confidence intervals, not empirically measured)

Two key structural features can be identified intuitively from Figure 23-6. First, the self-loop probability of the calm state (the probability of remaining in the current state) is the highest, indicating that the low-volatility regime has the strongest capacity for self-maintenance. Second, the probabilities of the two paths departing from the stressed state (regression toward calm and deterioration toward crisis) are not far apart, which means that the stressed state is a highly uncertain bifurcation point whose ultimate direction depends on the specific configuration of the slow variables at that moment.

Transitions between states are not a random walk but follow a specific set of empirical probability matrices. According to the HMM parameter estimates on historical high-frequency data (the following ranges are based on the same HMM parameter estimates

listed in the figure note above), the daily probability of the market jumping from the calm state to the stressed state is typically between 2% and 5%; once in the stressed state, the probability of further deterioration to the crisis state rises significantly, reaching 5% to 15%. This means that the stressed state is a highly unstable transitional period that either evolves rapidly into a full-blown crisis or returns to calm after turbulence. The probability of regression from the crisis state to the stressed state is relatively high, at about 15% to 30%, reflecting the fact that extreme liquidation events typically exhaust their momentum within a few days; however, the probability of complete regression from the stressed state to the calm state is only 10% to 20%. This parameter structure of the transition matrix indicates that the calm state has the strongest regime stickiness, with an expected dwell time of 20 to 50 days, whereas the crisis state has the shortest expected dwell time, typically only 3 to 7 days, though the microstructural damage it causes is prolonged through a longer stressed state.

The state-machine parameters above are estimated from daily data on a single trading pair (Binance BTC-USDT perpetual) and have three limitations. First, a single-pair model cannot capture state transitions transmitted from other exchanges or other assets; for example, the 2022 FTX collapse first hit FTT and SOL before being transmitted to BTC perpetual futures. Second, daily data may mask state transitions at the intraday microstructural level: a trading day classified as "calm" by a daily-frequency model may contain a localized crisis at the 15-minute level (such as a flash crash followed by rapid recovery). Third, the effective number of observations for some state-condition combinations (such as the low-liquidity range within the stressed state) is limited, so the confidence intervals of the transition-probability estimates may be wide. Multi-exchange joint HMM estimation or extended estimation on hourly data can mitigate these limitations to some extent, but this is beyond the scope of this chapter.

23.4.3 Transition asymmetry

In the three-state volatility model, a prominent dynamic feature is the pronounced asymmetry of state transitions: the market enters a high-volatility regime far faster than it exits one. Empirical data show that falling from the calm state, through the stressed state, fully into the crisis state often takes only 1 to 3 days, and in extreme cases the jump can be completed within hours; whereas cooling down from the crisis state, through the stressed state, and finally returning to a truly calm state typically requires a repair period of 5 to 20 days or even longer. This large difference in time scale is what gives volatility clusters their sawtooth shape—sharp rise, slow decay—on time-series charts.

By contrasting the typical time paths of entering and exiting the high-volatility state, Figure 23-7 illustrates this asymmetry intuitively.

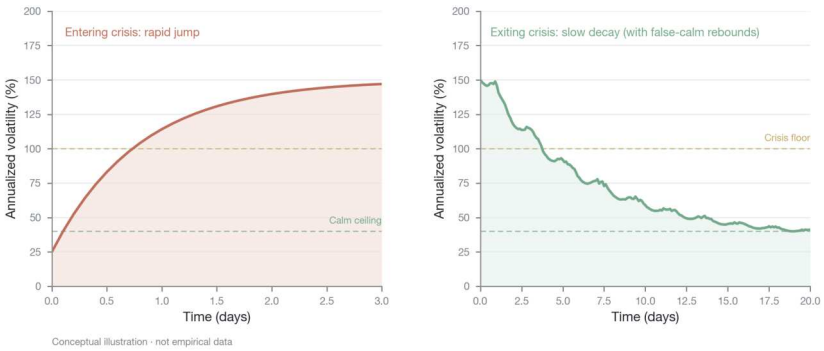

Figure 23-7. Comparison of the temporal asymmetry of volatility state transitions (Drawn by the author based on this chapter's analytical framework; conceptual illustration, not empirical data)

This macro-statistical asymmetry is rooted in the asymmetry of the behavioral patterns of micro-level market participants and of mechanism design. Entering a high-volatility state is usually initiated by a single triggering event. When an information shock exceeding expectations strikes a fragile market that has already accumulated high leverage and thin liquidity, it immediately triggers the automated liquidation engine. The high-leverage nature of perpetual futures causes liquidation orders to hit the order book as market orders regardless of cost, instantly draining buy-side or sell-side liquidity. This algorithmically forced selling is not constrained by human hesitation or wishful thinking, and its transmission speed is limited only by the processing capacity of the exchange's matching engine. At the same time, once market makers' risk-control models detect the jump in volatility and the loss of control over inventory risk, they automatically cancel orders or sharply widen spreads at millisecond speed. The positive feedback of automated liquidation and the instantaneous withdrawal of machine market makers superimpose on each other, so that the market completes its jump to the crisis state in an extremely short time.

By contrast, exiting a high-volatility state is a protracted process involving the psychological reconstruction of multiple parties and the redeployment of capital. First, although the liquidation cascade in the crisis state is fierce, it must wait for excessively leveraged positions to be fully and *naturally digested*, and this deleveraging process takes time to find a new price equilibrium. Second, after experiencing extreme volatility, market makers' VaR models significantly raise their expectations of future volatility, causing them to exercise great caution when resupplying liquidity. Redeploying capital must pass through reassessment and approval by risk-control departments, and market makers typically return tentatively and gradually with wider spreads and smaller sizes, rather than restoring liquidity depth to pre-crisis levels all at once. Finally, the emotional recovery of market participants likewise exhibits a lag effect: the memory of panic brought by extreme volatility causes traders to lower their leverage and reduce their trading frequency for a considerable period. These slow micro-level repair mechanisms jointly determine that the regression from a high-volatility regime to a low-volatility regime must be a gradual, repeatedly interrupted decay process.

23.4.4 The regulation by slow variables

Although the Markov regime-switching model provides an elegant framework for describing the discrete jumps of volatility, treating the transition-probability matrix as a fixed constant would ignore deeper market dynamics. In fact, the state machine does not operate in isolation in a vacuum; its internal transition probabilities are time-varying, and what determines these dynamic changes in probability is precisely the "slow variables" described in the first layer of explanation. The three major slow variables—the macroeconomic environment, the level of systemic leverage, and liquidity depth—constitute the underlying physical environment in which the state machine operates, and by regulating the sensitivity of the microscopic feedback loops, they directly determine the specific values of the individual elements of the transition matrix.

The level of systemic leverage is the most critical slow variable determining the transition probability from the calm state to the stressed state. During a prolonged calm period, the low-volatility environment entices traders to continually raise their leverage multiples in pursuit of capital efficiency, causing the system's overall effective leverage ratio to climb gradually. Once a high-leverage environment has formed, the market's tolerance for adverse price movement drops sharply. At this point, a minor information shock that would originally have been insufficient to cause a ripple can reach the liquidation lines of a large number of highly leveraged positions. Therefore, as the systemic leverage ratio rises, the transition probability from the calm state to the stressed state increases sharply and nonlinearly. High leverage lowers the market's tolerance for price disturbances to an extremely low level, so that a routine-scale information shock can trigger a liquidation cascade.

Liquidity depth and macroeconomic uncertainty mainly determine the probability of deterioration from the stressed state to the crisis state. When market-maker capital deployment is insufficient or the market is in a specific low-liquidity holiday period, the absorptive capacity of the order book is extremely fragile. In such a thin-liquidity environment, once the market enters the stressed state and an initial liquidation flow appears, the lack of sufficient counter-liquidity to absorb it causes prices to shift disproportionately and violently, rapidly triggering a larger-scale liquidation cascade. Empirical research shows that during periods when liquidity depth is in the bottom historical quartile, the probability of the market sliding from the stressed state into the crisis state is more than three times that of liquidity-ample periods (this multiple is based on a conditional HMM estimate on the aforementioned Binance BTC-USDT perpetual daily data: after grouping order-book depth by historical quartile, the state-transition matrix of each group is fitted separately, and the inter-group difference in the stressed-to-crisis transition probability is compared; because the number of joint observations with the stressed state and liquidity in Q1 is limited, the 95% confidence interval of this multiple estimate is wide, at approximately 2.1 to 4.8 times, and it should be regarded as an order-of-magnitude indication rather than a precise parameter). At the same time, if the macroeconomic environment is in a high-interest-rate or high-uncertainty cycle, the overall risk appetite for risk assets is suppressed, and all transition probabilities toward high-volatility states are systematically amplified [29]. It is precisely this deep interaction between slow variables and state-transition probabilities that explains why the intensity and frequency of volatility clustering in perpetual futures markets

vary significantly across different macro and micro market cycles.

23.5 The institutional amplifiers of perpetual futures

The preceding three sections established the three-layer explanation in turn: slow variables set the fragility baseline, feedback loops amplify shocks, and the state machine drives regime jumps. However, these mechanisms may exist in any leveraged derivatives market; the reason perpetual futures markets exhibit clustering intensity far exceeding that of traditional markets lies in the systematic amplification that their distinctive institutional design imposes on these three layers. The institutional features are not themselves independent sources of volatility; each of their core components enhances the clustering effect by lowering the feedback-activation threshold or accelerating the feedback transmission speed. This directly explains why the clustering intensity of perpetual futures observed in Section 23.1 is so much higher than in traditional financial markets. The three institutional features—the liquidation engine, funding rates, and around-the-clock trading—together construct an almost frictionless transmission environment, and their synergistic amplification logic is drawn together in Section 23.5.4.

23.5.1 Funding rates

The funding rate is a periodic payment mechanism designed for perpetual futures to maintain the anchoring of the contract price to the spot price (as described in Chapter 10). By design, the funding rate is first of all a convergence mechanism: by charging the deviating side and paying the reverting side, it incentivizes arbitrageurs to enter and correct the deviation, effectively suppressing excessive deviation between the contract price and the spot price in most market states. However, when the market is in a strong one-sided trend and volatility rises sharply, arbitrageurs cannot maintain opposing positions because they face extremely high liquidation risk, the rate's convergence function fails, and the mechanism flips from a stabilizer into an amplifier. The critical condition for this flip corresponds roughly to the funding rate remaining at an extreme value in the same direction for several consecutive settlement periods (for example, exceeding 0.1% for three consecutive 8-hour periods). In the context of volatility clustering, once the flip occurs, the funding rate amplifies the trend within a trend and amplifies volatility at turning points, becoming an endogenous positive feedback engine. In the calm state, the funding-rate pulse is minuscule and its effect on volatility is negligible; in the stressed or crisis state, however, an extreme rate significantly prolongs the duration of high volatility. The crypto spot-futures basis (carry) has been shown to embed amplification dynamics related to crash risk [30].

In a strong one-sided market, the positive feedback loop of the funding rate is especially evident. When long forces dominate the market, the contract price generates a premium, and the funding rate turns positive. In theory, a positive rate should incentivize shorts to enter and arbitrage, thereby depressing the price; but in the high-volatility state of a bull market, shorting faces extremely high liquidation risk, and shorts struggle to maintain positions. The result is that longs continue to accumulate, prices rise further, the funding rate is pushed to a higher level, and this instead attracts

more momentum-chasing speculators. When the market finally reverses, the destructive power of the feedback loop is released instantly. The funding rate swings sharply from an extreme positive value to negative, and the longs that had enjoyed the trend dividend begin to be penalized and are forced to close positions. The closing of long positions drives prices down, further deepening the negative shift of the funding rate, prompting more longs to be forced to close, and ultimately triggering a liquidation cascade.

Figure 23-8 shows the synchronization between funding-rate pulses and volatility clustering: during the market's transition from calm to crisis, the arbitrage-closing behavior triggered by extreme rates translates directly into additional directional volatility, giving volatility stronger persistence.

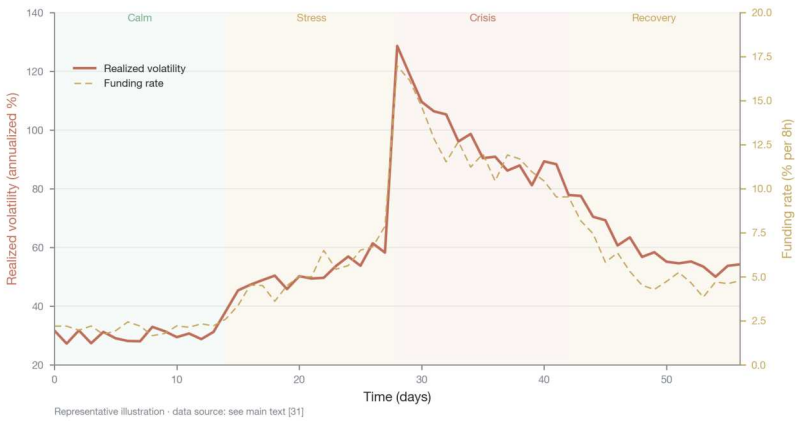

Figure 23-8. The linkage between funding-rate pulses and realized volatility (Representative illustration, synthetic series, not empirical data; the funding-rate axis in the figure is a synthetically amplified series that only illustrates its synchronization with volatility, not the true magnitude of the rate—the true perpetual rate is approximately 0.1%–0.3% per 8 hours, see main text; the volatility × leverage × liquidity framework mechanism is based on a crypto-market derivatives analysis report [31])

This pulse-superposition effect of the funding rate manifests in quantitative models as a higher persistence parameter in the GARCH model. Naimy et al. (2021) showed that, in capturing the volatility clustering characteristics of cryptocurrencies, a GARCH model incorporating asymmetric effects better reflects this mechanism-driven volatility jump, with a persistence parameter significantly higher than in traditional fiat-currency markets [9].

23.5.2 Automated liquidation

The core difference in margin mechanisms between traditional futures markets and perpetual futures lies in the execution speed of liquidation. In traditional delivery futures, when an account's margin is insufficient, the exchange issues a margin call, and the trader typically has a T+1 time window to add funds or close the position independently. This design provides a buffer for the market: liquidation is dispersed, and different traders respond at different points in time. Perpetual futures, by contrast, use

an automated liquidation engine: when the mark price reaches the bankruptcy price, the engine immediately takes over the position and liquidates it at market price, with no manual intervention at any point, and the mark price is monitored at millisecond frequency. From trigger detection to the generation of the liquidation order, this process is indeed completed on a millisecond scale; however, the actual execution of the liquidation order—that is, filling level by level on the order book until the position is fully closed—may last several seconds or longer in extreme markets, because the rapid evaporation of order-book depth forces the liquidation order to seek counterparties at ever more distant price levels. When large numbers of liquidations are triggered simultaneously, the matching engine may become congested or even degrade (for example, in May 2021 the latency of Binance's matching engine spiked to the second level), forming a "liquidation cliff" effect: after the engine recovers, the backlog of liquidation orders is released all at once, causing a price impact far greater than under continuous processing.

This speed difference fundamentally alters the transmission dynamics of volatility. In perpetual futures, liquidation is synchronous and concentrated. The engine simultaneously processes all triggered leveraged positions, and the concentrated liquidation flow directly hits the order book. Because market makers typically widen spreads and withdraw liquidity during high volatility, the order book's absorptive capacity is at its weakest. The liquidation flow creates a deeper price dip in the thin order book, and this new price low immediately triggers the next batch of originally safe positions, forming the classic liquidation cascade.

Using a scatter plot of 24-hour cumulative liquidation volume against contemporaneous realized volatility, Figure 23-9 reflects the positive feedback relationship between the two: the scatter exhibits pronounced nonlinearity, and once liquidation volume breaks through a critical level, the volatility response steepens sharply.

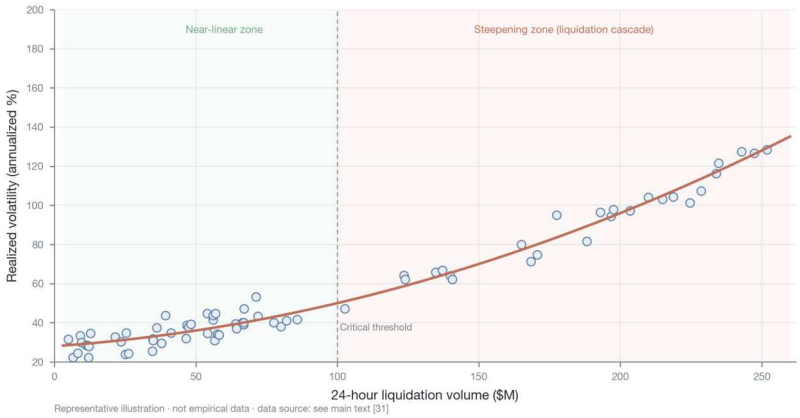

Figure 23-9. The positive feedback effect between 24-hour liquidation volume and realized volatility (Representative scatter illustration, synthetic series, not empirical data; mechanism based on a crypto-market derivatives analysis report [31])

In perpetual futures, leverage routinely reaches 100×, and superimposed on an instan-

taneous liquidation mechanism it gives the positive feedback an extremely high gain. The liquidation volume triggered by a 3% price decline in perpetual futures may be several times that in traditional futures markets. This additional volatility manufactured by the liquidation engine accumulates along the time series and directly causes deep volatility clustering. The liquidation cascade not only creates extreme volatility in the current period but also lays the foundation for high volatility in subsequent periods by thoroughly destroying the liquidity structure. The operational risk of the liquidation engine itself also constitutes an independent amplification channel: when engine overload causes liquidation delays, positions not liquidated in time continue to lose money and accumulate bankruptcy losses, ultimately triggering the exhaustion of the insurance fund and auto-deleveraging; the latter forcibly closes the positions of profitable counterparties, so that even traders who correctly predicted the direction are forced out of the market, further contracting liquidity. The regulatory evolution surrounding liquidation mechanisms is accelerating: for example, the European Union's MiCA framework imposes orderly-operation and risk-management requirements on crypto-asset service providers; some jurisdictions (such as Hong Kong) set caps on retail clients' virtual-asset leverage exposure; and several common-law jurisdictions have begun to examine whether automated liquidation under a manipulated mark price constitutes unfair trading conduct. If these regulatory interventions are fully implemented, they will fundamentally reshape the transmission dynamics of liquidation cascades.

23.5.3 Around-the-clock trading

Traditional financial markets have fixed closing times and weekend market closures. This design objectively acts as a systemic shock absorber. During the market close, market makers have time to reassess risk models and deploy capital, traders can calmly digest information, and algorithmic logic can be manually reviewed. Overnight information shocks are typically reflected as a one-time gap at the next day's open, rather than triggering continuous feedback transmission during the session.

Perpetual futures markets operate around-the-clock, continuous trading, which means the feedback loops are always in an activatable state. Information shocks can be transmitted at any point in time, especially during late-night or weekend hours when liquidity is naturally thin. In these low-liquidity windows, an order-flow shock of the same magnitude produces far greater price movement than during normal hours. Once volatility triggers the liquidation engine or an extreme value of the funding rate, the feedback loop operates continuously in an environment lacking sufficient liquidity buffer.

This continuous-trading mechanism facilitates the cross-time-zone relay transmission of volatility. Volatility originating in the Asian trading session may continue to be amplified in the European session because of insufficient liquidity, and then trigger a larger-scale leverage clearing in the American session. Volatility clustering can therefore cross the closing boundaries of traditional markets, forming high-volatility clusters lasting days or even weeks. The profound impact of around-the-clock trading on market microstructure has attracted wide attention, with related analyses noting that low-liquidity periods such as weekends and late nights have become high-incidence windows for volatility eruptions [32]; traditional exchanges such as CME have also begun to

launch around-the-clock crypto derivatives trading. While amplifying volatility, 24/7 trading also has a mitigating side: continuous trading eliminates the overnight gaps of traditional markets and allows information to be incorporated into prices more smoothly along the timeline; major exchanges have also deployed circuit-breaker-like mechanisms such as price-protection bands and extreme-market trading limits to partly compensate for the systemic fragility of having no market close, though the effectiveness of these mechanisms in extreme markets remains to be verified. Low-liquidity windows also invite strategic exploitation. In *liquidation hunting*, a trader places large directional orders during the thinnest-liquidity periods to trigger a cascade and profit from the resulting dislocation, which makes the fragility of these windows not merely a passive structural feature but an active, adversarial amplification mechanism.

23.5.4 Synergistic effects

The directional amplification of funding rates, the speed amplification of the automated liquidation engine, and the temporal amplification of around-the-clock trading—these three institutional features work together to make the volatility clustering intensity of perpetual futures systematically higher than in traditional markets. Figure 23-10 lays out how the three synergistically reinforce volatility clustering.

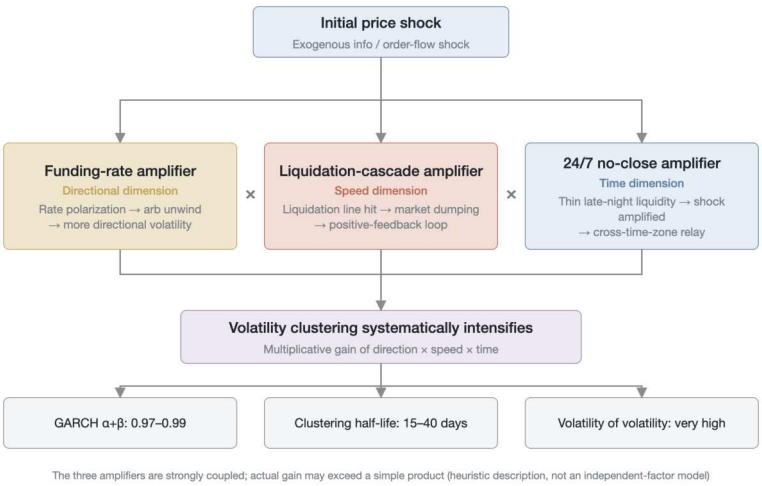

Figure 23-10. The conceptual transmission path of perpetual futures volatility amplifiers (Drawn by the author based on this chapter's analytical framework; conceptual mechanism illustration, not empirical data)

The transmission path in Figure 23-10 reveals the hierarchical relationship among the three amplifiers: the funding rate amplifies the trend and accumulates one-sided positions along the directional dimension, the automated liquidation engine instantaneously converts the fragility of positions into a market-price impact along the speed dimension, and around-the-clock trading eliminates the window for the system to cool naturally along the time dimension. The superposition of the three is not a simple linear summation but exhibits a multiplicative relationship: the larger the one-sided positions accumulated by the funding rate, the more violent the impact released when the liqui-

dation engine is triggered, and around-the-clock trading ensures that this impact can be detonated during the most fragile periods, such as the thinnest-liquidity late-night Asian hours. This "direction × speed × time" multiplicative effect is a heuristic description rather than a strict independent-factor model; strong coupling exists among the three amplifiers (24/7 trading allows funding rates to accumulate continuously, and extreme rates in turn trigger more liquidations), so the actual amplification factor may be higher than the simple product of the three. In addition, the analysis above focuses on the institutional design of centralized exchanges; on-chain order-book decentralized exchanges (DEXs), such as Hyperliquid and dYdX v4, face different but equally significant amplification mechanisms: the block-time constraint limits the liquidation-processing capacity per unit of time, the centralized single-point dependence of the sequencer may become a bottleneck under high load, and the update latency of the price oracle may cause a systematic deviation between the liquidation trigger and the true market price.

Returning to the cross-market comparison data in Table 23-1, the persistence parameter of perpetual futures is systematically higher than in traditional futures and spot markets, its shock-decay speed is the slowest, and its volatility half-life is the longest. The GARCH persistence parameter of traditional fiat-currency pairs is typically markedly lower than that of crypto perpetual futures, with a shorter volatility half-life and a shorter duration of extreme clustering episodes (the author's synthesis of multi-source estimates: fiat persistence of about 0.90–0.95, half-life of about 5–15 days, and clustering episodes of about 1–4 days); this directional difference is consistent with the empirical conclusions of [9].

The extreme volatility-of-volatility observed in perpetual futures markets does not stem from the intrinsic properties of the underlying asset but is the inevitable result of institutional design. If the automated liquidation engine were removed or trading circuit breakers introduced, the intensity of volatility clustering would decline structurally. This conclusion has important policy and design implications: in assessing and managing systemic risk in crypto markets, risk-control models cannot rest on the statistical extrapolation of historical volatility alone but must treat the nonlinear transmission logic of these institutional amplifiers as a core consideration.

23.6 The accumulation of fragility during low-volatility periods

In cryptocurrency perpetual futures markets, a prolonged low-volatility environment is often misinterpreted by market participants as a signal of reduced risk. From the perspective of system dynamics, however, this calm is not true safety but a process in which fragility accumulates covertly within the system. When the market remains in a low-volatility state for an extended period, the behavioral responses of traders, the market-making strategies of liquidity providers, and the parameter updates of risk-management models jointly constitute a self-reinforcing fragility-production mechanism. This mechanism explains why the most intense volatility clusters in cryptocurrency markets often erupt right after the longest calm periods. This section examines the

endogenous evolution of leverage and liquidity during low-volatility periods, traces the microscopic chain through which stability produces instability, and shows how the pattern appears in empirical data.

23.6.1 The endogenous accumulation of leverage

In the financial instability hypothesis, Minsky pointed out that the stable periods of a capitalist economy endogenously breed instability, because prolonged stability induces market participants to take on greater risk [33]. Minsky's theoretical framework divides the financial cycle into three stages: the hedge-financing stage (participants can repay debt through cash flow), the speculative-financing stage (participants can only repay interest but must borrow anew to repay principal), and the Ponzi-financing stage (participants cannot even repay interest and rely entirely on rising asset prices). Perpetual futures trading in cryptocurrency markets is an accelerated version of this evolution, and the low-volatility period is precisely the critical transition from hedge financing to speculative financing. However, the gradual deterioration from hedge financing to Ponzi financing in Minsky's framework depends on the relationship between debt-servicing cash flow and income, whereas perpetual futures trading does not generate "income" in the traditional sense, and participants' solvency depends entirely on the direction of asset-price movement. In this sense, highly leveraged directional perpetual futures positions have the characteristics of speculative or Ponzi financing from the moment they are opened, and Minsky's gradual-deterioration narrative is better understood in the crypto context as the accumulation process of total systemic leverage rather than a stage-by-stage evolution in the nature of financing. Geanakoplos's (2010) [34] leverage-cycle theory—whose core thesis is that changes in collateral value endogenously alter credit availability and produce procyclical fluctuations in leverage—may provide a theoretical anchor more directly applicable to crypto derivatives markets. This theory is especially pronounced in cryptocurrency perpetual futures markets, and its evolution is far faster than in traditional macroeconomic cycles. In the participant structure of cryptocurrency markets, the share of retail investors is far higher than in traditional financial markets, and retail investors' risk perception is often based on recent market performance rather than on long-run statistical regularities. When asset-price volatility remains low for a prolonged period, the behavioral patterns of market participants undergo a systematic change, and this change directly leads to a covert climb in the system's overall leverage level.

The starting point of the behavioral response is the interaction between risk perception and risk-management models. In a low-volatility environment, a VaR model estimated from historical data outputs extremely low risk assessments [35]. For institutional investors, this means that under the same risk budget, they can and must allocate a larger notional position to maintain the target rate of return. For individual traders, prolonged sideways movement or slow appreciation significantly lowers their vigilance toward tail risk, prompting them to adopt higher leverage multiples in perpetual futures. Over time, the ratio of the entire market's open-interest value to spot market capitalization continuously climbs. This phenomenon is especially pronounced in cryptocurrency markets, because the leverage caps of perpetual futures are often far higher than in traditional futures markets (BTC perpetual futures on some exchanges can

reach 100× leverage or higher), and retail investors, with relatively weak risk awareness, are more likely to adopt extreme leverage driven by the false sense of safety of low volatility.

This leverage-accumulation process is further amplified under the funding-rate mechanism unique to perpetual futures. When the market is in a calm period with a slight long bias, the funding rate tends to remain stable and positive. This stable income stream attracts a large number of arbitrageurs into the market to establish basis-arbitrage or funding-rate-arbitrage positions. Although these arbitrage positions are market-neutral by design, they greatly increase the total open interest of the perpetual futures market. At the same time, these seemingly low-risk positions are equally subject to maintenance-margin requirements when the market state changes abruptly. The distinction matters. Funding-rate arbitrage positions are delta-neutral by design—a spot long against a perpetual short—and their risk comes not from directional losses but from the margin calls caused by basis jumps and from the liquidity risk that the spot leg cannot be closed in time in extreme markets. Therefore, arbitrage open interest (OI) and speculative OI contribute to systemic fragility in different ways. In assessing systemic risk, the share of speculative OI is a more informative indicator than total OI. Nevertheless, when the calm period is broken and volatility rises sharply, both speculative and arbitrage positions of enormous size face margin pressure, instantly converting into potential liquidation momentum and providing ample fuel for subsequent volatility clustering.

At the microscopic level, leverage accumulation during low-volatility periods is also reflected in the dynamic adjustment of exchanges' margin systems. Exchange margin adjustment is in fact the superposition of multiple layers of mechanism: volatility-linked dynamic margin (procyclical—that is, lowering requirements when volatility is low, encouraging leverage), position-size tiered margin (countercyclical—that is, large accounts face higher margin rates, suppressing concentration), and, on some exchanges, pre-announced adjustment (buffering—that is, granting a 24-to-48-hour preparation period). On regulated exchanges (such as CME), margin adjustment is constrained by notice-period requirements, and its procyclical effect is buffered; on offshore exchanges, zero-notice margin adjustment can itself become a trigger of volatility. The net effect of the three remains procyclically dominated, because volatility-linked dynamic margin has the widest coverage and the largest adjustment magnitude. During low-volatility periods, dynamic margin requirements are gradually lowered, which further incentivizes traders to adopt higher leverage. Overall, this procyclically dominated margin-adjustment system is itself a fragility-amplification mechanism: when volatility suddenly rises, exchanges are often forced to rapidly raise margin requirements, and this sudden change in requirements triggers the forced liquidation of large numbers of positions, thereby intensifying the rise in volatility.

In extreme cases, exchanges may even suspend the liquidation function when market volatility rises to an extreme, in order to prevent a system collapse. Although this "circuit breaker" mechanism protects the exchange's system stability in the short term, it simultaneously freezes the market's price-discovery mechanism, so that trapped positions cannot be closed at any price, further intensifying the panic of market participants. This phenomenon was fully demonstrated in the "Black Thursday" event of March 2020, when the liquidation systems of several exchanges were temporarily

paralyzed by excessive traffic, leaving large numbers of positions unable to be closed in time and ultimately causing greater losses. On-chain liquidation systems exposed a different but equally serious fragility in the same event: MakerDAO's on-chain liquidation auctions were nearly paralyzed by severe congestion on the Ethereum network, as liquidators could not submit bid transactions because of the surge in gas fees, causing large amounts of collateral to be filled at zero bids. The fragility of on-chain liquidation stems from the throughput bottleneck of the underlying network rather than a design flaw in the liquidation engine itself, and it constitutes an amplification mechanism physically entirely different from the overload of a centralized exchange (CEX) liquidation engine.

23.6.2 Liquidity concentration

Accompanying the covert rise in leverage is a profound distortion of the liquidity structure. During low-volatility periods, market makers face a markedly different competitive environment and risk-return trade-off. Because prices fluctuate within a narrow range, orders far from the current market price have an extremely low probability of being executed, which greatly reduces the capital efficiency of providing liquidity across a wide price range. To capture limited trading volume and maximize capital utilization amid fierce competition, market makers rationally adjust their quoting strategy.

The core manifestation of this adjustment is the extreme concentration of liquidity. Market makers deploy the vast majority of their capital in an extremely narrow range hugging the current best bid and ask, compressing the bid-ask spread to the extreme and making the order book's apparent depth near the price appear exceptionally ample [36]. This surface abundance, however, masks the structural emptiness deeper in the order book. Because capital is drawn tightly toward the touchline, depth far from the current price declines sharply. In automated market maker (AMM) mechanisms, the widespread adoption of concentrated-liquidity design likewise intensifies this phenomenon, as liquidity providers tend to concentrate their funds near the current price to earn the highest fee income.

This distortion of the liquidity distribution greatly increases the fragility of the system. During calm periods, the extremely narrow spread and ample touchline depth create for traders an illusion of excellent market liquidity. However, once an information shock beyond ordinary expectations or a large sell order appears, the liquidity concentrated near the touchline is instantly broken through. Because far-end depth is empty, price jumps sharply as it searches for the next level of liquidity support. This discontinuous jump, triggered by a liquidity fault, produces a price impact far greater than under a normal liquidity distribution, pushing the system directly from a low-volatility state into an extreme high-volatility state within a very short time.

From the perspective of data microstructure, this phenomenon can be quantified through the shape parameters of the order book. During low-volatility periods, the order book typically exhibits a "spiked" shape—that is, an extremely high depth density near the current price, but a sharp decline in depth as the price distance increases. By comparison, the order-book shape under normal market conditions is more uniform and gradual. This spiking not only reduces static shock-absorption

capacity but also weakens the order book's recovery resilience—that is, the speed at which the order book returns to its pre-shock state after a price impact. Bouchaud et al. (2009) [37] showed that liquidity gaps in the order book amplify the price impact of a single order, and that the spread and depth recovery after a shock follow a slow power-law decay; this "slow recovery" feature corresponds directly to the "slow termination" feature of the liquidity loop described in Section 23.3. When the market shifts from calm to volatile, this spiked-shape order book cannot effectively absorb large order flow, forcing prices to jump to more distant price levels to find sufficient liquidity. In this process, each price jump triggers more liquidations, which in turn causes more sell orders to flood in, forming a self-reinforcing vicious cycle.

23.6.3 Empirical relationships

The "calm trap" is not merely a theoretical deduction but an empirical regularity deeply imprinted in the historical data of cryptocurrency markets. The evolution of slow variables (such as the leverage level and the liquidity structure) takes time; the longer a calm period lasts, the deeper these slow variables slide toward the danger range and the greater the fragility the system accumulates. A significant positive correlation therefore exists between the length of a calm period and the intensity of the volatility cluster that subsequently erupts.

Observation of Bitcoin's historical market movements clearly reveals this pattern. For example, before the violent crash of the Bitcoin price in mid-November 2018, the market experienced months of extremely low volatility, during which the Bollinger Bands narrowed to a historical extreme and open interest continuously climbed. Likewise, before the extreme "Black Thursday" market of March 2020, the market had also gone through a relatively calm, optimistic period. The May 2021 crash followed the same pattern: in the preceding weeks, Bitcoin oscillated repeatedly within the $45,000 to $65,000 range, volatility remained at a low level, yet open interest kept increasing. These historical events show that the eruption of extreme volatility clustering is often not an isolated random event but the inevitable result of continuously accumulating fragility during a long calm period.

Figure 23-11 shows the scatter relationship, based on Bitcoin historical data, between the length of calm periods and the intensity of subsequent volatility clustering: low-volatility calm periods lasting more than 50 days are often accompanied by subsequent extreme volatility clusters whose annualized volatility peaks exceed 100%, confirming that time is a key dimension of fragility accumulation. To quantify this relationship, defining a calm period as a continuous period in which the 30-day realized volatility is below an annualized 35%, and defining clustering intensity as the peak of the 30-day realized volatility that follows, the author identified about 15 independent calm-period–eruption-period pairs in BTC historical data from 2018 to 2024. The Spearman rank correlation coefficient is approximately 0.72 ($N=15$, $p<0.01$), though under such a small sample its confidence interval is wide (the 95% confidence interval is approximately 0.35 to 0.90), and removing the single most extreme event (March 2020) reduces the rank correlation to about 0.60. Although the precise value of the point estimate is sensitive to sample composition, the direction of the positive correlation remains robust

across various calm-period definition thresholds (25% to 45%) and volatility measures, indicating statistically meaningful support for the explanatory power of calm-period length over subsequent clustering intensity.

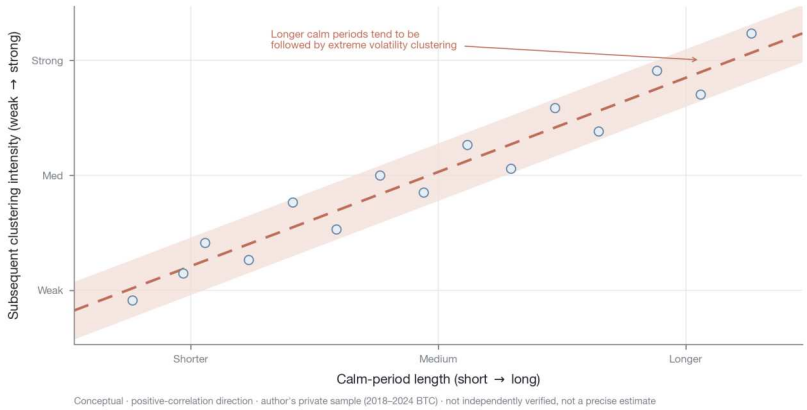

Figure 23-11. The positive correlation between calm-period length and subsequent volatility clustering intensity in Bitcoin historical data (Illustrative: direction of positive correlation; the author's proprietary sample of BTC from 2018 to 2024, not independently verified, not a precise estimate)

The mechanism behind this empirical relationship lies in the time-accumulation property of slow variables. The accumulation of leverage, the concentration of liquidity, and the parameter drift of risk models do not happen instantaneously but evolve slowly, day by day and week by week, during the calm period. A 30-day calm period may accumulate only enough fragility to support 50% volatility clustering, whereas a 70-day calm period may accumulate enough to support 150% volatility clustering. This nonlinear relationship explains why certain relatively small triggering events can provoke extreme market reactions after a long calm period.

23.6.4 Early-warning signals

Once the mechanism of fragility accumulation during low-volatility periods is understood, the core of risk management shifts from "predicting when a shock will occur" to "assessing how fragile the current system is." The VIX paradox in traditional financial markets points out that when the volatility index is at its lowest, it is often the moment when hedging demand is weakest and the system is least protected, and at this point the market's endogenous fragility is in fact highest [38]. In cryptocurrency perpetual futures markets, although a volatility-derivatives market of equal depth is lacking, we can identify the "calm trap" through a set of observable microstructural indicators.

In fragility assessment, leverage indicators are at the most upstream point of the causal chain. The ratio of the notional value of open interest to the market capitalization of the underlying asset is the most intuitive indicator of systemic leverage. In a low-volatility environment, if this ratio shows a persistent upward trend accompanied by the funding rate long deviating from a neutral level, it strongly suggests that a large number of highly leveraged positions extremely sensitive to one-directional price movement are

accumulating in the market. Figure 23-12 simulates the entire process in which open interest gradually climbs during the calm period, converts into liquidation momentum that pushes up volatility after the turning point, and then falls rapidly during the liquidation cascade—a process typically completed within hours to days.

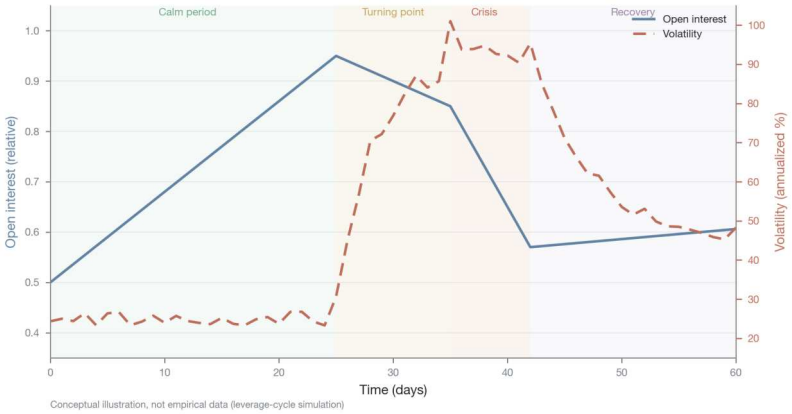

Figure 23-12. The temporal evolution dynamics of open interest and volatility in perpetual futures (Simulated by the author based on leverage-cycle theory; illustrative simulation, not empirical data)

Leverage accumulation determines the potential liquidation momentum, but whether this momentum can be absorbed by the market depends on the distribution structure of liquidity. Simply observing the touchline spread is often deceptive, because the extremely narrow spread of a low-volatility period is precisely the result of excessive liquidity concentration. A more reliable early-warning signal is the concentration indicator of order-book depth—that is, the ratio of quoted volume near the touchline (for example, within a 0.5% range) to quoted volume in a wider range (for example, within a 2% or 5% range). If this ratio rises significantly during a low-volatility period, it indicates that liquidity is becoming extremely concentrated, far-end depth is being hollowed out, and the market's capacity to absorb unexpected shocks is declining sharply. When this ratio exceeds 150% of the historical median, the system has already entered a high-fragility state. However, the depth-concentration ratio based on order-book snapshots has inherent limitations: visible quotes contain a large number of non-committed quotes (such as the ghost liquidity described in Chapter 20) that are rapidly withdrawn when the market moves, so the indicator may overestimate true depth. Alternative indicators based on actual transaction data—such as the time-weighted average price impact or the VPIN (volume-synchronized probability of informed trading) indicator—are less susceptible to illusory liquidity and can serve as cross-validation tools. More fundamentally, the early-warning indicators above have so far only been validated in-sample, and their out-of-sample predictive power (particularly sensitivity and specificity) still needs to be established through testing over a longer time series before operable early-warning thresholds can be set.

Above the objective fragility of the system constituted by leverage and liquidity, behavioral and sentiment indicators reflect market participants' subjective cognitive bias

toward this fragility. The extremization of the retail long-short ratio, the persistent exuberance of social-media sentiment indicators, and the narrowing of the spread between market makers' quoted implied volatility and historical realized volatility all indicate that market participants severely underprice tail risk. During low-volatility periods, if the spread between implied and realized volatility (commonly called the "volatility premium") remains persistently negative with a continuously expanding absolute value, this indicates that the market is collectively underestimating risk. This cognitive bias in turn reinforces leverage accumulation, because participants who underestimate risk are more inclined to raise their leverage multiples. Microstructural indicators such as the directionality of order flow, the arrival frequency of large orders, and market makers' inventory levels can further verify the above trends: when the arrival frequency of large buy orders persistently exceeds that of large sell orders during a low-volatility period, this suggests that market participants are actively building leveraged long positions.

Figure 23-13 summarizes the complete transmission mechanism of fragility accumulation during low-volatility periods. These early-warning signals cannot predict the timing and nature of the triggering event, but they can assess the system's current level of fragility, thereby shifting the focus of risk management from "when it will happen" to "how severe it will be if it happens."

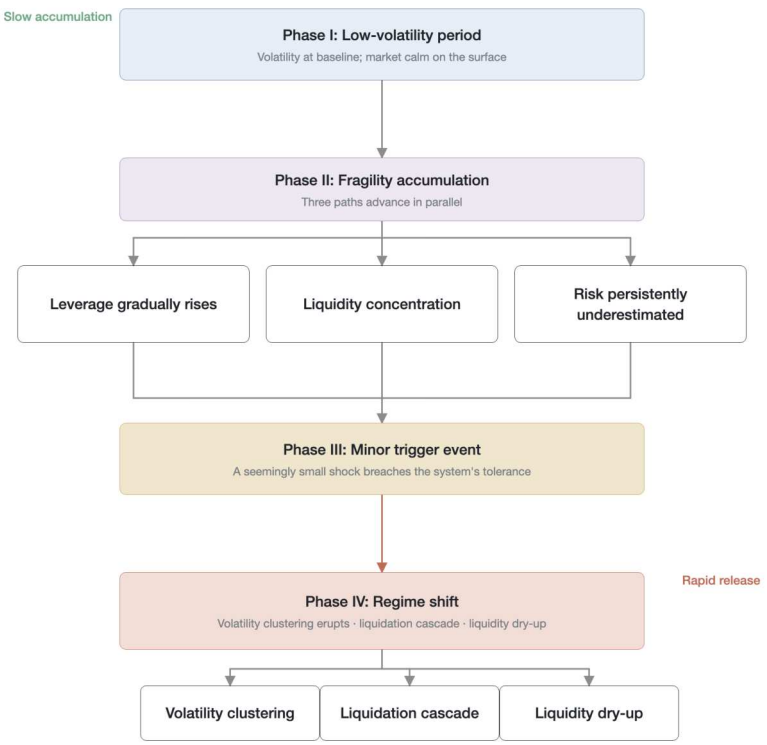

Figure 23-13. The mechanism of fragility accumulation and abrupt state change in a low-volatility environment (Drawn by the author based on this chapter's analytical framework; conceptual mechanism illustration, not empirical data)

The transmission path in Figure 23-13 clearly displays the complete logical closed loop of the "calm trap." Starting from the low-volatility environment at the top, three paths—leverage accumulation, liquidity concentration, and risk underestimation—advance in parallel, jointly pushing the system toward a high-fragility critical state. When an external triggering event breaks through the activation threshold set by the slow variables, the system jumps sharply from the upper part of the figure (the slow-accumulation stage) to the lower part (the rapid-release stage), and the positive feedback loop of liquidation cascade and liquidity exhaustion causes volatility to surge to extreme levels within a short time. The practical significance of this path diagram is that risk managers should focus their attention on the three accumulation paths in the middle of the figure, because they are the observable, measurable early-warning dimensions.

23.7 Case study: the life cycle of the May 2021 crash

To validate the three-layer explanatory framework of "slow variables → feedback loops → state machine" proposed above, we need a real market case with a complete life cycle. The Bitcoin market crash of May 2021 provides a classic natural experiment. This event was not a single random shock but a demonstration of the complete dynamic process of how volatility gradually accumulates fragility from a low level, how it is sharply amplified by positive feedback loops after a triggering event, and how the market state rapidly jumps from calm to crisis. By dissecting this historical case, we can clearly see how microstructural mechanisms shape the macro phenomenon of volatility clustering.

23.7.1 The state of the slow variables

The cryptocurrency market in the first quarter of 2021 was in a typical "calm" state, but this surface stability masked a sharp rise in underlying systemic fragility. The evolution of the slow variables set the tone for the subsequent violent volatility.

The level of systemic leverage, as the primary slow variable, underwent unprecedented expansion during this period. The Bitcoin price climbed from $29,000 at the start of 2021 to $64,000 by mid-April, a gain of more than 120%. In this strong uptrend, the endogenous character of leverage was fully displayed: as prices rose, the effective leverage ratio of long positions passively declined, prompting traders to continually add new leverage to maintain their target risk exposure. According to whole-market BTC perpetual futures data aggregated by Coinglass (including coin-margined and USDT-margined contracts), the notional value of open interest surged from about $10 billion at the start of 2021 to about $27 billion by mid-April, and climbed further to a peak of about $28 billion before the May crash [39]. At the same time, this leverage expansion was accompanied by extremely skewed market sentiment, with the funding rate long remaining at a level of 0.1% to 0.3% per 8-hour settlement period (a simple annualization of about 110% to 330%, though because arbitrageurs typically build positions when rates are low, the actual cost borne during the holding period is lower than the simple annualized value), indicating that longs not only held absolute dominance but were also willing to pay a high cost to maintain leverage.

Liquidity depth, another slow variable, was likewise gradually changing for the worse. Although the number of surface quotes on the order book appeared ample when prices were high, market makers' capital deployment exhibited a highly concentrated character. A large amount of liquidity clustered within an extremely narrow range near the current price, while the deep order book far from the current price was abnormally empty. This liquidity structure meant that once the price broke through the narrow high-liquidity range, the market would face a liquidity-fault zone with almost no buffer [20].

At the same time, changes in the participant structure further intensified the system's fragility. Blockchain data analysis shows that during this period the vast majority of Bitcoin addresses were in an unrealized-profit state, and large numbers of newly entered retail investors had established highly leveraged long positions at high prices [40]. These inexperienced investors had extremely low tolerance for price fluctuations, and their stop-loss orders were densely distributed not far below the current price. From the perspective of behavioral finance, the disposition effect (Shefrin & Statman 1985 [41]) meant that the large number of unrealized-profit holders constituted an enormous pool of potential sellers—profitable holders tend to close positions within the profit range; once a negative catalyst appeared, this seller pool could be rapidly activated, triggering large-scale profit-taking selling.

By this point, the slow variables had completed a dangerous combined configuration: elevated systemic leverage, weak deep liquidity, and highly concentrated stop-loss orders. This state of "high leverage + thin depth + high sentiment" constituted an extremely fragile market environment. In such an environment, the system did not need to withstand a large-scale external shock; a routine-scale piece of negative news was enough to break through the feedback-activation threshold that the slow variables had lowered to an extremely low level.

23.7.2 The trigger and initial shock

In mid-May 2021, the long-accumulated fragility finally met its triggering event. This trigger was not a single catastrophic piece of news but the superposition of a series of negative events that together broke through the critical point at which the system maintained equilibrium.

On May 12, Tesla CEO Elon Musk announced on social media that, out of concern about the environmental impact of Bitcoin mining, Tesla would stop accepting Bitcoin as a means of payment [42]. This statement directly struck one of the core narratives underpinning the first-quarter bull market—institutional adoption. Immediately afterward, on May 13, Chinese regulators reiterated their ban on financial institutions and payment companies providing cryptocurrency-related services, further intensifying market panic. Such regulatory shocks amplify and spread risk through the contagion channel between crypto assets and traditional securities markets [43]. Unlike a one-time information shock such as the Musk tweet, the Chinese regulatory tightening was essentially a structural institutional change; it not only triggered panic in the short term but also, over the medium to long term, set off a series of structural adjustments—including mining migration, the shift of exchange users to offshore platforms, and the closure of fiat on-ramps—and these supply-side changes lasting for months prolonged the tail of

the volatility clustering.

These pieces of news constituted the initial information shock. The Bitcoin price fell at one point in mid-May from about $57,000 to near $52,000, a single-day decline of about 9%. In a traditional spot market, a 9% decline, though significant, would typically be regarded as a normal correction. In the highly leveraged environment of perpetual futures, however, this initial shock underwent a qualitative change.

The initial price decline first caused a sharp reversal in the funding rate. The positive funding rate that had long remained high rapidly turned negative, marking a sudden reversal of market sentiment, and some highly leveraged longs began to be forced to close positions. At the same time, the 9% decline was enough to reach the maintenance-margin lines of a large number of highly leveraged long positions established above $55,000. Initial liquidations began to occur, and the market sell orders automatically generated by the liquidation engine began to hit the order book.

At this stage, the market state machine underwent its first discrete jump: from the "calm" state to the "stressed" state. Volatility indicators responded immediately to this jump, with Bitcoin's realized volatility jumping rapidly from the calm-period range of an annualized 30% to 45% to a level of an annualized 75% to 85%. Market makers began to sense the risk, spreads widened from a normal 3 basis points, and some ghost liquidity (as described in Chapter 20, referring to non-committed market-making quotes that are displayed under normal market conditions but rapidly withdrawn under stress) began to retreat. At this point, however, the system was still in a state of strained support, and a full-blown cascade had not yet erupted.

23.7.3 The cascade and crisis

After the initial shock pushed prices down and triggered the first wave of liquidations, the second-layer mechanism—the feedback loops—was fully activated. From May 13 to 19, the market witnessed one of the most violent liquidation cascades in cryptocurrency history, precisely the result of the mutual reinforcement of the volatility-leverage feedback loop and the volatility-liquidity feedback loop.

As prices fell further, the volatility-leverage feedback loop began to operate continuously. Falling prices eroded the margin of more long positions, the effective leverage ratio rose passively, and the liquidation trigger distance shortened. When the price broke below the key psychological threshold of $50,000, it triggered densely distributed stop-loss orders and liquidation orders. These forced sell orders hit the market indiscriminately, driving prices down further and, in turn, triggering deeper liquidations [12].

At the same time, the volatility-liquidity feedback loop intensified this process. Facing sharply rising volatility and one-directional liquidation selling pressure, market makers faced extremely high adverse-selection risk and inventory risk. To protect their own capital, market makers sharply widened the bid-ask spread and even withdrew buy orders entirely. At the most extreme moment, market depth evaporated and the order book became extremely thin [20]. The exhaustion of liquidity meant that the same quantity of liquidation sell orders caused a far larger price impact than usual.

These two feedback loops formed a self-reinforcing downward spiral: liquidation trig-

gered → price decline → liquidity withdrawal → price impact amplified → more positions liquidated. This process peaked on May 19. That day, the Bitcoin price plunged by about 32% within less than 12 hours (an intraday-peak measure; about −30% on a daily-close basis), touching a low below $30,000; Ethereum's decline was deeper, with an intraday maximum drop of about 46% [44].

The data clearly record the severity of this crisis. According to statistics from several data-aggregation platforms (Coinglass, The Block), the notional value of positions forcibly liquidated across the entire crypto market on May 19 exceeded $8 billion (about $8.6 billion by multi-source aggregation; this figure is the notional size of liquidated positions rather than the actual loss amount, the latter being difficult to estimate precisely because of slippage and bankruptcy); among them, Deribit alone saw 296 Ethereum positions and 609 Bitcoin positions undergo bankruptcy liquidation [44]. Whole-market BTC perpetual open interest plunged from about $28 billion to near $10 billion within just a few days, indicating that leverage within the system was violently cleared out [39].

At this stage, the market state machine completed its second jump: from the "stressed" state fully into the "crisis" state. Volatility was no longer continuous but exhibited jump-like behavior, soaring directly from around an annualized 80% to an extreme level of an annualized 150% to 200%. Cross-exchange spreads widened sharply, and the arbitrage mechanism temporarily failed in the face of an extremely congested network and exhausted capital. The cross-instrument contagion effect of this crisis was equally significant: Ethereum perpetual futures plunged 46% on the same day, a decline far exceeding BTC's 32%. This difference may stem from the ETH market's higher starting leverage ratio and thinner deep liquidity, as well as traders under a unified margin account preferentially liquidating the more liquid ETH positions to free up BTC margin. At the peak of liquidation, the insurance funds of several exchanges suffered large drawdowns, and some platforms triggered the auto-deleveraging mechanism (the reverse cascade described in Section 23.5.2, which forcibly closes profitable counterparties' positions), further compressing the supply of liquidity.

Figure 23-14 superimposes four time series from this life cycle—the price trajectory, 24-hour liquidation volume, open-interest size, and realized volatility—so that the reader can trace, on a single timeline, the successive activation and transmission of each layer of mechanism.

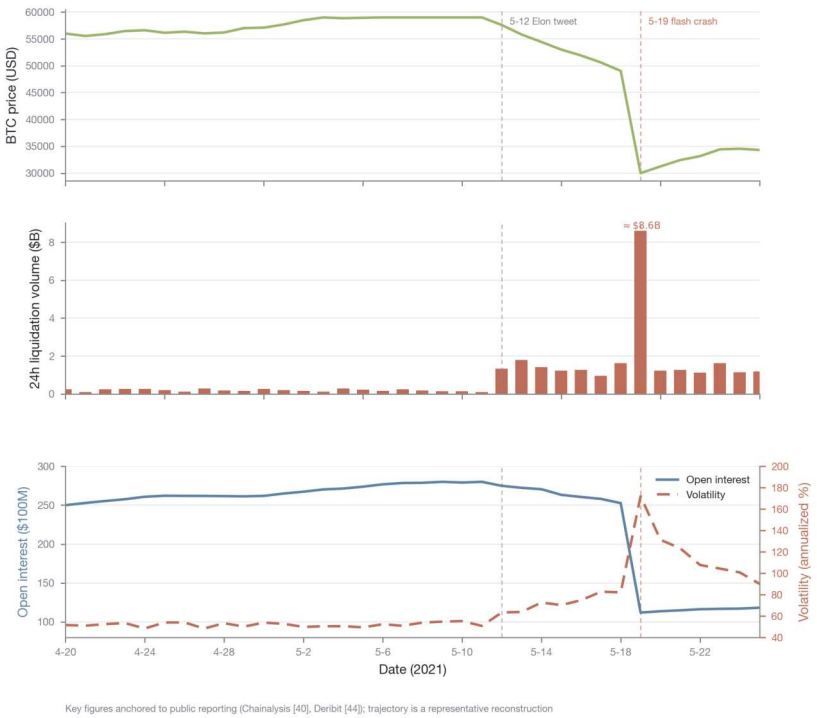

Figure 23-14. The volatility clustering life cycle of the May 2021 BTC crash (Empirical figure; price and liquidation-volume data sources: Chainalysis [40] and Deribit Insights [44]; open-interest series source: Coinglass [39]; realized volatility is the author's calculation based on daily returns; ETH's intraday maximum drop of about 46% is an intraday-peak measure, about −40% on a daily-close basis)

In Figure 23-14, the three stages corresponding to Sections 23.7.1–23.7.3—incubation, stress, and crisis—can be clearly identified: open interest first climbs to a peak during the calm period, then declines off a cliff during the crisis period, while liquidation volume and realized volatility surge synchronously to extreme values on May 19. The violent movements of the four curves are highly synchronized on the timeline, precisely mapping the positive-feedback transmission path of liquidation cascade → liquidity exhaustion → volatility surge.

23.7.4 Theoretical validation

The May 2021 crash case provides a consistent illustration of the three-layer explanatory framework proposed in this chapter, demonstrating the framework's structural advantages in explaining extreme market behavior. The ex-post analysis of a single case carries inherent methodological limitations, however: selective interpretation after the fact may exaggerate the framework's explanatory power, and the framework's applicability to other historical events, such as the 2022 LUNA/UST collapse, still requires independent validation. The discussion that follows should be read under this constraint.

First, the analysis at the slow-variable level successfully explains why the system was

in an extremely fragile state before the shock. Traditional statistical models (such as GARCH) can only make lagged adjustments after volatility has already risen and cannot warn of the accumulation of fragility during the calm period. By observing the expansion of open interest and the persistently elevated funding rate, the slow-variable framework accurately captured the potential of "how severe the reaction would be if a shock occurred." This proves that the crisis was not caused unilaterally by Musk's tweet or the regulatory news alone but was the joint result of an extremely fragile environment and an ordinary information shock.

Second, the analysis at the feedback-loop level explains why volatility exhibits clustering and persistence. In the flash crash of May 19, the plunge in price far exceeded what any fundamental information could explain. The closed loop formed by the liquidation engine's mechanical selling and market makers' liquidity withdrawal clearly demonstrates how the shock was self-amplified by the system's internal mechanisms. It is precisely these microstructural feedback loops that constitute the physical basis of the "long memory" in the volatility time series, allowing the high-volatility state to sustain itself for several days after being triggered.

Finally, the state-machine model accurately describes the nonlinear character of market dynamics. The case shows that the transition from "calm" to "stressed" was relatively gradual, but the jump from "stressed" to "crisis" erupted within a few hours. In the crisis state, the dominant source of volatility switched completely from fundamental information to mechanistic liquidation and the absence of liquidity. This asymmetry of state transitions—very fast entry into crisis, slow exit from it—is the fundamental reason volatility clusters in perpetual futures markets display a sawtooth distribution [45].

However, this case also reveals the inherent limitations of the theoretical framework. Although the three-layer framework can accurately assess the system's fragility and explain the amplification mechanism of the feedback loops, it cannot predict the specific timing, nature, and exact magnitude of the triggering event. This limitation does not diminish the framework's value; rather, it points to the correct path for risk management: rather than trying to predict unpredictable triggering events, it is better to focus on monitoring and managing the observable slow variables and feedback states.

Abstracting the causal chain distilled from this case one step further, one can construct a systemic-crisis formation-path model applicable to more general situations. Figure 23-15 decomposes this path into four progressive stages: preconditions, the trigger layer, the transmission layer, and the amplification layer.

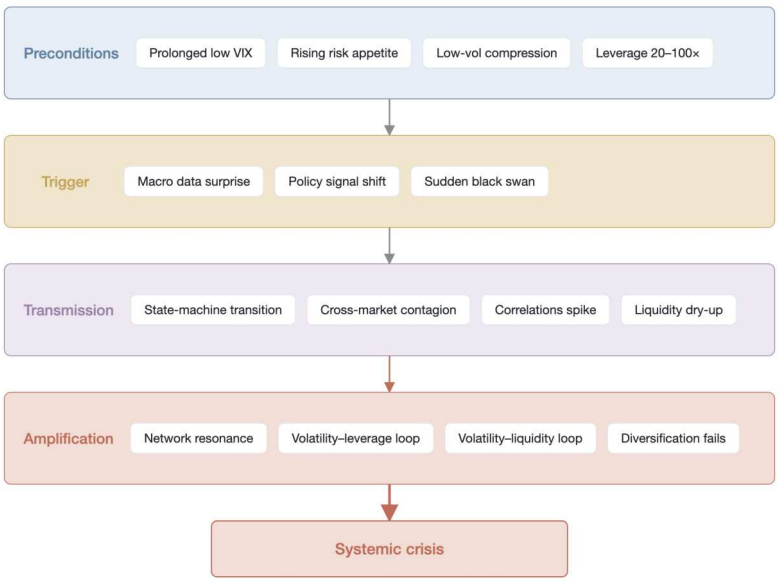

Figure 23-15. The formation path of a systemic financial crisis (Drawn by the author based on this chapter's analytical framework; conceptual mechanism illustration, not empirical data)

Figure 23-15 expresses this chapter's "slow variables → feedback loops → state machine" framework as a structured path and precisely maps the nonlinear dynamics observed in the May 2021 cryptocurrency market crash: a crisis is not triggered by a single external shock but is the inevitable result of the interaction between the long-term accumulation of internal systemic fragility and specific triggering conditions.

Along this path: in the precondition stage, the evolution of slow variables raises the system's fragility baseline, with the 20× to 100× leverage of perpetual futures acting here as a significant amplifier that raises the system's sensitivity to minor price changes exponentially; in the trigger layer, an exogenous shock shatters the illusion of low volatility and reaches the maintenance-margin lines of a large number of long positions, triggering initial liquidations; the transmission layer corresponds to the state machine's state switching, as the market jumps rapidly from calm to crisis and cross-market contagion and liquidity exhaustion appear in succession; and the amplification layer is the macro-network resonance of the feedback loops, in which the positive feedback of volatility-leverage and volatility-liquidity intertwines and self-reinforces, ultimately evolving local volatility into a full-blown systemic crisis. The policy implication of this formation path is that although a systemic crisis is abrupt, the accumulation of its underlying fragility and the evolution of its transmission mechanisms are traceable, structured processes: through continuous monitoring of the slow variables and feedback states, regulators and market participants may be able to identify the system's critical state before a crisis fully erupts, and thereby adopt more forward-looking risk-management measures.

23.8 Chapter summary

In empirical data, volatility clustering manifests as the dependence of the conditional variance on past shocks, a phenomenon that has been widely documented in time-series analysis. However, purely statistical models cannot explain the microscopic source of this memory effect. The three-layer explanatory framework proposed in this chapter fills this theoretical gap, reducing the phenomenon of volatility clustering to an identifiable process of market microstructure evolution. The first layer is the slow variables, including the macroeconomic environment, the level of systemic leverage, and liquidity depth; these variables evolve over longer time scales, and their core role is not to directly generate volatility but to set the baseline fragility for the entire system, determining how high or low the threshold for activating the feedback loops is. The second layer is the feedback loops, which constitute the microscopic dynamic basis for the self-amplification of shocks: significant positive feedback mechanisms exist between volatility and liquidity, leverage, and market behavior, and when an initial shock crosses the activation threshold set by the slow variables, market makers' withdrawal thins liquidity while the erosion of margin triggers passive leverage increases and liquidations—the rational reactions of these micro-agents converge at the macro level into the self-perpetuation of volatility. The third layer is the state-machine model, which discretizes the market's evolution into three states—calm, stressed, and crisis—with transitions among the different states exhibiting strong asymmetry: the process of entering a crisis is often driven by positive feedback and completed within an extremely short time, whereas exiting a crisis requires waiting for the momentum of the feedback loops to be exhausted and for liquidity to recover slowly. Figure 23-16 shows the overall structure of this framework.

Figure 23-16 condenses the core argumentative structure of this chapter into a bottom-

up three-layer architecture diagram. The practical value of this framework is that it provides a layered diagnostic tool for volatility forecasting and risk management: first assess the range in which the slow variables lie to judge systemic fragility; next monitor the activation signals of the feedback loops to identify the precursors of state transitions; and finally select the corresponding forecasting model and hedging strategy according to the current state.

Compared with traditional financial markets, crypto-asset perpetual futures markets exhibit a more violent volatility clustering effect, and this difference stems not from higher uncertainty in the intrinsic value of the underlying asset but from amplification by the market's distinctive institutional design. The liquidation cascade mechanism, under conditions of extremely high leverage and the absence of a margin-call buffer, instantly converts adverse price movements into market-price liquidation orders, producing an extremely high positive-feedback gain. The pulse-superposition effect of funding rates prolongs the duration of high volatility in the stressed or crisis state. The around-the-clock, no-close trading rule eliminates the window for market-maker capital resetting and emotional cooling that the market-close periods of traditional markets provide. To reduce the systemic risk of this market, policymaking and protocol design must intervene in these institutional features—for example, by introducing smoother liquidation-execution algorithms or setting dynamic caps on funding rates. These suggestions are better understood as directions for optimization at the protocol-design level than as top-down regulatory requirements, because trading volume in perpetual futures markets is concentrated mainly on offshore exchanges beyond the reach of most regulators, and globally unified mandatory rules are difficult to achieve in the short term. In addition, if a funding-rate cap is set improperly, it may introduce new distortions: persistent rate suppression would cause a systematic deviation between the contract price and the spot price, or drive trading activity to migrate to platforms without caps, producing regulatory arbitrage.

Low-volatility periods are usually intuitively regarded as safe periods for the market, but this chapter's analysis reveals that they are in essence the stage in which systemic fragility accumulates fastest. During a prolonged calm state, traders gradually raise leverage as confidence strengthens, market makers narrow spreads amid competition and cause liquidity concentration to rise, and the system's overall risk exposure continuously increases—even though all observable volatility indicators are at low levels. This mechanism poses a fundamental challenge to the traditional risk-management paradigm: a VaR model based on historical volatility systematically underestimates tail risk during calm periods. For example, in the calm period before the May 2021 event, the 99% VaR estimated from the past 30 days' realized volatility was about a single-day decline of 8% to 10%, whereas the actual single-day decline on May 19 reached 32%, more than three times the VaR prediction; even switching the risk measure to expected shortfall would struggle to close this gap, because the nonlinear amplification effect of the liquidation cascade exceeds the capture range of any static risk model based on the extrapolation of historical distributions. Therefore, the focus of risk management must shift from merely monitoring the current volatility level to continuously assessing the system's underlying fragility, integrating real-time monitoring of the leverage distribution, liquidity depth, and order-book concentration.

By deconstructing the microstructural mechanisms of volatility clustering, this chapter has answered the core question of why a high-volatility state self-perpetuates. Having clarified the driving mechanisms, the focus of the analysis will turn to how to exploit these regularities. The three-layer framework directly leads to a layered forecasting and decision-making system: first, identify the current market state through observable slow variables and microstructural indicators; next, select the corresponding forecasting model according to the dominant volatility dynamics of each state; and finally, formulate dynamic trading and hedging strategies based on the state-specific path of risk evolution. This logical progression—from mechanistic understanding to quantitative forecasting and then to strategy execution—constitutes the core thread of the next stage of analysis.

Volatility Forecasting and Decision-Making

In mid-March 2024, as the price of Bitcoin repeatedly set new record highs, open interest in the derivatives market briefly approached a peak of nearly $38 billion, after which a price pullback of just 7% triggered more than $800 million in cascading liquidations [1]. This episode highlights a core structural feature of the crypto-asset derivatives market: the eruption of systemic risk often stems not from a fundamental reversal in price direction but from a nonlinear expansion of volatility over an extremely short interval. For market participants, understanding the sources and clustering mechanisms of volatility is only the first step; the more challenging question is how to translate this theoretical understanding into executable forecasting models and risk-control decisions. That question is the central analytical objective of this chapter.

A market maker need not forecast the direction of Bitcoin's next-day price move, but must estimate its next-day volatility accurately. When expected volatility rises, the rational response is to widen the quoted spread, reduce order book depth, and tighten inventory limits; when volatility is expected to stay low, the market maker can quote narrower spreads and provide deeper liquidity [2]. What the market maker forecasts, in short, is not direction but the dynamics of volatility. The same holds for a portfolio manager, for whom the precise level of returns matters far less than the width of the return distribution, because that width drives the calibration of value at risk (VaR) and the sizing of positions [3]. And for exchanges and protocol designers, guarding against systemic risk turns on predicting which level of volatility will push liquidation volume past safety thresholds, so that margin requirements can be raised preemptively [4].

Volatility forecasting cannot reveal the specific events that will occur, but it can quantify the magnitude of the impact that potential events would have on market prices. Chapter 22 established a framework decomposing volatility into four sources, and Chapter 23 analyzed the clustering and regime-switching of volatility; the task of this chapter is to build, on that foundation, a set of operational forecasting models and a decision-making system. Classical volatility-clustering theory holds that large price changes tend to be followed by further large changes [5], an empirical regularity widely verified in traditional financial markets. The crypto-asset perpetual futures market, however, has distinctive properties—24/7 continuous trading, periodic funding settlement, and the absence of a deep options market—that call for targeted structural adjustments to the classical generalized autoregressive conditional heteroskedasticity (GARCH) model

and the heterogeneous autoregressive (HAR) model [6].

This chapter begins with the volatility information set specific to the perpetual futures market and examines the predictive power of the funding rate, liquidation heatmaps, and order book shape in the absence of implied volatility. On that basis, it proposes a source-decomposed volatility forecasting framework that models informational, liquidity, mechanical, and transmission volatility separately before aggregating them, precisely because these sources differ so fundamentally in predictability and time scale. Those forecasts are then embedded in a three-layer decision architecture spanning micro-level market-making quotes, meso-level position management, and macro-level systemic defenses. By the end of the chapter, the reader should be able to judge where different volatility-forecasting models apply to perpetual futures data, use alternative signals to read the market's risk state, and locate the boundary between the modelable and the intrinsically unpredictable components of volatility—the knowledge on which more resilient trading and risk-control systems are built.

24.1 The set of alternative volatility signals for perpetual futures

In traditional financial markets, option-implied volatility provides participants with a unified, forward-looking volatility benchmark. In the cryptocurrency perpetual futures market, however, the vast majority of assets lack a deep options market. This structural gap forces participants to construct an alternative system of volatility signals from dimensions such as the funding rate, liquidation heatmaps, order book microstructure, and on-chain data. This section analyzes the information content and predictive power of these signals in turn, assessing the conditions under which each class applies across different time scales.

24.1.1 The absence of implied volatility

In traditional financial markets, the core input for volatility forecasting is the implied volatility supplied by the options market. The Chicago Board Options Exchange's VIX, a measure of the implied volatility of S&P 500 index options, is widely used as a benchmark for gauging market risk expectations and the level of volatility over the next 30 days [7]. The distinctive value of implied volatility lies in its forward-looking nature: it is not a simple extrapolation of historical price movements but a consensus price reached by market participants through actual option-trading positions. When market makers and institutional investors expect volatility to rise, they demand higher option premiums, which directly pushes up the implied-volatility measure.

Although the cryptocurrency market has developed a derivatives ecosystem of some scale, its structure differs markedly from that of traditional finance. Platforms such as Deribit offer options trading on Bitcoin and Ethereum and have launched a VIX-like index, the Deribit volatility index (DVOL) [8]; nonetheless, the depth, liquidity, and breadth of participation in crypto options markets remain far below those of traditional markets. More important, although platforms such as Deribit have extended options coverage to leading altcoins such as SOL and XRP, and decentralized options platforms

such as Aevo offer a broader product line, most altcoins still lack options markets with sufficient depth and liquidity. As a result of this structural feature, perpetual futures participants cannot rely on a unified, deep implied-volatility indicator when making trading and risk-management decisions.

The absence of implied volatility has forced the perpetual futures ecosystem to develop a distinctive system of alternative signals. These signals are scattered across the funding rate, order book shape, liquidation data, and on-chain fund flows. Although no single signal can match the precision of the VIX, by cross-validating microstructure data across multiple dimensions, participants can still construct a highly informative set of volatility predictors. Figure 24-1 maps these six classes of volatility information source against the time scale over which each forecasts effectively and its relative predictive power, giving an overview of the volatility information available in the perpetual futures ecosystem.

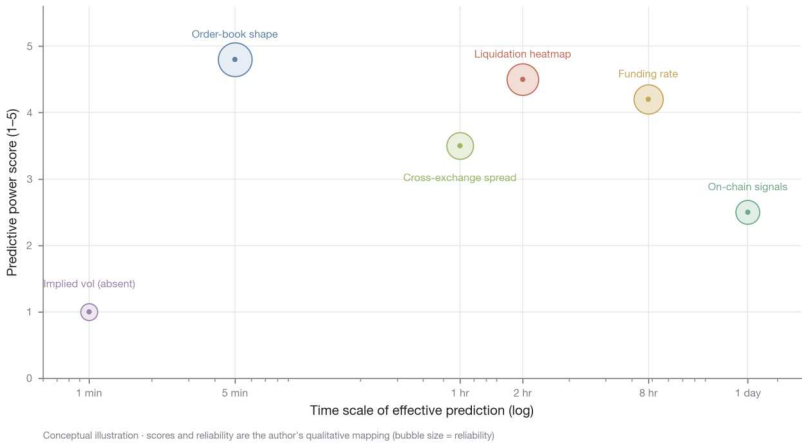

Figure 24-1. A panorama of the volatility information set for perpetual futures (conceptual mapping: the horizontal time-scale axis reflects true orders of magnitude, whereas the vertical predictive-power scores and the bubble reliability are the author's qualitative assignments rather than measured data; data source: compiled by the author)

The signals form a complementary gradient across time scales, running from minute-level order book shape to multi-day on-chain and cross-market signals. It is this layered, multi-scale structure that compensates for the missing implied-volatility benchmark: no single signal replaces the breadth of information in the VIX, but the six sources together yield useful forward-looking judgments within the windows where each is strongest. The subsections below take up the mechanism and predictive logic of each class in turn.

24.1.2 The funding rate as a volatility signal

The funding rate is the core mechanism in perpetual futures that regulates the balance of long and short positions and anchors the contract to the spot price (as discussed in Chapter 17) [9]. Beyond its own arbitrage value, its dynamics carry information for forecasting volatility. When the funding rate turns extreme—when its absolute value deviates sharply from baseline levels—it is often a reliable precursor to rising market

volatility, because an extreme reading directly reflects a severe imbalance between long and short forces in the market.

The intrinsic link between extreme funding rates and rising volatility stems from a severe imbalance in directional demand. A very high positive rate indicates that longs dominate, with large amounts of leveraged capital chasing the uptrend; a deeply negative rate reflects extreme crowding on the short side. Such an imbalance is inherently fragile. When the market price moves in the opposite direction, the side bearing the high funding cost faces enormous pressure to close positions. This closing activity consumes liquidity on one side, which in turn amplifies price volatility. Extreme funding rates therefore not only reflect an excessive concentration of the market's current directional preference but also foreshadow potential future liquidation risk and volatility jumps.

Beyond the absolute level of the rate, the speed at which the funding rate changes—the volatility of the rate—is likewise a highly informative predictor. When the funding rate fluctuates violently over a short interval, especially when it flips rapidly from strongly positive to strongly negative, it signals that the market structure is undergoing an abrupt reorganization. This reorganization is accompanied by the opening and closing of large volumes of positions, which is itself a direct manifestation of a liquidity shock. Empirical observation indicates that the speed of funding-rate changes tends to correlate positively with realized volatility over the subsequent 1 to 24 hours, consistent with the rapid transmission of rate information under the cross-platform tiered structure of the crypto funding rate market [10]. Figure 24-2 illustrates how extreme funding rates and their rate of change predict short-term volatility, plotting subsequent realized volatility against the absolute level of the rate in one panel and against the speed of rate changes in the other.

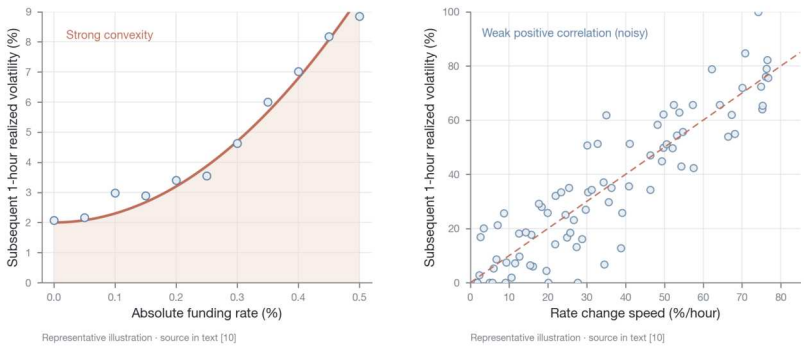

Figure 24-2. The predictive relationship between extreme funding rates and subsequent volatility (representative illustrative relationship: noisy scatter, not an empirical dataset; the tiered structure of the funding rate market follows Zhivkov 2026 [10])

The figure reveals two noteworthy patterns. When the absolute value of the funding rate exceeds two standard deviations above its historical mean, the probability of a marked jump in realized volatility over the subsequent 1 to 24 hours increases substantially; this threshold effect makes extreme funding rates an early-warning signal with a well-defined trigger condition. The speed of rate changes has independent predictive value as well:

even when the absolute level of the rate has not yet reached the extreme zone, rapid changes in it reveal that the market microstructure is undergoing an abrupt adjustment. The combination of these two dimensions forms a two-dimensional rate-warning matrix, in which the "high absolute level plus rapid change" quadrant corresponds to the highest short-term volatility risk.

24.1.3 Liquidation heatmaps

A distinctive source of risk in the perpetual futures market is the cascade effect triggered by the automatic liquidation mechanism (as discussed in Chapter 22). A liquidation heatmap maps the liquidation prices of all current open positions onto specific price ranges, giving a direct view of the scale of liquidations latent at different price levels. This spatial distribution is essentially a map of volatility risk, providing a key microstructure clue for forecasting mechanical volatility [11].

The predictive logic of a liquidation heatmap rests on the spatial distance between the price and dense clusters of liquidations. If the current market price is only a very short distance from a cluster containing a large volume of liquidatable positions, and the expected liquidation volume in that zone far exceeds the absorptive capacity of the current order book, then once the price reaches that zone it will inevitably trigger a liquidation cascade. In such a scenario, the liquidation engine dumps a large number of market orders into the market, instantly draining liquidity on one side and causing a nonlinear, extreme jump in price.

For market makers and risk-control systems, the liquidation heatmap provides a quantitative early warning of tail risk. When the price approaches a high-density liquidation cluster, the model should automatically raise its expectation of future mechanical volatility even if the current realized volatility is low. This conditional forecast, based on spatial distance, enables the risk-management system to take defensive measures—widening quoted spreads or raising margin requirements—before volatility actually erupts.

The data quality of liquidation heatmaps, however, has limitations that cannot be ignored. The liquidation heatmaps in widespread use today (such as the data provided by third-party platforms like Coinglass) do not come from complete liquidation-price distributions officially disclosed by exchanges; rather, they are estimates based on public open-interest data and assumed leverage distributions. Centralized exchanges' liquidation data depend on voluntary disclosure and suffer from coverage bias; decentralized protocols' liquidation data, though verifiable on-chain, currently account for only a small share of the perpetual futures market. More critically, large traders have every incentive to conceal their true liquidation-price levels—for example, by distributing positions across exchanges, dynamically adding margin, or using over-the-counter (OTC) hedges—so that their observable liquidation exposure is far smaller than its actual scale. Observable liquidation heatmaps should therefore be treated as a lower-bound estimate of tail liquidation risk rather than a precise measure, and risk-control systems should systematically reserve a safety margin when using liquidation-heatmap data.

24.1.4 Changes in order book shape

In a millisecond-level high-frequency trading environment, subtle changes in the shape of the order book often lead actual price movements. As the primary providers of liquidity, market makers' perception of market risk is directly reflected in their quoting behavior. When market makers expect short-term volatility to rise, their most immediate response is to reduce order book depth, even before the bid-ask spread widens noticeably. This systematic withdrawal of depth is itself a leading signal that volatility is about to rise [12].

The dynamics of quote skew further reveal market makers' directional expectations. When many market makers simultaneously accumulate thicker resting depth on the bid or the ask, this asymmetry reflects a consensus judgment about the direction of short-term price movement. If such skew is accompanied by a decline in overall depth, it often foreshadows an imminent directional breakout and a sharp amplification of volatility.

In addition, changes in the proportion of ghost liquidity are a key indicator for forecasting the evaporation of volatility. Ghost liquidity refers to resting orders that are observable in the order book but that, because of high-frequency cancellation, cannot in fact be executed. When the share of true depth in the order book falls while ghost liquidity proliferates, the market's capacity to absorb large orders is severely overstated [13]. This divergence between apparent and true liquidity greatly increases the probability that the market will experience a liquidity dry-up and a volatility spike when hit by an external shock. These changes in order book shape typically lead actual increases in volatility by minutes to tens of minutes and are the most informative inputs in ultra-short-term volatility forecasting.

24.1.5 Cross-exchange and cross-asset spillover signals

Liquidity in the cryptocurrency market is highly fragmented, and the process of price discovery for the same asset across different exchanges exhibits small time differences. Under normal market conditions, arbitrageurs maintain tight co-movement of prices across platforms through cross-exchange arbitrage. When the price spread among leading exchanges suddenly widens from the usual few basis points to tens of basis points, however, this often signals that certain large market makers or arbitrage capital have begun to withdraw from the market [14]. An abnormal widening of cross-exchange spreads is an early warning of deteriorating liquidity and imminent systemic volatility. Such widening can also arise, however, from technical factors at a single venue—a matching-engine failure or API latency—which carry no systemic implication. Before treating a widening spread as a warning signal, one must therefore rule out a single-exchange anomaly; the signal acquires systemic-risk value only once spreads are confirmed to have widened simultaneously across several independent platforms.

Cross-asset volatility spillover likewise provides an effective forecasting window. In crypto markets, volatility often transmits along a path spreading from core assets to peripheral assets. If Bitcoin's volatility remains stable while Ethereum's has already begun to rise markedly, this lead-lag relationship greatly increases the probability that Bitcoin's volatility will rise in the future. By constructing a cross-asset volatility spillover

index, a model can capture this micro-level process of risk contagion.

Macro signals from traditional financial markets also affect crypto-market volatility through specific transmission mechanisms. When the VIX index climbs sharply or U.S. Treasury yields move violently, such macro liquidity shocks typically transmit to the cryptocurrency market within hours. For perpetual futures participants, incorporating these cross-market and cross-asset spillover signals into the monitoring framework is a necessary means of forecasting transmission volatility.

24.1.6 On-chain signals

The transparency of the blockchain ledger provides a distinctive on-chain data dimension for volatility forecasting. The fund-transfer behavior of large holders often exerts a disproportionate influence on market liquidity. When a large amount of Bitcoin or Ethereum moves from private cold wallets to centralized exchanges, this large inflow is often interpreted in traditional analytical frameworks as a potential selling signal. Exchange inflows, however, may equally serve many other purposes—collateralized lending, cross-exchange arbitrage, OTC delivery, or replenishing market-making margin—and in recent years their reliability as a selling signal has been substantially challenged. Even so, when cross-validated against other signals, an abnormal large inflow can still serve as a reference factor for downside volatility; conversely, a large inflow of stablecoins to exchanges suggests an accumulation of buying power that may drive upside volatility [15].

Beyond exchange fund flows, a sharp change in the total value locked (TVL) in DeFi protocols is likewise an effective predictor of volatility. When the TVL of a key protocol is withdrawn on a large scale over a short interval, it indicates that capital is undertaking an emergency risk-avoidance move or a reallocation of liquidity. Such a violent restructuring of on-chain liquidity often transmits rapidly, through arbitrage channels, to the perpetual futures markets on centralized exchanges.

On-chain signals are, however, distinctly noisy. Not every large transfer becomes an actual market trade, and on-chain data used in isolation tend to generate a high false-positive rate. Their real value therefore lies in cross-validation with other microstructure signals, such as changes in order book depth or extreme funding rates. Only when signals across several dimensions align does an on-chain volatility forecast become reliable enough to guide trading decisions.

24.2 Volatility forecasting models: adapting classical methods

In traditional financial markets, volatility-forecasting models rely mainly on daily returns computed from daily closing prices. The perpetual futures market, however, has features such as round-the-clock uninterrupted trading, price jumps triggered by high-frequency liquidations, and periodic pulses from funding settlement. These structural differences mean that classical volatility-forecasting models, applied directly to perpetual futures data, often produce systematic forecasting biases. This section evaluates the performance of realized volatility, GARCH models, HAR models, and machine-learning

methods in the perpetual futures market and discusses how to make the necessary structural adaptations.

24.2.1 Realized volatility

Realized volatility estimates daily volatility by summing the squares of intraday high-frequency returns; its theoretical foundation is the theory of quadratic variation. In an idealized continuous-time martingale process, as the sampling frequency tends to infinity, realized volatility converges in probability to the true integrated volatility [16]. In traditional equity markets, a 5-minute or 10-minute sampling frequency typically strikes a balance between microstructure noise and information loss. In the perpetual futures market, however, constructing realized volatility faces three distinctive challenges.

The first is the effect of round-the-clock continuous trading on the definition of a "day." Traditional financial markets have clear opening and closing times, whereas the perpetual futures market lacks natural daily boundaries. Using midnight Coordinated Universal Time (UTC) as the dividing point for the daily cycle can truncate a volatility-clustering process that straddles that moment. Empirical studies show that computing realized volatility over a volume-weighted rolling 24-hour window reflects shifts in market state more smoothly and improves its stability as a predictor [17].

A more serious challenge arises from the price jumps produced by liquidation cascades. As noted earlier, when the market price reaches a dense cluster of liquidation triggers, forced-liquidation orders instantly consume order book liquidity, causing the price to drop precipitously or spike within a very short interval. Left unadjusted, realized volatility computed from high-frequency data becomes dominated by a few extreme 5-minute returns, overstating the market's continuous volatility. To separate the continuous-volatility and jump components, one must introduce bipower variation or truncated realized volatility. By computing the product of the absolute values of adjacent returns, bipower variation asymptotically removes the influence of the jump component, thereby extracting a purer measure of continuous volatility [18].

The periodic pulse injected by funding settlement is a microstructure feature unique to perpetual futures. Around each 8-hour funding settlement window, the concentrated position-building or position-closing of arbitrageurs and directional traders triggers systematic price movements. Whether this mechanism-induced volatility should be removed from realized volatility depends on the forecasting objective. If the goal is to set global margin requirements, this total volatility is a risk that must be covered; but if the goal is to extract a pure informational-volatility signal, then the anomalous returns around funding settlement should be removed through dummy-variable regression or local smoothing techniques, so that the periodic pulse does not contaminate judgments about the true market trend [19].

24.2.2 GARCH models

The GARCH model is the most basic volatility-forecasting tool in traditional finance; its core assumption is that the current conditional variance is jointly determined by past conditional variances and past squared errors. This framework was founded on the autoregressive conditional heteroskedasticity (ARCH) model proposed by Engle

(1982) and generalized by Bollerslev (1986) into its generalized form, GARCH [20][21]. On perpetual futures data, the most basic version of the model clearly captures a pronounced volatility-clustering effect. When the market is hit by an information shock, volatility rises markedly and then exhibits a slowly decaying memory, closely matching the model's characterization of the autoregressive effect [22].

In handling asymmetry, however, the leverage effect common in traditional financial markets exhibits a different directionality in cryptocurrency markets. In equity markets, negative news typically induces a larger rise in volatility than positive news, an asymmetry that can be captured by the exponential GARCH (EGARCH) model or the threshold GJR-GARCH model, which allows for asymmetric effects. In the perpetual futures market, however, because of the large amount of speculative long leverage, the irrational exuberance triggered by positive news can likewise produce a sharp spike in volatility. Empirical tests indicate that volatility asymmetry in cryptocurrency markets is often weak, or in certain market cycles exhibits an inverse leverage effect, in which the volatility increase from a positive return shock may be no smaller than that from a negative shock of equal magnitude. The distinctive price dynamics and volatility-jump characteristics of the Bitcoin derivatives market further corroborate that its volatility structure differs from that of traditional equity markets [23].

The core limitation of the GARCH model in the perpetual futures market lies in its inherent assumption that the volatility process is continuous—that is, that volatility changes smoothly and gradually—whereas liquidation cascades in this market often produce instantaneous jumps in volatility. In extreme conditions, for example, annualized volatility can jump from 20% to 100% within an hour and then fall back rapidly. Conventional continuous models cannot capture such "volatility jumps," leading to a severe underestimation of tail risk when extreme events occur. To remedy this shortcoming, researchers typically relax the assumed return distribution from the normal to a Student's t-distribution or a generalized error distribution to accommodate fatter tails, or directly combine the model with a jump-diffusion process to build a composite volatility model that includes a jump component [24].

24.2.3 HAR models

The HAR model decomposes realized volatility into components at three time scales—daily, weekly, and monthly—and uses each as a predictor, thereby ingeniously capturing the multi-scale volatility structure that arises because market participants trade at different frequencies. High-frequency market makers focus on intraday volatility, intraday arbitrageurs on daily volatility, and medium-term trend traders and long-term holders on weekly and monthly volatility, respectively. This intuitive and computationally simple linear architecture achieves performance comparable to that of complex nonlinear models in forecasting long-memory features [25].

When applied to the perpetual futures market, the model requires domain-specific extensions. The first is to introduce a funding-settlement cycle component. Because funding settlement typically occurs on an 8-hour cycle, the traditional daily, weekly, and monthly partition cannot capture this high-frequency periodic structure. Adding a volatility component based on an 8-hour rolling window can markedly improve the

forecasting accuracy for short-term volatility pulses.

Second, liquidation volume can be integrated into the model as an additional forward-looking predictor. Historical liquidation volume not only reflects past extreme volatility; its spatial distribution (as shown in a liquidation heatmap) also hints at future potential mechanical-volatility risk. Adding lagged relative liquidation intensity as an independent explanatory variable can effectively improve the model's ability to forecast the secondary volatility induced by liquidation cascades.

A cross-market spillover component is another key dimension of extension. Pronounced lead-lag relationships exist within the cryptocurrency market—for example, a jump in Bitcoin's volatility often precedes a rise in volatility across the whole market. Introducing the volatility of a core asset or of a traditional financial market (such as an equity volatility index) as an exogenous variable can capture early signals of transmission volatility, yielding a more comprehensive multi-factor forecasting framework [26].

24.2.4 Machine-learning methods

As high-frequency data have accumulated, machine-learning methods have found increasingly wide application in volatility forecasting. Feature-engineering-based methods, such as XGBoost (extreme gradient boosting) and random forests, can combine multiple market signals nonlinearly. These models can simultaneously process heterogeneous features such as extreme funding rates, distance to a liquidation cluster, and changes in order book depth, and can automatically capture interaction effects among features. For example, when the funding rate deviates extremely from its center and the price approaches a large-scale liquidation trigger point, a tree-based model can identify this specific nonlinear combination and output a very high volatility forecast—something that traditional linear regression models struggle to achieve [27].

Deep-learning methods—such as long short-term memory (LSTM) networks and the Transformer architecture based on the self-attention mechanism—attempt to bypass manual feature engineering and learn the evolution of volatility directly from raw high-frequency return series or order book snapshots. Such end-to-end models have a theoretical advantage in capturing complex temporal dependencies, and they perform especially well on ultra-short-term (for example, 5-minute to 1-hour) microstructure dynamics.

Machine-learning methods, however, face an extremely high risk of overfitting in the perpetual futures market. A model's value lies not in its accuracy in historical backtests but in its robustness when the market microstructure or the macro environment changes. The evolution of the perpetual futures market's rules, the launch of new protocols, and shifts in the composition of participants can all cause a fundamental change in the data distribution. Empirical experience indicates that a complex deep-learning model trained during a particular market cycle may have a predictive half-life of only 3 to 6 months. Once the market enters a new state, such models' forecast errors often expand sharply, sometimes performing worse than the simplest historical-mean model [28].

24.2.5 Model comparison and combination

Different classes of volatility-forecasting model exhibit their own comparative advantages at different time scales. In ultra-short-term forecasting of 5 minutes to 1 hour, machine-learning models based on high-frequency realized volatility and order book microstructure features generally have the highest accuracy. In short- to medium-term forecasting of one day to one week, HAR models that include a jump component exhibit the best robustness, effectively balancing the capture of long memory against responsiveness to sudden shocks. In long-term forecasting beyond one week, performance differences among models gradually narrow, and the mean-reversion tendency of volatility becomes the dominant factor.

Figure 24-3 compares the forecasting accuracy of realized volatility, the GARCH family, HAR models, and machine-learning methods across time windows from ultra-short-term to long-term, and the central lesson is that no single model dominates at every time scale.

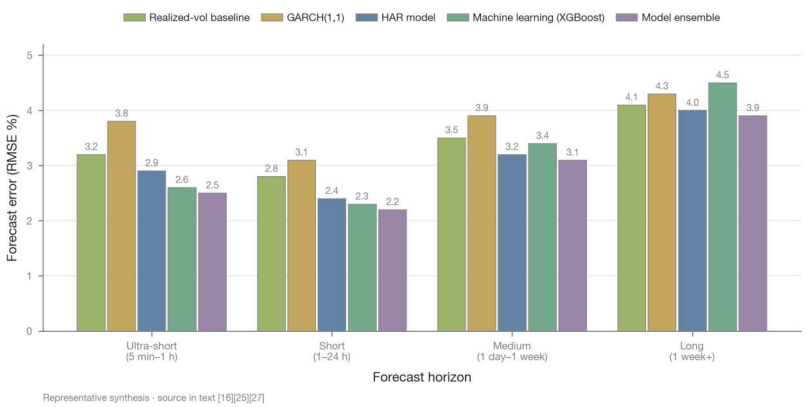

Figure 24-3. A comparison of forecast errors of volatility-forecasting models across time scales (representative composite illustration: the RMSE values shown are representative magnitudes synthesized from the literature, not exact values from any single source; data source: based on empirical studies of volatility forecasting in cryptocurrency and equity markets [16][25][27])

Each class of model has its own zone of comparative advantage: in the ultra-short-term window of 5 minutes to 1 hour, machine-learning models that process order book microstructure features directly (such as XGBoost) exhibit the lowest forecast error among the baseline models; in the short- to medium-term window of one day to one week, HAR models gradually surpass machine learning thanks to their multi-scale decomposition architecture; and once the forecast horizon exceeds one week, the errors of all classes of model converge, with mean reversion becoming dominant and complex models providing little incremental value. This pattern offers clear guidance for a model-combination strategy: emphasize machine learning in the short term, rely on HAR in the medium term, and respect mean reversion in the long term. Table 24-1 further summarizes, at the mechanistic level, the core features and applicable scenarios of each class of model in the perpetual futures market.

Model class	Core mechanism	Perpetual-futures adaptation	Strengths	Weaknesses and limitations
Realized volatility	Sum of squared high-frequency returns	Bipower variation to remove jumps; handling of settlement pulses	Solid theoretical foundation; precise measurement	Only an ex post measure, not a direct forecasting model
GARCH	Autoregression of the conditional variance	Introduce a Student's t-distribution; combine with a jump-diffusion process	Captures volatility clustering; parameters are interpretable	Assumes a continuous process; struggles with liquidation jumps
HAR	Linear combination of multi-scale volatility	Add a funding-settlement cycle component and a liquidation-volume factor	Simple, robust structure; matches the stratification of market participants	Underfits extreme nonlinear interaction effects
Machine learning and deep learning	Nonlinear feature mapping and end-to-end learning	Fuse multidimensional heterogeneous signals (funding rate, order book, etc.)	Excels at ultra-short-term forecasting; captures complex nonlinear patterns	Black-box nature; very high risk of overfitting

Faced with the limitations of any single model, forecast combination offers a more robust solution. Taking a weighted average of the forecasts of several heterogeneous models can effectively diversify the risk that any individual model fails under a particular market state. The weights can be adjusted dynamically in inverse proportion to historical forecast errors, or set using an exponentially weighted moving average to give greater weight to models that have performed better recently. More important, quantitative models should be embedded within a three-layer risk-control framework that incorporates human judgment and hard stop-loss mechanisms, so that the system retains basic survivability when a model encounters a black swan event or a structural break [29].

24.3 A source-decomposed volatility forecasting framework

Forecasting the total volatility of the cryptocurrency market often runs into a structural dilemma: when we mix volatility from all sources together and try to fit it with a single unified model, volatility components of different natures interfere with one another, degrading forecast accuracy. The solution is not to seek an ever more complex unified model but to adopt a divide-and-conquer strategy. As Chapter 22 discussed, volatility in the perpetual futures market can be decomposed into four distinct sources: informational, liquidity, mechanical, and transmission volatility. Each source has entirely different drivers, time scales, and predictability characteristics. This section shows how to build a separate forecasting model for each of these four sources and then aggregate

them into a forecast of total volatility; this framework constitutes the chapter's core methodological innovation.

The core idea of the source-decomposed framework derives from a basic principle of microstructure theory and signal processing: when multiple independent information sources drive an observed variable simultaneously, the optimal estimation strategy is to extract and process each source separately rather than to invert directly from the mixed signal. This principle is especially applicable in crypto markets, because the four volatility sources differ completely not only in physical mechanism but also in statistical properties. Informational volatility exhibits sparse, pulse-like behavior; liquidity volatility is strongly periodic; mechanical volatility is determined by protocol rules; and transmission volatility manifests as time-lagged cross-asset correlation. Attempting to capture all four properties with a single parameterized model amounts to asking one model to fit four data-generating processes with entirely different statistical characteristics, which inevitably lowers the efficiency of parameter estimation.

Figure 24-4 presents the complete architecture of the source-decomposed volatility forecasting framework in bottom-up logic: from the extraction of alternative signals at the base layer, to the independent modeling of the four volatility sources in the middle layer, to the variance aggregation and total-volatility forecast output at the top layer.

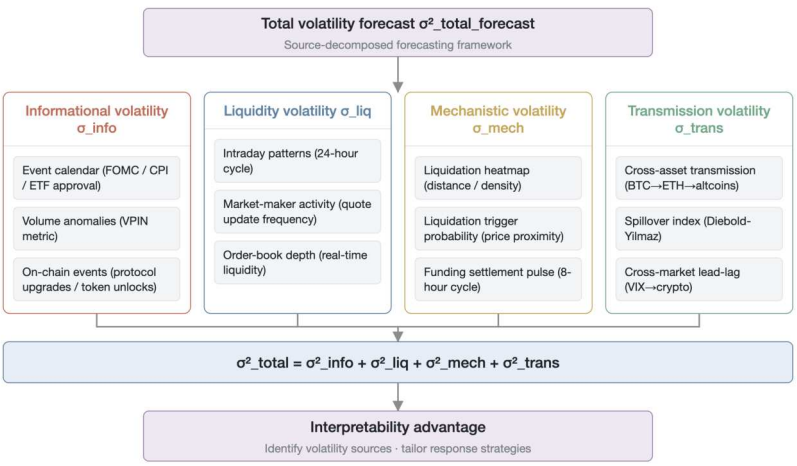

Figure 24-4. The conceptual architecture of the source-decomposed volatility forecasting framework (structural illustration, not measured data; data source: compiled by the author)

The core design principle of this architecture is embodied in three layers of information processing. At the base layer, different market signals (funding rate, liquidation heatmap, order book shape, on-chain data, and so on) are assigned to the volatility-source channel that best matches their physical mechanism, rather than being mixed as input to a single unified model. At the middle layer, each channel adopts the forecasting method best suited to its statistical properties: event-calendar regression for informational volatility, an HAR model for liquidity volatility, a threshold model for mechanical volatility, and a VAR spillover index for transmission volatility. At the top layer, the four independent forecasts are aggregated into a composite forecast of

total volatility through variance summation and calibration of interaction terms. This layered processing ensures that the distinctive time scale and statistical properties of each volatility source are exploited to the fullest, rather than being averaged away in the parameter competition of a unified model.

24.3.1 Forecasting informational volatility

Informational volatility (σ_info) arises from the process by which new information reaches the market and is absorbed into prices. From a forecasting standpoint, informational volatility can be divided into a highly predictable component and an intrinsically unpredictable component. The predictable part consists mainly of the known event calendar, including macroeconomic data releases (such as Federal Open Market Committee (FOMC) decisions, Consumer Price Index (CPI) reports, and nonfarm payrolls data) and scheduled events specific to crypto markets (such as protocol upgrade dates, token unlock schedules, and exchange-traded fund (ETF) approval deadlines). Within the windows of these known events, the rate of information arrival to the market rises systematically.

Ben Omrane et al. (2025) [30] show that the volatility of Bitcoin and Ethereum reacts significantly and asymmetrically to macroeconomic data releases. Analyzing 5-minute-frequency data from 2016 to 2023, the study finds that volatility reacts significantly to only a few news categories, among which U.S. monetary policy news has a longer-lasting effect than the others. U.S. monetary policy news in particular drives volatility higher before, during, and after the announcement, and Ethereum is more sensitive to U.S. macroeconomic announcements than Bitcoin. This rise in volatility ahead of an announcement reflects participants adjusting their positions before the uncertainty is resolved, a phenomenon known as the pre-announcement volatility run-up effect. A forecasting model can therefore use event-calendar regression to automatically raise the baseline estimate of informational volatility during known event windows.

Concretely, one builds a piecewise event-calendar regression model. For each known macroeconomic event, a time window is defined—typically from 2 hours before to 4 hours after the release—and a dummy variable is set within this window. The model can be written as:

$\sigma_{\text{info},t} = \alpha + \sum_i \beta_i \cdot D_{i,t} + \gamma \cdot \text{VPIN}_t + \varepsilon_t$

where D_{i,t} is the dummy variable for event i, and VPIN_t is the volume-synchronized probability of informed trading (VPIN), used to approximate the information arrival rate. The coefficients β_i and γ must be estimated empirically within-sample; their stability depends on the event type and market state, and they should not be applied directly across periods. VPIN was proposed by Easley, López de Prado, and O'Hara (2012) [31]; its essence is to divide trading volume into fixed-size volume buckets and estimate the degree of buy-sell order imbalance within each bucket to infer the active share of informed traders. Compared with the traditional probability of informed trading (PIN) model, it requires no maximum likelihood estimation and is more computationally efficient, and its volume-synchronized nature is naturally suited to the vast differences in activity across the 24/7 crypto market, avoiding the signal distortion of fixed time windows. This hybrid approach captures both the structured

impact of known events and, through VPIN, changes in the information arrival rate outside event periods. One caveat is that in crypto markets VPIN is exposed to the contamination of volume by wash trading: at some exchanges wash trading may account for a substantial share, so a VPIN built on unfiltered volume develops a systematic bias. In practice, one should use wash-trading-filtered volume, or data from exchanges with a low share of wash trading, as input.

For informational volatility outside event periods, although there is no explicit calendar guidance, its baseline level is determined by the market's actual information arrival rate. In traditional microstructure theory, VPIN and volume anomalies are widely used to approximate the information arrival rate. When volume deviates markedly from its historical mean, or when buy and sell order flow becomes severely imbalanced, this usually signals an inflow of undisclosed information and thus foreshadows a near-term rise in informational volatility. The unpredictable component includes sudden "black swan" events such as regulatory raids, exchange bankruptcies, and protocol hacks. The timing of such events cannot be foreseen, so they cannot be incorporated into a point-forecast model and can only be addressed through a portfolio-level tail-risk budget.

In practice, on-chain events in crypto markets—such as protocol upgrades, major governance votes, and token unlocks—are also highly predictable. The dates of these events are typically announced weeks or months in advance, allowing participants to adjust their risk exposure ahead of time. Ethereum's major upgrades, such as the Shanghai and Dencun upgrades, for example, had their dates fixed months in advance, giving forecasting models a clear timing for the information shock.

24.3.2 Forecasting liquidity volatility

Liquidity volatility (σ_liq) is caused by changes in market depth and by market-maker behavior. Unlike informational volatility, liquidity volatility contains a large, highly predictable component. Most notable is the intraday pattern: the level of liquidity in crypto markets fluctuates with high regularity over a 24-hour cycle. Hansen et al. (2024) [32] find that crypto markets exhibit a clear intraday cycle in volatility and liquidity, a periodicity that is closely related to the activity of traders in different geographic time zones and to the execution times of algorithmic trading. For example, at the handover between the Asian and the European-American trading sessions, liquidity often reaches a trough, so that even a small order can trigger a large price move. The study further finds that crypto-market volatility and liquidity metrics exhibit pronounced intraday variation, which means that liquidity is highly predictable.

The mechanisms that produce this intraday liquidity pattern are several. First, traders in different time zones have clearly defined active hours: Asian traders are most active during Asian working hours, while European and American traders dominate during their working hours. During the handover between time zones (such as the gap between the Asian close and the European-American open), the number of participants falls to a trough, market makers' incentive to quote declines accordingly, and liquidity tightens noticeably. Second, the execution times of algorithmic trading are also highly regular: many institutional traders execute large orders at specific times (such as on the hour or half-hour), causing a sudden rise in liquidity demand at those points. Third, funding

settlement times (though belonging to the category of mechanical volatility) also affect liquidity, because traders adjust their positions around settlement.

Beyond static time-of-day effects, market makers' real-time activity provides a dynamic forecasting signal. If the frequency with which market makers update their quotes suddenly drops, or the apparent depth of the order book begins to shrink, this usually signals that market makers perceive some latent risk and are reducing their risk exposure. Such defensive behavior is itself a strong leading signal that liquidity volatility is about to rise. In practice, one can track market makers' activity in real time by monitoring the quote refresh rate of the order book. Taking the BTC perpetual futures on a leading exchange as an example, when the quote refresh rate falls to 10% to 20% of its normal level, this usually presages an impending liquidity crunch.

In terms of forecasting method, the classic HAR model performs well in handling liquidity volatility. Brauneis and Sahiner (2026) [33] demonstrate that, although the HAR model effectively captures the clustering and long-memory features of volatility, forecast accuracy can be further improved by introducing machine-learning methods such as LightGBM (light gradient boosting machine) and XGBoost. The basic form of the HAR model is:

$$RV_{t+1} = \alpha + \beta_d \cdot RV_t + \beta_w \cdot \overline{RV}_{t-6:t} + \beta_m \cdot \overline{RV}_{t-29:t} + \varepsilon_t$$

where RV denotes realized volatility, and the subscripts denote the daily, weekly, and monthly scales, respectively. Here a crypto-market convention is used: the weekly term $\overline{RV}_{t-6:t}$ is the average over the most recent seven calendar days and the monthly term $\overline{RV}_{t-29:t}$ is the average over the most recent 30 calendar days—both including the current period t and thus consistent with the daily term RV_t—rather than the five and 21 trading days used in traditional finance. Even so, crypto-market participants still behave according to calendar cycles (weekend trading volume falls markedly, and intraday liquidity fluctuates regularly under the influence of geographic time zones), so the daily/weekly/monthly decomposition remains empirically effective; researchers need only note the difference in time-scale definitions when making cross-market comparisons. This multi-scale decomposition is naturally suited to forecasting liquidity volatility, because liquidity changes contain intraday, day-to-day, and week-to-week periodicity simultaneously. Within the source-decomposed framework, real-time order book depth, bid-ask spread skew, and market-maker activity can be fed as additional factors into an HAR or machine-learning model to fit the liquidity-volatility component specifically; when the state machine defined in Chapter 23 enters the "stressed" state, the model should automatically raise the baseline expectation for liquidity volatility.

24.3.3 Forecasting mechanical volatility

Mechanical volatility (σ_mech) is a feature unique to the perpetual futures market, created endogenously by protocol rules and the leverage-liquidation mechanism. Of the four volatility sources, mechanical volatility contains the most predictable deterministic component: the funding-settlement pulse. Funding settlement times are known: at traditional centralized exchanges such as Binance, settlement occurs every 8 hours (for example, at 00:00, 08:00, and 16:00 UTC), but a new generation of protocols has markedly increased the frequency—Hyperliquid and dYdX v4 both settle hourly, and

Bybit has moved some contracts to settlement every 4 hours. Differences in settlement frequency directly shape the character of the mechanical-volatility pulse: a higher frequency means a smaller amplitude per pulse (because rate deviations are corrected over shorter intervals) but a greater frequency of pulses. Regardless of the specific frequency, the rate level is already observable in the order book and on derivatives data platforms before settlement. When the rate reaches an extreme level, arbitrageurs and directional traders concentrate their closing and opening of positions around settlement, either to avoid paying the high funding cost or to capture funding income. This foreseeable concentration of order flow inevitably produces a volatility pulse within the settlement window.

The settlement pulse can be forecast with a simple yet effective method. First, compute the deviation of the current rate from its historical mean; when the rate is at an extreme level (for example, an annualized rate above 100% or below −50%), the amplitude of the settlement pulse increases substantially. Second, monitor the speed of rate changes; the faster the rate moves, the stronger the market's directional bias and the greater the closing pressure at settlement. From the absolute level and rate of change of the current rate, the forecasting model can reasonably estimate the direction and magnitude of the settlement pulse. A simplified form of the model is:

$$\sigma_{\text{mech,settlement}} = \alpha + \beta_1 \cdot |f_t| + \beta_2 \cdot |\Delta f_t| + \beta_3 \cdot OI_t$$

where f_t is the current rate, Δf_t is its change, and OI_t is total open interest. The coefficients of this equation must be calibrated empirically within-sample and vary with the exchange's funding-settlement frequency and market state; they should serve as directional guidance rather than a ready-made fixed rule.

Another key source of mechanical volatility is the liquidation cascade. Although the triggering of a liquidation cascade is abrupt, its underlying risk distribution is highly transparent. By aggregating open-interest data across the entire market, a liquidation heatmap can precisely compute the scale of liquidations distributed at different price levels. The distance from the current market price to the nearest "liquidation cluster" is a powerful conditioning factor for forecasting mechanical volatility. For example, if the current Bitcoin price is $45,000, with $10 million of clustered long liquidations at $44,500 and $8 million of clustered short liquidations at $45,500, then these two price zones become high-risk areas.

A model for forecasting liquidation cascades should output a conditional volatility whose magnitude depends on the distance between the price and a liquidation cluster. A common approach uses a Gaussian kernel function to measure this distance:

$$\sigma_{\text{mech,liquidation}} = \sigma_{\text{base}} \cdot \exp\left(-\frac{(P_t - L^*)^2}{2h_d^2}\right)$$

where h_d is the bandwidth of the Gaussian kernel, characterizing the price scale over which a liquidation cluster exerts influence; its dimension is the same as that of P_t and L^* (both a quote currency such as USD), not that of volatility. The larger the bandwidth, the more widely the cluster's influence spreads along the price axis. This form ensures that as the price approaches a liquidation cluster, the estimated mechanical volatility rises sharply. In real markets, liquidation clusters usually exist at several price levels simultaneously, and clustered long liquidations (concentrated below the

current price) and clustered short liquidations (concentrated above it) are distributed asymmetrically. A more complete form of the model should therefore perform a kernel-density summation over all known liquidation clusters:

$$\sigma_{\text{mech}} = \sigma_{\text{base}} + \sum_{k} w_k \cdot \exp\left(-\frac{(P_t - L_k)^2}{2h_{d,k}^2}\right)$$

where L_k is the center price of the k-th liquidation cluster, $h_{d,k}$ is the bandwidth corresponding to the k-th cluster (again a price scale), and the weight w_k is determined by the estimated liquidation scale of that cluster. Note that, whereas the single-cluster equation treats σ_{base} as a multiplicative factor, the multi-cluster equation makes it an additive base: the kernel-summation term is added directly on top of the baseline volatility, so the two equations do not reduce to the same form even when only a single cluster is present. The liquidation-cluster data used here come from third-party estimates rather than precise exchange disclosures (as discussed in Section 24.1.3), so the model output is itself an estimate.

Forecasting liquidation cascades, however, has an inherent nonlinear boundary: whether a cascade will start can be predicted from the probability that the price approaches a liquidation cluster, but how violent the cascade will be once it starts is difficult to estimate precisely. This is because the intensity of a cascade depends on the order book liquidity at the moment of triggering, and that liquidity evaporates rapidly once the cascade begins. This "liquidity evaporation" was especially evident in the March 2020 crypto crash, when Bitcoin fell by more than 50% within a few hours and triggered a liquidation cascade of several billion dollars. A model for mechanical volatility should therefore output an asymmetric probability distribution: as the price approaches a liquidation cluster, the model must not only raise the mean forecast of volatility but also substantially increase the probability weight on extreme tail movements. This is usually achieved by using a Student's t-distribution or a generalized Pareto distribution.

24.3.4 Forecasting transmission volatility

Transmission volatility (σ_trans) reflects the spread of a shock from one asset or market to another. This transmission is not instantaneous but involves a physical delay of minutes to hours, and that delay provides an exploitable time window for volatility forecasting. At the macro level, volatility in traditional financial markets often leads that in crypto markets. For example, when the VIX—the implied volatility of S&P 500 options—rises sharply or U.S. Treasury yields jump, crypto-market volatility typically responds within minutes to hours, and this transmission lag has been shrinking steadily as institutional capital enters crypto through the ETF channel. Moreover, the direction of transmission is not always one-way: in certain events, such as the 2022 FTX collapse, crypto-market volatility can also propagate back to traditional financial assets. This increasingly tight and bidirectional cross-market linkage means that forecasting transmission volatility must incorporate the two-way spillover paths between traditional finance and crypto markets.

Within crypto markets, clear lead-lag relationships also exist among assets. As the market's liquidity anchor and the representative "risk asset," Bitcoin's volatility increases

often lead Ethereum's and then propagate to less liquid altcoins. This transmission lag is typically minutes to hours, depending on each asset's liquidity depth and the attention traders pay to it. Shahrour et al. (2025) [34] quantify this cross-market spillover using a time-varying parameter vector autoregression (TVP-VAR) technique and find that, within their particular sample period and asset set, Bitcoin and the NEAR protocol are the main transmitters of volatility, influencing 68.17% and 71.63% of other assets' volatility, respectively, whereas traditional financial instruments such as Treasury bills act more as net receivers of volatility. The finding that NEAR's spillover influence exceeds Bitcoin's may reflect the particular asset selection and sample-period bias of that study; because NEAR's market capitalization and liquidity are far smaller than BTC's, whether such a high spillover coefficient is robust across different samples remains to be tested.

To exploit this transmission mechanism systematically within a forecasting model, one can introduce a real-time version of the Diebold-Yilmaz spillover index. Through variance decomposition, this index dynamically measures "who is transmitting volatility to whom" and the strength of that transmission. The Diebold-Yilmaz index is computed from the variance decomposition of a vector autoregression (VAR, to be distinguished from value at risk, VaR) model:

$$S = \frac{\sum_{i \neq j} \theta_{ij}}{\sum_{i,j} \theta_{ij}} \times 100$$

where θ_{ij} is the contribution of a shock to asset i to the variance of asset j, and S is the Diebold-Yilmaz spillover index. When the monitoring system detects a sharp rise in the overall spillover index, or a marked strengthening of the directional spillover from a particular asset (such as Bitcoin) to others, the forecasting model should automatically raise the estimated transmission volatility of the target asset. This approach converts changes in the cross-market topological structure into direct inputs for volatility forecasting.

24.3.5 Aggregating the four-source forecast

Once the four volatility sources have been forecast independently, the forecast of total volatility can be obtained by summing the variances of the individual forecasts (plus empirically calibrated interaction terms). This source-decomposed aggregation is significantly superior, both in theory and in practice, to a unified model that forecasts total volatility directly. The aggregation formula is:

$$\hat{\sigma}^2_{\text{total}} = \hat{\sigma}^2_{\text{info}} + \hat{\sigma}^2_{\text{liq}} + \hat{\sigma}^2_{\text{mech}} + \hat{\sigma}^2_{\text{trans}} + 2\rho \cdot \hat{\sigma}_{\text{info}} \cdot \hat{\sigma}_{\text{liq}} + \cdots$$

where ρ is an empirically calibrated interaction coefficient. In practice, these interaction terms are usually small, because the drivers of the four volatility sources are relatively independent.

The reasonableness of the four-source independence assumption depends on the state the market is in. In a calm state, the drivers of the four volatility sources do indeed differ fundamentally: informational volatility is driven by the news arrival rate, liquidity volatility by market-maker behavior and the intraday cycle, mechanical volatility by funding settlement and liquidation trigger conditions, and transmission volatility by cross-market fund flows. Under normal market conditions, these drivers are weakly

correlated, so the interaction terms contribute little to the total forecast.

In a crisis state, however, the independence assumption may be significantly violated. When a major information shock (such as a sudden regulatory action) simultaneously triggers a sharp price drop, the withdrawal of liquidity providers (liquidity volatility), the triggering of liquidation clusters (mechanical volatility), and cross-asset panic transmission (transmission volatility) may all activate synchronously within minutes. In such an extreme scenario, the interaction terms among the four volatility sources may account for a significant share of total variance, and simple variance summation will underestimate the true total volatility. Both the "Black Thursday" of March 2020 and the 2022 FTX collapse exhibited this feature of synchronous multi-source activation. Feasible ways to handle this limitation include introducing state-dependent interaction coefficients that automatically amplify the interaction-term weights when the state machine identifies a "stressed" or "crisis" state, or adopting a conditional-correlation structure (such as a dynamic conditional correlation (DCC) model) to model the time-varying correlations among the four volatility sources. This limitation is a known structural constraint of the framework, and readers should pay particular attention to the reliability of the model's output in a crisis state.

Moreover, the decomposition into four volatility sources is not, in the statistical sense, a unique decomposition. Different decomposition methods (such as principal component analysis, independent component analysis, or attribution based on different microstructure feature sets) may yield different definitions of the "four sources" and different independence properties. This framework's decomposition rests on the physical-mechanism prior classification proposed in Chapter 22—information arrival, liquidity supply, protocol rules, and cross-market transmission—which gives it a relatively stable economic meaning across different samples and model specifications rather than being a purely statistical artifact. In day-to-day operation, however, precise attribution still faces the challenge of multicollinearity: a single large liquidation (mechanical) may simultaneously alter order book depth (liquidity) and transmit through cross-asset positions to other markets (transmission), so the boundaries of attribution are inevitably blurred. In practice, source-decomposed forecasts should be treated as an approximate tool that provides directional guidance rather than a quantitative decomposition accurate to the decimal point.

Table 24-2 systematically compares the differentiated positioning of the four volatility sources within the forecasting framework along three dimensions—predictability profile, core predictors, and optimal forecasting method: the four have almost no overlap in the source of their predictability, their time scale, or their optimal mathematical tool.

Volatility source	Predictability profile	Core predictors	Optimal forecasting method
Informational volatility (σ_info)	High during event windows, low otherwise	Macro event calendar, VPIN, on-chain events	Event-calendar regression + order-flow imbalance model
Liquidity volatility (σ_liq)	Strongly periodic, highly predictable	Order book depth, market-maker quote frequency, time of day	HAR model with depth features / machine learning
Mechanical volatility (σ_mech)	Conditionally triggered, highly nonlinear	Funding rate level, distance on the liquidation heatmap	Threshold model + extreme value theory (EVT)
Transmission volatility (σ_trans)	Time-lagged, traceable	VIX index, cross-asset lead-lag relationships	Diebold-Yilmaz spillover index + VAR

Table 24-2. A comparison of the forecasting characteristics and methods of the four volatility sources (data source: compiled by the author)

The reason divide-and-conquer outperforms a unified model is, fundamentally, that it avoids feature confusion during model learning. A unified GARCH or machine-learning model tries to make the same set of parameters learn the 8-hour funding pulse, the 24-hour intraday liquidity pattern, and the multi-day macro transmission all at once. Such multi-scale, multi-driver mixed input often leaves the model wavering between states, ultimately producing a mediocre mean forecast. Source-decomposed forecasting, by contrast, allows the most suitable mathematical tool and time scale to be chosen for each physical mechanism.

Another core advantage of source-decomposed forecasting is its interpretability. When a unified model forecasts that tomorrow's volatility will reach 80%, a market maker knows only that risk has increased, not how to respond. A source-decomposed model, by contrast, can state explicitly whether the rise in volatility is because "the price is only 2% away from a large-scale liquidation cluster" (mechanical volatility dominant), because "there is an FOMC rate decision tomorrow evening" (informational volatility dominant), or because "the VIX index has spiked suddenly and cross-market spillover has strengthened" (transmission volatility dominant). Different attributions lead directly to different trading and risk-control decisions: if liquidation risk dominates, a trader may choose to reduce leverage or adjust the direction of the position; if a macro event dominates, the trader may choose to increase position size but lower leverage; if cross-market transmission dominates, the trader may choose to hedge the exposure to the source asset. This is precisely the core value of turning volatility theory into an engineering application.

Figure 24-5 makes the case for the source-decomposed framework along two dimensions: the left panel compares the forecast errors of the source-decomposed aggregation method against a traditional unified GARCH model across four time windows, while the right panel reports the predictability of each of the four volatility sources—together giving intuitive support for the decomposition strategy.

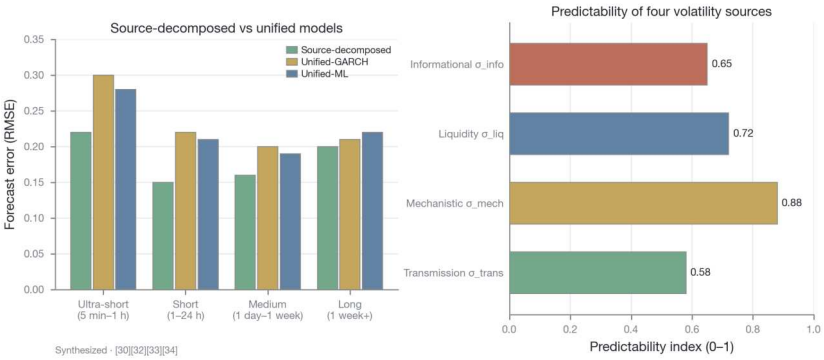

Figure 24-5. A performance comparison of source-decomposed and unified-model forecasting, and the predictability of each source (illustrative synthesis extrapolated from the literature, not independent empirical evidence: the RMSE and predictability values shown are relative magnitudes, not measured data; data source: the author's synthesis based on the literature [30][32][33][34])

Building on the above literature's empirical findings on crypto-market volatility forecasting, this book extrapolates the performance advantage of the source-decomposed aggregation method over a unified model. In ultra-short-term (5 minutes to 1 hour) and short-term (1 to 24 hours) forecasting, the source-decomposed method is expected to achieve a significant improvement in error, because at these time scales the periodic features of liquidity volatility and mechanical volatility are especially pronounced and the source-decomposed method can capture these regularities precisely. In medium- and long-term forecasting, the advantage is expected to weaken but to still preserve some improvement in error. These performance estimates are conceptual judgments synthesized from the literature, not independent empirical conclusions.

Moreover, based on the physical mechanisms of each volatility source and the qualitative analysis in the literature, the predictability of the four volatility sources differs systematically, ranging from highest to lowest as follows: mechanical (funding settlement times are fixed and the liquidation heatmap is transparent), liquidity (the intraday pattern is highly regular; Hansen et al. (2024) [32] document a pronounced intraday periodicity), informational (the event calendar is known, but information arrival outside events remains random), and transmission (the lag and strength of cross-market transmission vary considerably). This systematic difference in predictability across sources further supports source-decomposed modeling over unified modeling.

The performance advantage of the source-decomposed forecasting framework described above currently rests on theoretical extrapolation and a synthesis of the literature and awaits independent empirical testing. An ideal validation scheme should contain the following elements: at the sample-asset level, coverage of perpetual futures data for at least BTC, ETH, and two or more altcoins; in terms of time span, coverage of a complete bull-bear cycle (at least three years is recommended) including at least two known liquidation-cascade events; at the benchmark-model level, a standard GARCH(1,1), an HAR-RV, and a unified machine-learning model as control groups; and in terms of evaluation metrics, simultaneous reporting of root mean square error (RMSE), mean absolute error (MAE), and a quantile loss function, evaluated separately across different

time scales (intraday, daily, weekly). This validation work constitutes the key follow-up research direction for taking the framework from theory to empirical evidence.

The four outputs of the source-decomposed forecasting framework—the independent estimates of informational, liquidity, mechanical, and transmission volatility—constitute the core inputs to the subsequent three-layer decision system. At the micro level, market makers dynamically adjust their quoting strategy based on real-time identification of the volatility source; at the meso level, directional traders and portfolio managers use source-decomposed forecasts for position sizing and tail-risk management; at the macro level, exchanges and protocol designers embed the forecast signals in dynamic margin calibration and liquidity early-warning systems. The following three sections develop the specific applications of these three levels in turn.

24.4 Applying volatility in market-making decisions

Market makers are the most direct consumers of volatility forecasts, and every gain in forecast quality translates into a better quoting decision. This section connects the market-making profit equation of Chapter 19 with the volatility analysis of Chapters 22 through 24 to show how such knowledge enters real-time decision-making.

24.4.1 Volatility and the optimal spread

Starting from the profit equation of Section 19.1.4, the market maker's profit structure comprises four core parts: market-making profit equals spread revenue minus adverse-selection loss, minus inventory-volatility loss, and finally minus institutional cost. This equation provides a basic framework for understanding how volatility affects market-making decisions. The different components of volatility have asymmetric effects on the terms of the profit equation. Adverse-selection loss is positively related to informational volatility: when informational volatility rises, informed traders are more active in the market and the adverse-selection risk faced by market makers rises accordingly. Inventory-volatility loss is positively related to total volatility, and the relationship between the two is markedly convex [35]. When total volatility doubles, the risk cost of a market maker holding inventory rises by more than a factor of two. In addition, institutional cost is positively related mainly to mechanical volatility: extreme events such as liquidation cascades significantly increase a market maker's potential loss in the tail.

The setting of the optimal spread must dynamically reflect this nonlinear risk structure. Theoretical models show that a market maker's optimal spread should widen nonlinearly as volatility rises. Wyart et al. (2008) established, in order-driven markets, that the bid-ask spread is approximately proportional to volatility [35], and under an inventory-risk-based optimal market-making framework the optimal spread contains a nonlinear term directly related to the variance of volatility [36]. This book adopts an illustrative elasticity range slightly above 1 (roughly 1.2 to 1.5) to characterize the convex sensitivity of the spread to volatility; this range is an illustrative modeling assumption rather than a figure from any single empirical source, and given the higher leverage and more extreme liquidity swings of perpetual futures, the actual elasticity

coefficient may deviate from this range and awaits independent validation in the crypto perpetual futures market. This implies that when realized volatility rises by 10%, a market maker seeking to remain risk-neutral should widen the optimal quoted spread by 12% to 15%. Figure 24-6 shows the convex relationship between volatility and the optimal market-making spread derived from this theory.

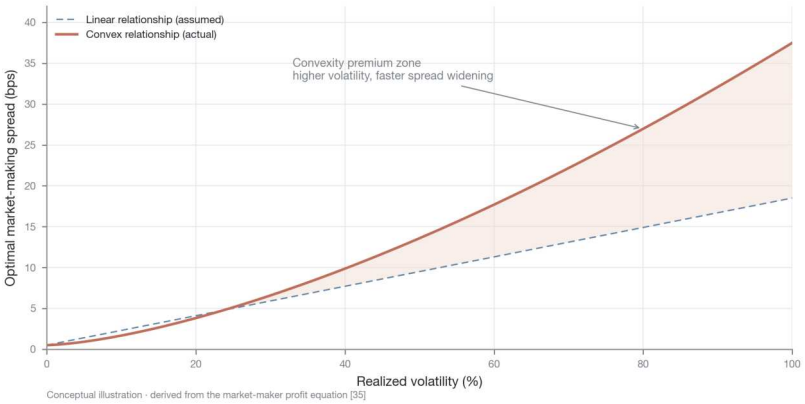

Figure 24-6. The convex relationship between volatility and the optimal market-making spread (theoretical-derivation illustration, not measured data: the elasticity of roughly 1.2 to 1.5 is an illustrative modeling assumption and awaits independent validation for crypto perpetual futures; data source: derived theoretically from the market-maker profit equation [35])

The convex curve in Figure 24-6 carries a concrete practical implication: spread adjustment cannot follow a simple linear mapping but must build in acceleration, so that once the volatility forecast breaks through a threshold, the pace at which the spread widens itself accelerates. A market-making system that handles this convexity poorly will suffer severe adverse-selection losses in the critical interval where volatility jumps from moderate to extreme.

24.4.2 State identification and strategy switching

The state-machine model proposed in Chapter 23 has direct engineering value in market-making strategy. Rather than using one set of static parameters to cope with all market environments, a market maker switches dynamically among three distinct market-making modes based on the volatility state. In the calm state, where volatility is at a historical low with no clear upward trend, the market-making system runs in standard mode, characterized by extremely narrow spreads, deep order book depth, and an active willingness to fill orders, with the goal of maximizing spread revenue. When volatility breaks through the first threshold and enters the stressed state, the system automatically switches to defensive mode. Here the spread typically widens by 50% to 100%, the resting depth at each price level is halved, and inventory limits are tightened sharply. If volatility continues to surge and triggers the crisis state, the market-making system enters minimal-market-making or market-making-suspension mode, quoting extremely wide spreads or withdrawing orders entirely, placing the protection of capital first.

Figure 24-7 integrates the switching logic, trigger conditions, and effects on quoted

spread, order book depth, and inventory limits of these three market-making modes into a single decision flowchart. State identification in real time draws on signals across several dimensions: the system tracks not only the level and trend of current realized volatility but also the leading signals discussed in Section 24.1—the proximity of the liquidation heatmap and micro-level changes in order book shape—which together let the state machine estimate the most probable current market state on the fly.

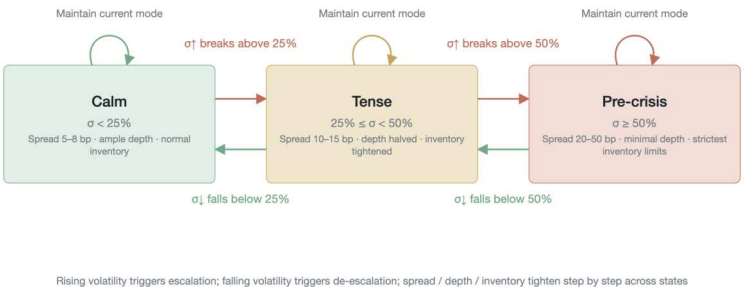

Figure 24-7. Volatility-triggered switching of a three-mode market-making strategy (structural illustration, not measured data: the three bands $\sigma < 25\%$, 25% to 50%, and $\sigma \geq 50\%$ are illustrative regime thresholds introduced by this figure and are not stated in the main text; data source: extrapolated from an application of the state-machine model [37])

The figure makes clear that switching among the three modes is not a symmetric design. The threshold for switching from calm to stressed is deliberately set at a relatively low volatility level, making the system highly sensitive to rising risk; the threshold for returning from stressed to calm is set markedly lower, forming a hysteresis window. The core reason for this asymmetry is that a market maker would rather bear the potential profit loss of defending too early than be exposed to enormous adverse-selection risk when volatility erupts; the system must confirm that volatility has substantively fallen back and that liquidation risk has completely receded before it gradually relaxes inventory limits and narrows spreads, so as to prevent a second loss from resuming normal market-making too early during a volatility aftershock.

24.4.3 Distinguishing liquidation volatility from informational volatility

When facing a sharp price drop, a market maker confronts the core difficulty described in Section 19.4.3: it must judge, within an extremely short interval, whether the current plunge is driven by informed trading or triggered by a liquidation cascade. The optimal responses to these two cases are exactly opposite. If the drop is driven by informed trading, this means the asset's fundamentals have changed, the price will not revert in the short term, and a market maker that fills orders will face a certain adverse-selection loss, so the optimal strategy is to withdraw immediately. If the drop is driven by a liquidation cascade—a form of mechanical volatility—the price often rebounds once the liquidation selling pressure is exhausted, so although filling orders entails short-term inventory risk, the expected return is very high.

Decomposing the volatility signal provides a key tool for distinguishing these two sce-

narios. An informed-trading-driven drop is usually accompanied by a rise in the volume-synchronized probability of informed trading, an increase in permanent price impact, and a refusal of the price to mean-revert after the shock, which manifests as a marked rise in the informational-volatility component. A liquidation-driven drop, by contrast, manifests as a spike in liquidation volume, a sharp fall in open interest, and an amplification of transitory price impact, corresponding to a surge in the mechanical-volatility component [38]. Figure 24-8 uses a decision tree to show how a market-making system, based on real-time signals across multiple dimensions—including the rate of change of liquidation volume, the change in open interest, the VPIN value, and the persistence of price impact—makes a millisecond-level choice between two entirely different response strategies.

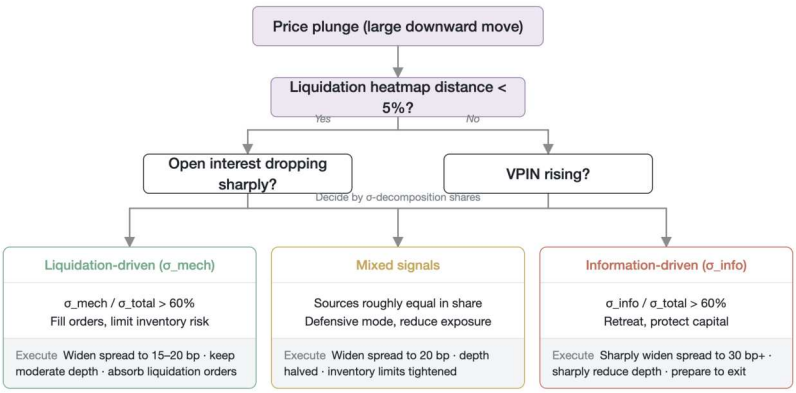

Figure 24-8. Real-time signals for distinguishing liquidation volatility from informational volatility (structural illustration, not measured data: the ratio of mechanical volatility to total volatility uses 60% as a simplified illustrative threshold; data source: extrapolated from the volatility-decomposition framework [38])

The core branching logic of the decision tree is that liquidation-driven and information-driven drops are highly distinguishable at the microstructure level: a liquidation event is accompanied by a sharp contraction of open interest, whereas in an information event open interest usually remains stable or even increases. The market-making system accordingly computes the ratio of mechanical volatility to total volatility in real time; if this ratio exceeds a preset threshold (60% as a simplified example), it judges the move to be driven mainly by liquidations and leans toward staying in the market and absorbing liquidation orders. Conversely, if the share of informational volatility exceeds the threshold, it judges the move to be an information-driven structural decline and triggers the withdrawal mechanism. In practice, real systems use a probabilistic soft threshold—a Bayesian posterior probability, say—rather than a hard cutoff, because the four-source decomposition must run in real time, entails a computational delay of hundreds of milliseconds to seconds, and loses considerable accuracy in extreme conditions.

24.4.4 Risk management for protocol market-making vaults

Automated market-making mechanisms at the protocol level face challenges different from those of traditional market makers. Take Hyperliquid's Hyperliquidity Provider (HLP) vault as an example: as the protocol's native liquidity provider, it bears responsibility for supplying baseline liquidity to the entire platform. Unlike traditional high-frequency market makers, which can exit the market at any time, HLP is designed to provide liquidity continuously in normal operation [39]. Although liquidity providers (LPs) can submit redemption requests (subject to a lock-up period and a queue), and although in extreme circumstances governance mechanisms such as validator voting can intervene to adjust operating parameters (the JELLY incident of March 2025 being one such intervention), HLP is designed to keep running under the vast majority of market conditions. Being unable to withdraw, however, does not mean abandoning risk management; HLP achieves a volatility-driven degradation mode by dynamically adjusting its strategy parameters.

When the risk indicators output by the volatility-forecasting model exceed a warning threshold, the HLP vault automatically triggers a degradation mechanism. This mechanism comprises three levels of response: first, the quoted spread automatically widens several-fold according to the volatility level, to compensate for the sharply rising adverse-selection risk; second, the resting depth on each side of the order book shrinks to a small fraction of its normal level, strictly limiting the maximum inventory that could accumulate in a one-sided market; and finally, the system suspends market-making on high-volatility altcoins, concentrating its limited capital on the most liquid, most controllable core assets [40]. This do-not-withdraw-but-degrade philosophy is precisely the concrete implementation of the crisis behavior of market-making vaults discussed in Section 21.4.2. The volatility-forecasting model constitutes the core engine driving this degradation mechanism, ensuring that the protocol dynamically balances the provision of baseline liquidity against the protection of liquidity providers' capital. A decentralized market-making vault also faces a risk dimension that centralized exchange (CEX) market makers do not: oracle dependence. HLP's mark-price computation and liquidation triggering rely on oracle inputs, and if the oracle is manipulated or delayed, the vault's entire risk-control logic can be bypassed. In the 2023 Mango Markets incident, an attacker manipulated the oracle price and caused protocol-level losses exceeding $100 million, showing that the trust-stack risk faced by decentralized exchange (DEX) market-making vaults (from oracle to mark price to liquidation triggering) differs structurally in nature from the risk faced by CEX market makers.

24.5 Applying volatility in directional trading and portfolio management

Volatility is not only a core input for market makers setting spreads and managing inventory; directional traders and portfolio managers likewise rely on volatility information to decide on position size, risk exposure, and stop-loss settings. In the perpetual futures ecosystem, which lacks a deep options market, participants cannot isolate and trade volatility risk directly through options. This missing market structure requires

traders and portfolio managers to use indirect means to achieve volatility adjustment, volatility timing, and tail-risk management. The core argument of this section is that the application of volatility information is not an optional optimization but a basic competency that perpetual futures participants must master. For individual traders and institutional portfolio managers alike, the degree to which they understand volatility directly determines their probability of survival in a high-risk market.

24.5.1 Volatility-adjusted position sizing

The Kelly formula is a classic method in quantitative trading for determining the optimal position size; its core logic is that the optimal position size is proportional to the strategy's reward-to-risk ratio [41]. In the standard discrete form, the Kelly formula is $f^* = \frac{p \cdot b - q}{b}$, where p is the strategy's win probability, q is the loss probability $(1-p)$, and b is the average win-loss ratio. In the continuous case, when returns follow a normal distribution, the Kelly criterion generalizes to $f^* = \mu/\sigma^2$, where μ is the expected excess return and σ^2 is the return variance. The logic of the generalization from discrete to continuous is that as trading frequency tends to infinity and the return per trade tends to zero, the limiting form of the discrete Kelly formula converges to the continuous expression μ/σ^2, which also intuitively shows that the optimal position is proportional to expected return and inversely proportional to the square of volatility (on the effect of betting frequency on the long-run performance of a Kelly strategy, see [42]). The deeper implication is that, by maximizing the expected growth rate of log wealth, the formula identifies the position size that minimizes the probability of ruin in long-run trading [41]. In the crypto perpetual futures market, however, the return distribution exhibits pronounced fat tails (with kurtosis far above that of the normal distribution), and applying the classical Kelly formula directly often leads to excessive position sizes. In practice, one usually applies a conservative correction via fractional Kelly—investing only 50% to 75% of the Kelly-optimal fraction—in exchange for a markedly lower probability of ruin and a smoother equity curve. The theoretical rationale for fractional Kelly is that when the return distribution departs from the normal assumption (especially in the presence of fat tails), the actual risk of full Kelly is far higher than the model predicts, and moderately reducing the fraction can greatly improve worst-case performance at the cost of only a small sacrifice in long-run growth rate [43].

Volatility adjustment in perpetual futures requires the four-source-weighted forecast rather than simple historical volatility. As Chapter 22 discussed, the four volatility sources carry entirely different implications for trading decisions. Informational volatility may accompany a directional trading opportunity, because the price is moving toward a new fundamental equilibrium; mechanical volatility (such as a liquidation cascade) and liquidity volatility, by contrast, are usually pure microstructure noise. If the forecast shows that the future rise in volatility is driven mainly by mechanical volatility, the trader should sharply reduce position size to avoid being liquidated by disorderly price jumps; but if the rise is caused by an information shock and the trader's strategy itself depends on capturing fundamental trends, the reduction in position size should be relatively small. The two differ significantly in the direction and magnitude of their ef-

fect on position size. This source-decomposed approach to position adjustment is more refined than mechanically reducing positions according to the level of total volatility, and it better fits the actual risk profile of the trading strategy.

The compounding effect of leverage further complicates position-sizing decisions in perpetual futures. In traditional equity markets, reducing position size usually means reducing the notional principal; in the perpetual futures market, however, a trader faces a choice along two dimensions—reducing notional principal and reducing the leverage ratio. In a high-volatility environment, reducing the leverage ratio is more critical than merely shrinking the notional principal. This is because high leverage significantly shortens the liquidation distance, and nonlinear jumps in volatility can easily trigger the liquidation mechanism. As a concrete example, suppose a trader holds a $10 million notional BTC long at 10x leverage, with a liquidation distance of about 10% of the current price. If volatility jumps from a normal 30% to 100% (which is common in a liquidation cascade), the price could fall by more than 12% within a few hours—enough to trigger liquidation. Even 10x, a relatively conservative level of leverage, still carries substantial forced-liquidation risk in an extreme volatility environment, and the risk at higher leverage is naturally more severe. Rules of thumb from practice indicate that there is a convex relationship between volatility and extreme loss: when volatility doubles, in order to maintain the same probability of ruin, position size should be reduced not merely linearly to 50% of the original but usually to between 50% and 70% of it [43]. This range is an empirical estimate from trading practice; the exact value depends on the fat-tailedness of the return distribution and the leverage actually used, and should not be applied as a hard rule. This convexity comes from the nonlinear nature of risk: the loss under extreme volatility is not merely a linear multiple of the loss under normal volatility.

Figure 24-9 shows the nonlinear relationship between the level of volatility and the Kelly-optimal position fraction. This convexly decreasing curve is one of the most important reference benchmarks for perpetual futures traders in managing position size.

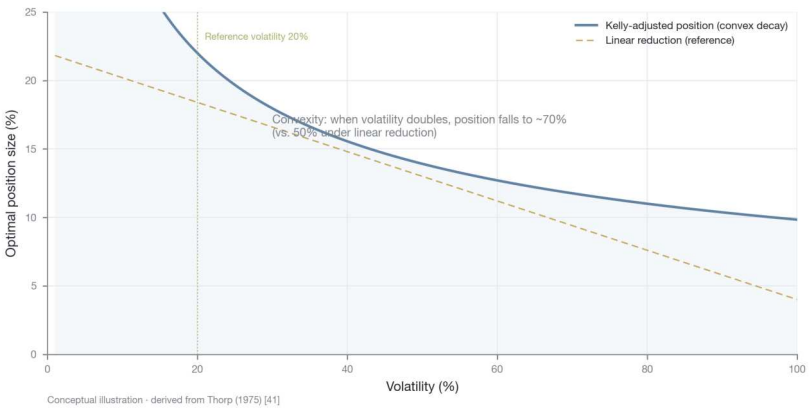

Figure 24-9. The convex function of Kelly position size adjusted for volatility (theoretical-derivation illustration, not measured data: the curve is an illustrative convex decline in which a doubling of volatility reduces position size to roughly 70%, aligned with the fractional-Kelly rule of thumb of 50% to 70% in the main text [43]; the Kelly criterion follows the theoretical derivation of Thorp 1975 [41])

The convexity in the figure has direct practical implications. In the low-volatility interval (such as 20% to 40% annualized), the curve's downward slope is steepest and position size is most sensitive to changes in volatility; when volatility enters the high interval (such as above 80% annualized), the slope flattens markedly, and although position size continues to fall, the marginal reduction per unit change in volatility shrinks. In the extreme volatility environment peculiar to crypto markets (where annualized volatility can exceed 200% during a liquidation cascade), this curve approaches zero, conveying a clear message: from the standpoint of long-run capital growth, maintaining any significant directional position amid extreme volatility is irrational.

24.5.2 Volatility timing

Volatility-timing strategies rest on the premise that market volatility exhibits identifiable regime shifts. As in the state-machine model constructed in Chapter 23, the market switches among three states—calm, stressed, and crisis. Directional traders can dynamically adjust their risk exposure by identifying these state transitions, thereby reducing drawdowns while improving risk-adjusted returns [37]. The key advantage of the state-machine model is that it does not try to predict the absolute level of volatility but instead identifies qualitative changes in market structure. Such identification is often more reliable than a precise volatility forecast, because transitions in market structure usually produce observable signals.

When the market moves from the calm state into the stressed state, the optimal response is to reduce directional risk exposure and raise the cash allocation. The stressed state is usually accompanied by thinning order book depth and extreme funding rates, which not only increases the slippage cost of trading but also raises the probability of mechanical volatility. At this stage, many traders' intuitive reaction is to double down, hoping to capture larger gains amid high volatility. This approach, however, often leads to severe losses, because the stressed state itself signals the fragility of market structure, in which any small shock can trigger a chain reaction. If the market deteriorates further in the stressed state and approaches the crisis state, the trader should reduce risk further or establish explicit hedging positions. The crisis state is characterized by a sharp rise in cross-asset correlation, and traditional diversification often fails at such times because all assets fall in unison. In this situation, holding positions in multiple different crypto assets provides no effective diversification protection.

The transition period from the crisis state back toward the stressed state is often the best window for contrarian traders and mean-reversion strategies to step in. In extreme events such as liquidation cascades, volatility usually overreacts and the price is pushed away from its fundamental equilibrium. As liquidity begins to recover and market risk aversion recedes, this mean-reversion tendency of volatility offers liquidity providers and reversal traders trading opportunities with highly asymmetric returns [44]. In the "Black Thursday" of March 2020 and the June 2022 Luna collapse, traders who established long positions at what proved, with hindsight, to be the optimal entry point earned short-term returns exceeding 200% over the subsequent days to weeks (BTC, for instance, rebounded from a low of about $3,800 on March 12, 2020, and some altcoins staged oversold rebounds after the June 2022 Luna collapse). This figure, however,

suffers from severe survivorship bias: in live trading, participants cannot know whether the current price is the bottom. In the March 2020 event, many traders who tried to buy the dip at the $5,000 to $6,000 level were liquidated by the subsequent decline, and only the few who had reserved an ample margin buffer ultimately profited. In practice, volatility-timing strategies face a core pitfall: state transitions in volatility are not knowable instantaneously and can only ever be confirmed statistically after the fact. In live trading, state identification entails an unavoidable delay, and a strategy's design must be able to tolerate the friction cost of this delay; otherwise, frequent misjudgments and repeated repositioning will erode all of the strategy's excess return.

24.5.3 Indirect volatility trading in perpetual futures

In traditional financial markets, the core instrument for volatility trading is the option; traders can build pure volatility exposure by buying or selling a straddle or by trading volatility-index futures (such as VIX futures) directly [45]. An option's sensitivity to volatility—its vega exposure—enables traders to isolate volatility risk precisely, independent of the underlying asset's directional movement. In the crypto options market, which lacks depth, perpetual futures traders must construct strategies that are long or short volatility through indirect means. The core logic of these indirect strategies is to exploit the microstructure features peculiar to perpetual futures to capture changes in volatility.

The calendar-spread volatility strategy is a method of trading volatility indirectly by using funding-rate forecasts. When future market volatility is expected to rise sharply, the volatility of the funding rate usually rises with it. A trader can build long-short funding-rate positions across different perpetual futures (such as the same asset on different exchanges, or highly correlated assets within the same ecosystem). The return on this strategy does not depend on the absolute price direction of the underlying asset but on the realized volatility of the funding-rate differential. If rate volatility widens as expected, the trader can capture the return from basis widening by dynamically adjusting the weights of the long and short legs. The return of this strategy can be decomposed, in simplified form, as $R_{\text{spread}} = (f_A - f_B) \cdot \Delta t + \Delta\text{basis}_{A,B}$, where $f_A - f_B$ is the difference in funding rates between the two contracts, Δt is the number of funding settlements over the holding period, and $\Delta\text{basis}_{A,B}$ is the change in the basis between the two contracts. The strategy is profitable when the cumulative income from the rate differential exceeds the loss from the change in basis plus transaction costs. The equation above is an illustrative decomposition of the return structure; its parameters depend on the specific contract pair and holding period and must be calibrated empirically before use in live trading. The strength of this strategy lies in its low correlation and high Sharpe ratio, but its weakness is that it requires continuous dynamic management and a deep understanding of the rate structure. In addition, the strategy carries a key margin-fragmentation risk: the trader must lock up margin separately on the two exchanges, and in extreme conditions an unrealized loss on one side may trigger insufficient margin and cause a one-sided forced liquidation, suddenly exposing a supposedly direction-neutral strategy to one-sided directional risk. The mitigation used in practice is to reserve an excess margin buffer on each exchange, but this markedly reduces capital efficiency.

The intraday mean-reversion strategy is, in essence, an indirect strategy that is short liquidity volatility. During periods of high liquidity volatility—especially after a liquidation cascade—the price is often pushed to extreme levels by a liquidity vacuum and then mean-reverts as market makers step back in. By trading against the extreme deviation, the trader is in effect betting on the fading of liquidity volatility and the price's reversion to a short-term mean [46]. Implementing this strategy requires high-frequency order book monitoring and millisecond-level execution speed, so it is usually executed by an algorithmic trading system rather than a human trader. The strategy, however, faces a systematic execution risk: during a liquidation cascade, an exchange's API latency often spikes from its normal level to several seconds, and order requests are rejected or time out in large numbers. The strategy faces a degradation of execution capacity at precisely the moment it most needs to execute, a constraint that significantly limits the practical feasibility of mean-reversion strategies in extreme conditions. In addition, the cross-exchange volatility-spread strategy exploits the realized-volatility differences that may exist for the same asset across different exchanges. When such a difference becomes abnormal because of localized liquidity dry-up or a liquidation event at a specific exchange, a trader can build a cross-exchange hedge whose return comes from the eventual convergence of the volatility difference between the two exchanges.

These indirect volatility-trading strategies face a common core limitation. Unlike options, which can isolate volatility exposure precisely (achieving neutrality to the underlying's price direction—delta-neutral—while retaining only vega and the rate of change of delta, namely gamma exposure), indirect strategies in perpetual futures always contain non-volatility risk components. For example, the calendar-spread rate strategy bears exchange counterparty risk and the cost of margin-use efficiency; the intraday mean-reversion strategy bears the risk of directional trend-continuation in extreme cases. These non-volatility risks make volatility trading in perpetual futures more complex and require more refined dynamic hedging mechanisms.

24.5.4 Portfolio-level tail-risk management

In multi-asset portfolio management, VaR is the standard tool for measuring market risk. Standard VaR models, however, usually assume that asset returns follow a normal distribution or rely on a simple historical-simulation method. In the perpetual futures market, liquidation cascades and leverage effects cause return distributions to exhibit extreme fat tails, so that a VaR based on the normality assumption severely underestimates tail risk [47]. To adapt to this market feature, a portfolio manager must correct the standard VaR, at a minimum using a Student's t-distribution or a Cornish-Fisher expansion (which corrects for skewness and kurtosis) to capture the effect of skewness and kurtosis on the risk measure. The Student's t-distribution has fatter tails than the normal distribution and can more accurately reflect the frequency of extreme events in crypto markets. The effectiveness of these corrections, however, depends heavily on the accuracy of parameter estimation. The degrees-of-freedom parameter of the Student's t-distribution may vary from 3 (extreme fat tails) to above 20 (near-normal) across different market states, and rolling-window estimation and full-sample estimation may give markedly different results. If the degrees-of-freedom parameter is systematically overestimated during calm periods (that is, tail thickness is underestimated), the cor-

rected VaR may, when a crisis arrives, give an even more dangerous false sense of security than the uncorrected version. Parameter estimation should therefore itself use a state-dependent approach, automatically adopting more conservative parameter settings when the state machine identifies a "stressed" or "crisis" state.

The historical-simulation method also requires improvement for use in perpetual futures. The traditional historical-simulation method treats all historical data within the look-back window equally, which is unreasonable in a market with clear regime shifts. A portfolio manager must distinguish normal-period history from crisis-period history. Combined with the state-machine model of Chapter 23, the risk-control system can dynamically adjust the sampling weights of historical data according to the current market state: giving recent data higher weight in the calm state, while in the stressed or crisis state forcibly introducing extreme data from historical crisis periods to calibrate the risk model. This state-dependent VaR computation can avoid being misled by a false low-risk estimate during calm periods.

Conditional value at risk (CVaR) is more important than VaR in perpetual futures risk management. VaR answers only the minimum loss at a given confidence level, whereas CVaR answers what the expected loss actually is in the tail region beyond VaR [48]. Because liquidation cascades in perpetual futures often cause precipitous drops beyond conventional expectations, CVaR is more sensitive to such extreme losses. In managing correlation risk across a multi-asset portfolio, a correlation matrix estimated in normal times often fails in a crisis. In extreme volatility events, correlations among crypto assets rise sharply toward one, and this everything-falls-together scenario must be incorporated into tail-risk management through stress testing. As a concrete example, in the 2022 FTX collapse almost all crypto assets fell by more than 20% within a single day, and this complete rise in correlation caused many portfolios that relied on diversification to suffer severe losses.

24.5.5 Designing stress-test scenarios

Stress testing is a key tool for compensating for the limitations of VaR and CVaR in extreme, nonlinear scenarios. An effective stress test should not merely assume mechanically that asset prices fall by 20% or 30% but should design internally consistent scenarios based on microstructure and volatility-driving mechanisms. Building on the four-source framework of Chapter 22, a stress test of a perpetual futures portfolio can be designed around five core scenarios.

The information-shock scenario simulates sudden events such as a major regulatory ban or a hack of a core protocol. This scenario is characterized by an instantaneous repricing with a clear direction, often accompanied by an isolated plunge in a specific asset. The liquidity-evaporation scenario simulates the situation in which leading market makers withdraw simultaneously for external reasons. In this scenario, even without major negative news, a sharp drop in order book depth causes ordinary order flow to trigger enormous price swings. The liquidation-cascade scenario targets mechanical volatility directly, simulating a price fall into the liquidation cluster of current open positions. This scenario requires the risk-control system to input not only the price shock but also the accompanying liquidity dry-up and extreme imbalance between buying and selling

forces.

The contagion scenario simulates the transmission of a shock from the macro financial market or a specific large entity—for example, a huge single-day net redemption from a Bitcoin spot ETF, or a liquidity crisis in traditional financial markets that pulls capital out of crypto. The full-crisis scenario is the simultaneous activation of the four sources above and represents the market state machine entering its deepest crisis state. Although this scenario has the lowest probability of occurrence, its potential loss to a portfolio is the largest and it must therefore be included in the risk-control framework.

Figure 24-10 arranges these five stress-test scenarios into a matrix by the activation combination of volatility sources and the expected severity, annotating each scenario with its typical price-shock magnitude, degree of liquidity deterioration, and corresponding risk-control response.

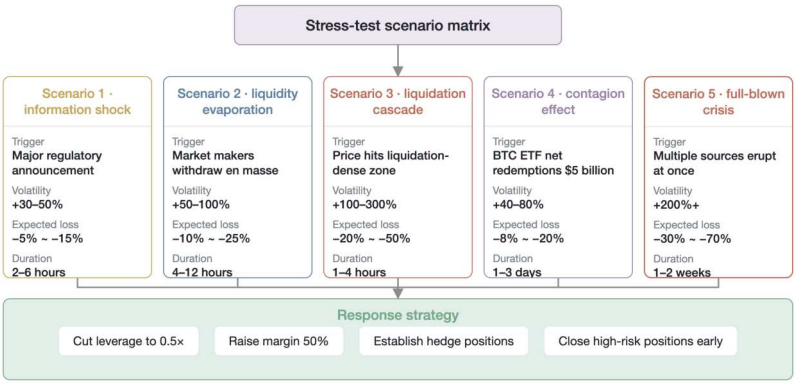

Figure 24-10. A four-source stress-test scenario matrix and response strategies (simulated-stress illustration, not measured data: the volatility, losses, and durations for each scenario are simulated magnitudes drawn from extreme events in crypto history, and the $5 billion net redemption from a BTC ETF is a hypothetical stress rather than a historical observation; data source: simulation parameters based on historical extreme events in crypto markets [49])

A core insight from the matrix is that the expected losses of the five scenarios do not grow linearly with the number of activated sources. Single-source scenarios usually cause manageable losses, because the other, unaffected market mechanisms can still provide a buffer; but when two or more volatility sources activate simultaneously, losses grow markedly superlinearly, owing to the interactive amplification among the volatility sources, and the expected loss of the full-crisis scenario may reach several to several dozen times that of a single-source scenario. In each scenario, the portfolio manager must measure three core metrics: the portfolio's overall expected loss, the position or asset that contributes most to the loss, and whether the remaining margin after the loss is sufficient—thereby identifying the portfolio's key vulnerabilities. The ultimate purpose of stress testing is not to predict when an extreme event will occur but to guide action: once the loss under a plausible scenario is unacceptable or would trigger cross-margin chain liquidations, the portfolio manager must reduce leverage, optimize holdings, or buy tail-hedging instruments before the scenario occurs, rather than reacting passively to depleted liquidity in a crisis. This forward-looking

risk-control framework is a necessary condition for maintaining long-term operation in the perpetual futures market.

In practice, a portfolio manager should establish a systematic stress-testing process. First, the complete five-scenario stress test should be rerun at the end of each trading day, tracking the change in expected loss under each scenario. Second, when the market state machine transitions from one state to another, an additional stress test should be triggered immediately, because market structure is undergoing a qualitative change at that moment. Third, any newly added position or strategy must undergo an independent stress test before being incorporated into the portfolio, to assess its impact on overall portfolio risk under extreme scenarios. This continuous, multidimensional stress-testing framework can significantly improve a portfolio's resilience in a crisis and provides the portfolio manager with an objective, quantifiable basis for risk decisions. Beyond the forward scenario design above, reverse stress testing offers a complementary analytical perspective: instead of assuming a scenario and then computing the loss, it assumes an intolerable loss level (for example, 50% of total capital or the complete exhaustion of margin) and then works backward to infer what combination of market conditions would cause that loss. This approach helps uncover hidden vulnerabilities that forward scenarios miss. For example, reverse stress testing may reveal that certain seemingly diversified multi-asset portfolios in fact have highly concentrated risk exposure under a specific correlation-jump condition.

24.6 Applying volatility in systemic risk management

Volatility forecasting is a tool not only for micro-level traders and portfolio managers; it is equally a core input to the systemic risk management of cryptocurrency exchanges and decentralized derivatives protocols. In traditional risk-control frameworks, exchanges often rely on static parameters to manage risk, but in the perpetual futures market—which trades around the clock and carries extremely high leverage—static parameters cannot keep pace with rapid transitions in the volatility state. This section explores how to embed volatility-forecasting signals in the underlying architecture of exchanges and protocols, from dynamic margin calibration, to sensitivity adjustment of liquidation parameters, to a multi-tier liquidity early-warning system, ultimately building a volatility-driven real-time monitoring loop.

24.6.1 Dynamic margin calibration

In current perpetual futures market practice, most exchanges and protocols use a fixed maintenance margin rate. Although mainstream exchanges have adopted a tiered margin system based on position size (for example, Binance's maintenance margin rate for BTC perpetual futures rises in tiers from 0.4% to 5% with notional position size), the margin rate still does not adjust in real time to the market's volatility state [50]. This static design maximizes capital efficiency during calm periods, but when volatility rises sharply, a fixed margin rate cannot provide enough buffer, leaving the liquidation engine facing a substantial risk of accounts breaching into negative equity.

The core logic of a dynamic margin design is to establish a functional relationship

between the margin rate and forecast volatility. When the system forecasts that future volatility will rise significantly, the exchange proactively raises margin requirements, forcing highly leveraged traders to reduce leverage or add margin before systemic risk accumulates. From the standpoint of statistical calibration, given the volatility forecast for a specific time window, the maintenance margin rate should be set so that, within a specified confidence interval, an extreme price move will not drive position equity below zero [51]. This mechanism ties micro-level margin requirements directly to macro-level volatility expectations.

Such dynamic calibration is not merely a mathematical tool of risk management but a concrete implementation of the "prevention layer" mechanism in protocol governance (as discussed in Section 21.2.2). When the volatility-forecasting model indicates an imminent high-volatility state, dynamically raising margin in effect transmits a risk signal to the market, suppressing speculative position-building by raising the cost of capital. Research shows that treating crypto assets as an independent risk class and calibrating margin according to their distinctive volatility characteristics can significantly reduce the probability of systemic default [52].

The dynamic margin mechanism, however, itself harbors a procyclicality risk that cannot be ignored. Raising margin requirements when volatility rises forces undermargined traders to close positions, and this concentrated closing itself pushes volatility higher, forming a positive feedback loop—precisely the margin-level counterpart of the model-homogeneity problem discussed in Section 24.7.2. Traditional financial regulatory frameworks have proposed systematic responses to this problem: Basel III's countercyclical capital buffer requires banks to accumulate extra capital during booms to meet demand during downturns, and the CPMI-IOSCO central counterparty (CCP) margin standards explicitly require central counterparties to incorporate anti-procyclicality mechanisms into their margin models. Dynamic margin design in crypto markets can draw on this experience—for example, by setting a speed cap on margin increases to avoid violent adjustments over a short interval, or by pre-collecting a "countercyclical margin add-on" during low-volatility periods to reduce the size of margin calls in high-volatility periods. In addition, dynamic margin faces challenges on the compliance front: in traditional finance, margin changes usually require advance notice to traders (CME, for example, gives one trading day's notice), and a crypto exchange that raises margin in real time without prior notice may face legal challenges regarding users' right to be informed, especially under emerging regulatory frameworks such as MiCA.

24.6.2 Adjusting liquidation parameters

The parameter settings of the liquidation engine directly determine the market's survivability in extreme conditions. In crypto derivatives markets, liquidation is usually benchmarked to the mark price rather than the last traded price, to prevent malicious manipulation caused by a short-term absence of liquidity [53]. The mark price is usually computed by combining the spot index price with a funding-rate basis component, and platforms differ in the specific method: Binance uses a moving average of the spot index plus basis, Hyperliquid uses a weighted median price, and dYdX v4 uses a

multi-source median. Regardless of the specific method, the mark price always contains some form of smoothing parameter, and the fixity of this parameter in a high-volatility environment can become a source of systemic risk.

In a high-volatility environment, a longer smoothing window causes the mark price to lag severely behind the spot price. This lag not only provides arbitrageurs with risk-free attack exposure but, more dangerously, triggers an accumulation-release effect (see Section 22.4.3). When the lagging mark price finally catches up with the spot price, liquidation orders that should have triggered dispersed across different price levels are instead triggered simultaneously within an extremely short window, detonating a liquidation cascade [54].

Simply shortening the smoothing window, however, is also risky: it significantly increases the probability of noise liquidations, causing normal small price fluctuations to trigger unnecessary forced liquidations. Here the volatility-forecasting model provides a dynamic benchmark for resolving this trade-off: in the calm state, the system maintains a longer window to filter noise; when the volatility forecast rises sharply, the system automatically shortens the window to improve the mark price's responsiveness. This volatility-sensitive parameter-adjustment mechanism lets the liquidation engine strike a dynamic balance between smoothness and responsiveness. Dynamic parameter adjustment can, however, itself become an attack vector: an attacker who can predict the timing and direction of a parameter switch can profit from the change in liquidation rules at the moment it occurs. Parameter adjustment should therefore use gradual, continuous change rather than discrete jumps, so as to reduce the exploitable time window.

24.6.3 Liquidity early-warning systems

A more advanced form of embedding volatility signals in systemic risk management is to build a multi-tier liquidity early-warning system. Based on the five-stage liquidity model proposed in Chapter 20, an exchange can design an automated response mechanism spanning from a micro-trigger to a liquidation cascade. When a crisis erupts, human decision-makers often cannot keep pace with the execution speed of algorithmic trading, so the warning system's action responses must be highly automated.

Figure 24-11 uses a flowchart to show the three-tier response architecture of this liquidity early-warning system—tier-one micro-trigger detection, tier-two liquidity-ebb response, and tier-three liquidation-cascade emergency intervention—with each tier corresponding to progressively stricter trigger conditions and increasingly forceful risk-control measures.

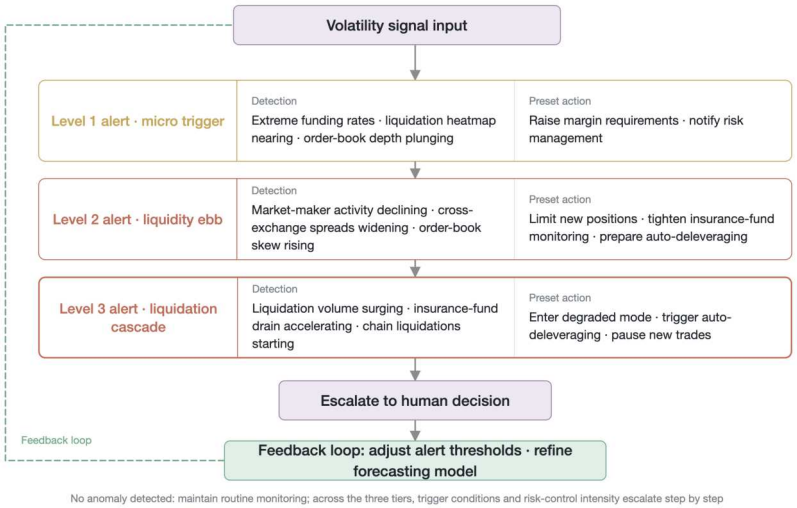

Figure 24-11. A flowchart of a volatility-signal-based liquidity early-warning and automated response system (structural illustration, not measured data; data source: an abstract construction of a protocol risk-management framework [55])

The key design feature of the architecture in the figure is that each warning tier pairs a "trigger condition" with a "preset action," and the mapping between the two is fixed in advance and executes automatically, without human intervention. Tier one is micro-trigger detection: triggered when a signal of surging volatility resonates with the proximity of a liquidation heatmap, its preset actions include raising the initial margin for new positions and sending a liquidity-demand signal to market makers. Research shows that such early turning points usually appear days or hours before violent market swings, providing an ample time window for proactive intervention [55].

If order book depth drops sharply and market makers' quote frequency declines markedly, the system escalates to tier two (liquidity ebb), taking more forceful measures such as restricting new positions in high-risk contracts and raising the maintenance margin rate. When liquidation volume grows exponentially and insurance-fund depletion breaches a safety threshold, the system enters tier three (liquidation cascade), and the protocol must automatically initiate a degradation mode—including suspending trading or activating auto-deleveraging (ADL)—to sever the positive feedback loop between falling prices and forced liquidations [56].

Implementing the warning and degradation mechanisms above faces fundamentally different governance challenges at centralized exchanges and decentralized protocols. A centralized exchange can have its risk-control team make an immediate decision to suspend trading—fast in response but opaque in process; a decentralized protocol's parameter adjustments usually require a governance process such as a multisig or a DAO vote, which simply cannot respond within the few minutes of a crisis. Concentrating the suspension authority in a single admin key, however, introduces a centralized single point of failure and a trust assumption. Both Hyperliquid's JELLY incident of 2025 and the Mango Markets incident of 2023 exposed this governance dilemma: the former was ultimately resolved through an emergency validator vote, while the latter was handled only retroactively through a governance process after the attack had

occurred. Decentralized protocols must find a balance between response speed and decision legitimacy—for example, by using pre-authorized automated risk parameters (which trigger automatically under preset conditions, without a real-time vote) to ease this tension.

In addition, the calibration of warning thresholds is itself an ongoing practical challenge. If thresholds are set too sensitively, they generate too many tier-one warnings, and the system and its users gradually grow immune to the warning signals (the "crying wolf" effect); if set too insensitively, warnings may arrive only after the crisis has already erupted. In practice, the thresholds themselves must also be adjusted dynamically as the market's baseline volatility level and structure change, creating a second-order "calibration of the warning system" problem.

24.6.4 The volatility dashboard

To put the risk-control logic above into practice, exchanges and large protocols need a real-time monitoring framework that integrates all the underlying signals. This system, called the "volatility dashboard," not only aggregates forecast data from different sources but also serves as the hub connecting signals to automated decisions.

Figure 24-12 shows the conceptual design of this volatility dashboard, arranging five core monitoring panels in logical order from micro to macro, with each panel corresponding to an independent risk dimension while achieving cross-panel correlation through an underlying data pipeline.

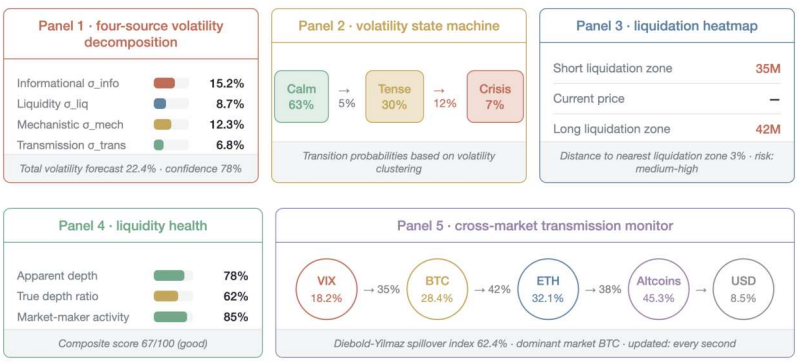

Figure 24-12. The conceptual design of a volatility dashboard and its real-time monitoring panels (conceptual-design illustration: the panel values are representative examples, not a measured snapshot; the variance sum of the four source components is approximately 22.4%, consistent with the conventions of the main text; data source: the author's design based on financial risk-monitoring architecture)

The dashboard's design follows the principle of "single view, multidimensional drill-down": on one interface, risk-control personnel can simultaneously observe the real-time decomposition of four-source volatility, the transition probabilities of the state machine, the spatial distribution of the liquidation heatmap, liquidity health, and cross-market transmission strength. The interconnection among these five panels is the core value of

the system. For example, when panel one shows a sharp rise in estimated mechanical volatility, panel three simultaneously shows a narrowing distance to a liquidation cluster, and panel four confirms that liquidity depth is falling, the resonance of the three automatically triggers an escalated response from the warning system. This monitoring framework closes the full loop—from signal collection, to warning triggering, to execution of preset actions, to feedback adjustment—and is where systemic risk management in the perpetual futures market finally takes concrete form.

24.7 The limits of volatility forecasting

Understanding the limits of forecasting capability is an indispensable part of volatility modeling. Volatility forecasting is an effective tool, but over-reliance on models leads to an accumulation of model risk. This section systematically reviews the inherent limitations of volatility forecasting to help the reader develop a healthy skepticism toward models and avoid treating forecast outputs as certainties. Effective risk control is not about predicting everything but about modeling the predictable part and defending against the unpredictable part.

24.7.1 The decay of predictability

The capability of volatility forecasting does not extend linearly over time but has a clear physical boundary. Within this boundary, market microstructure and historical data provide rich information; beyond it, a forecasting model's effectiveness rapidly decays to no better than a random walk. The speed and degree of this decay are the core metric for evaluating the practical value of any volatility model.

Short-term (one to four hours) realized volatility is highly predictable. This predictive power comes mainly from the clustering effect of volatility—periods of high volatility tend to be followed by periods of high volatility. As earlier chapters discussed, the state-machine model provides powerful medium-term conditional forecasting capability by identifying the market's calm, stressed, or crisis state. In addition, intraday and intra-week periodic patterns, as well as the periodic pulse of funding settlement, all provide highly deterministic inputs for short-term forecasting. When the price approaches a liquidation cluster, the conditional probability of a rise in volatility can be computed precisely from the liquidation heatmap, which is the most valuable forecast of tail risk.

When the forecast horizon exceeds one to two days, however, a half-life effect on information begins to appear. The classic study by Engle and Patton (2001) [57] shows that volatility is highly persistent, with markedly different characterizations of persistence across model specifications—their estimate of the half-life of market volatility is about 73 days. This divergence itself reflects a deeper problem: our understanding of volatility dynamics is far from mature. In cryptocurrency markets, this decay is even more severe. The empirical study of cryptocurrency volatility forecasting by Ftiti et al. (2021) [58] shows that the predictive power of every class of volatility model decays rapidly as the forecast horizon lengthens, with forecast accuracy falling sharply beyond the short-to-medium term. This finding has major implications for risk control in the perpetual futures market: position-sizing decisions that rely on multi-day volatility forecasts lack

sufficient statistical support, and their forecast errors exceed the precision acceptable for risk management.

Figure 24-13 depicts the complete trajectory along which the forecasting power (measured by R^2 or the correlation coefficient) of different types of volatility-forecasting models decays as the forecast horizon lengthens. This decay curve is the most intuitive tool for understanding the practical boundary of volatility forecasting.

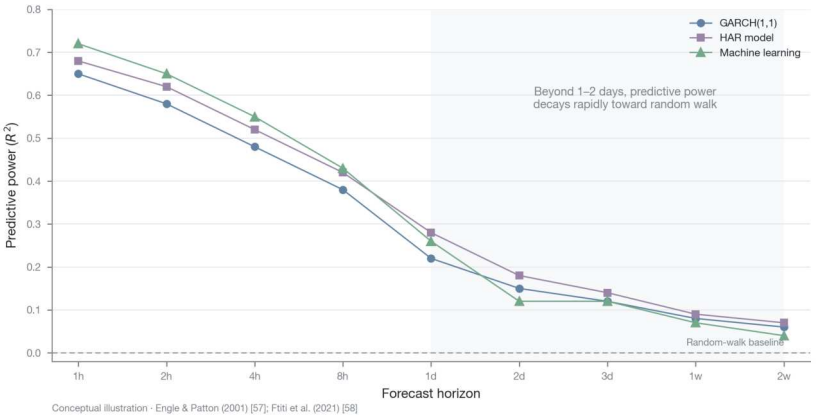

Figure 24-13. The decay curve of volatility-forecasting power over the forecast horizon (conceptual depiction, not measured data: the R^2 magnitudes and the shape of the decay are anchored to the empirical findings of Engle & Patton 2001 [57] and Ftiti et al. 2021 [58], and the claim that predictability approaches a random walk beyond one to two days is a qualitative conclusion; this figure depicts the decay of forecast R^2 over the forecast horizon, a distinct concept from the roughly 73-day half-life of volatility persistence in [57])

The most striking feature in the figure is the nonlinear shape of the decay curve. Within the short-term window (one to four hours), every class of model maintains relatively high forecast accuracy and the curve declines gently; but in the critical region of one to two days, the curve exhibits a sharp "cliff," with forecasting power collapsing dramatically over a very short interval. In cryptocurrency markets, this cliff is steeper than in traditional financial markets, reflecting their faster structural change and shorter information half-life. Beyond the cliff the curve flattens, the differences in forecasting power among the classes of model disappear, and all approach a random walk. The implication for risk-control practice is clear: volatility forecasts beyond two days are statistically unreliable, and position decisions based on such long-term forecasts lack adequate support. Especially difficult to predict is volatility driven by sudden events—true "news" such as a regulatory raid or the bankruptcy of a large exchange—whose timing is intrinsically impossible to infer from any known signal; and market-institutional changes such as the entry and exit of new market makers, the launch of new types of derivatives, or shifts in regulatory policy fundamentally alter the underlying structure of volatility. Even when a liquidity crisis's vulnerability can be identified from the liquidation heatmap, its exact trigger point and the subsequent nonlinear evolution path lie beyond the forecasting capability of statistical models, because extreme events often involve a qualitative rather than a quantitative change in participants' behavior.

24.7.2 Model-homogeneity risk

When most participants in the market use similar volatility-forecasting models, the models themselves become a source of risk. This phenomenon, the accumulation of "model risk," reveals a deep paradox in modern quantitative finance: rational risk management at the individual level may, at the macro level, lead to systemic irrational collapse. The root of this paradox is that participants' behavior is not independent but is tightly coupled through market mechanisms.

Model homogeneity leads to synchronization of collective behavior. When the market experiences a slight anomaly, highly similar forecasting models issue "high-volatility warning" signals to their respective users at the same time. Participants receiving these signals make rational individual responses: market makers widen the bid-ask spread to protect inventory, directional traders reduce positions to control risk, and exchanges' risk-control systems automatically raise margin requirements. These behaviors are robust risk-control measures under normal conditions, but when they occur synchronously, driven by homogeneous signals, they trigger a systemic liquidity dry-up.

Figure 24-14 uses a cyclical flowchart to depict how model homogeneity, through the positive feedback loop of "model warning → synchronized withdrawal → liquidity dry-up → volatility spike → renewed model warning," amplifies a tiny initial disturbance into a systemic liquidity crisis.

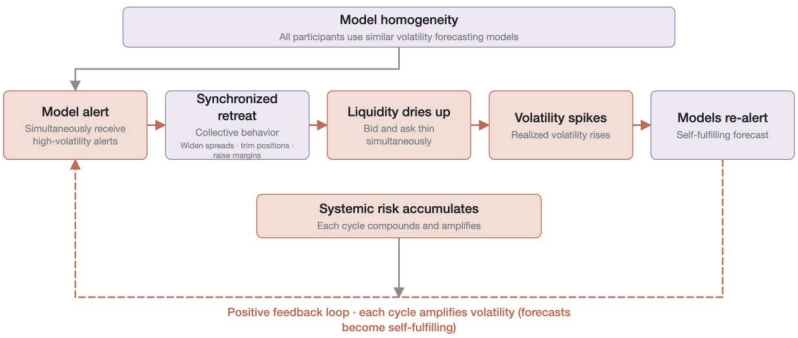

Figure 24-14. The accumulation of systemic risk triggered by the homogeneity of volatility-forecasting models (structural illustration, not measured data: a closed positive-feedback loop; the empirical anchor for the October 2025 cascade of roughly $19 billion in notional liquidations is given in the main text [60]; data source: compiled by the author)

The key node in the positive feedback loop shown in the figure is the step "volatility spike → renewed model warning": the rise in volatility induced by synchronized withdrawal is itself a product of deteriorating market microstructure, not a genuine fundamental information shock, but homogeneous forecasting models cannot distinguish the two and simply feed the higher volatility data into the next round of computation, outputting a higher-level warning signal. This synchronized withdrawal directly causes market liquidity to evaporate suddenly. The absence of liquidity means that even normal trading demand generates enormous price slippage, which further pushes up the actually observed volatility. This higher volatility data is then fed back into the forecasting models, triggering a new round of higher-level warnings. This positive feedback

loop turns the models' forecasts into a self-fulfilling process through the synchronized behavior of participants. In traditional financial markets, in the Flash Crash of May 6, 2010, the homogeneous responses of algorithmic trading systems greatly worsened the market collapse, causing the S&P 500 index to fall by more than 5% within about 15 minutes and the Dow Jones Industrial Average to briefly plunge nearly 1,000 points [59].

In cryptocurrency markets, this homogeneity risk manifests even more extremely. Ali (2025) [60] dissects the October 2025 liquidation cascade and shows that similar risk-control parameter settings and automated liquidation programs triggered roughly $19 billion in liquidations (notional liquidation scale, not wiped-out open interest or actual losses) within about 36 hours. This liquidation cascade was characterized by a self-reinforcing spiral once triggered: the initial liquidation triggered a price drop, the drop set off more liquidations, and the additional liquidations further worsened the drop. Throughout this process, all exchanges and risk-control systems using the same liquidation trigger conditions executed the same operations at the same time, so that liquidity vanished entirely and price gaps became the norm.

The fundamental cause of model homogeneity is the concentration of "best practice" in the market. When a particular volatility-forecasting method is recognized by academia or industry as the "standard," all rational participants have an incentive to adopt it. This produces a "competitive convergence" in which most participants ultimately use the same or highly similar models. This convergence is itself harmless—even efficient—until the market faces a situation outside the models' assumptions. At that point, the homogeneous models fail simultaneously, producing systemic risk.

In crypto markets, model homogeneity has an additional, behavioral source that goes beyond the rational-choice framework: the concentration of information sources. When large numbers of traders follow the same social-media volatility-warning accounts, the same liquidation-data dashboards, or the same on-chain analytics platforms, the synchronization of their behavior comes not only from the similarity of the models themselves but also from the resonance of information inputs and narrative frames. This information-concentration-driven behavioral synchronization also exists in traditional financial markets (such as reliance on the Bloomberg terminal and on the same set of analyst reports), but in crypto markets it is further amplified by the instantaneous transmission effect of social media. Looking ahead, as AI-agent trading spreads, if these agents are based on similar model architectures and training data, model homogeneity may reach an unprecedented magnitude, creating an "algorithmic monoculture" risk in which all agents produce almost identical outputs when facing the same inputs, and the system's diversity defense is completely dismantled.

The paths to mitigating model-homogeneity risk can be developed at three levels. At the individual level, participants can deliberately introduce a heterogeneous mix of models—for example, combining a statistical time-series GARCH model with a machine-learning-based nonparametric model, or incorporating contrarian indicators into the model inputs (such as a contrarian volatility signal: when most models forecast falling volatility, deliberately retaining a certain share of high-volatility estimates as a hedge). At the market level, large market makers and institutions can design asyn-

chronous risk-control triggers, avoiding a situation in which all participants execute the same operation at exactly the same threshold. At the protocol level, decentralized derivatives protocols can consider introducing asynchronous liquidation triggers—for example, setting slightly different liquidation trigger conditions or time delays for positions of different sizes—so as to structurally break the positive feedback loop of synchronized liquidation. Although these measures cannot completely eliminate model-homogeneity risk, they can significantly reduce the probability of a systemic liquidity dry-up caused by synchronized behavior.

24.7.3 Overfitting and out-of-sample failure

A model that shines in backtesting but fails in live trading is a characteristic hazard of volatility forecasting: strong historical fit often gives way to mediocre—or even loss-making—out-of-sample performance. The core cause is overfitting: the model learns not only the true regularities in the data but also memorizes historical noise.

Overfitting is especially severe in cryptocurrency markets. The history of the perpetual futures market is relatively short, the data sample is limited, and samples of extreme events are especially rare. When researchers use high-dimensional machine-learning models with hundreds of features, the algorithm inevitably overfits these rare extreme events. Moreover, multiple-testing bias further worsens the problem. Researchers usually test hundreds or thousands of parameter combinations and select the best-performing one, ignoring the risk of statistical invalidity introduced by this selection process itself. López de Prado (2018) [61] points out that without appropriate correction for multiple-hypothesis testing, backtest results often severely overstate true predictive power.

A deeper cause lies in the continual evolution of market structure. The entry of new participant types (such as institutional investors or AI agents), the launch of new types of derivatives, and changes in regulatory policy all continually alter the data-generating process, causing models trained on past data to fail in the future. As discussed in Section 24.2.4, the "half-life" of an effective volatility-forecasting model in the perpetual futures market may be only 3 to 6 months; even a model that performs perfectly on the past two years of data cannot be guaranteed to remain effective over the next two months.

Practical recommendations for coping with overfitting include rigorous out-of-sample validation and time-series cross-validation. Keeping the model simple is another key principle: following Occam's razor, it is better to use a simple model that is slightly less accurate but robust than to rely on a complex black box that is perfect in backtesting but fragile in live trading. In addition, one should not over-rely on any single model; a combination of models with different underlying assumptions usually provides more robust forecasts. Finally, backtest results should be systematically discounted, assuming that live performance will be 20% to 50% lower than the backtest result—a conservative practice, but one that avoids major losses caused by overconfidence.

24.7.4 Black swan events

Extreme events, or "black swans," are by their nature events beyond the historical distribution and beyond the cognitive range of existing models. Any volatility-forecasting model calibrated entirely on historical data is, by definition, unable to predict the occurrence of such events. Attempting to use a statistical model to predict the timing and specific form of such events is methodologically infeasible, and such attempts produce a false sense of security that reduces the risk-management system's actual defense against extreme events.

Volatility-forecasting models fail in specific ways during extreme events. GARCH-family models assume that volatility evolves continuously and cannot capture the price jumps triggered by liquidation cascades (as discussed in Section 24.2.2). Liao (2013) [62] points out that if jumps are not modeled explicitly, the value of traditional realized-volatility models in risk management is greatly diminished. In the perpetual futures market, price jumps caused by liquidation cascades are a common phenomenon rather than a rare event, which casts serious doubt on the applicability of the standard GARCH model in this market.

Likewise, VaR models based on historical simulation severely underestimate risk during extreme events, because the current tail event may be more extreme than anything recorded in the historical sample. Daníelsson et al. (2013) [63] give a rigorous characterization of the subadditivity condition for VaR under multivariate fat-tailed distributions, showing that the reliability of tail-risk measures depends heavily on the assumptions about the distribution's tails: once the actual tail is fatter than the model assumes, standard methods easily distort the characterization of extreme losses. This means that even a risk model that has performed well over the past decade cannot be guaranteed to correctly estimate risk under extreme market stress.

More deceptive still is the "calm trap." On the eve of many black swan events, the market often maintains a low volatility level, and all forecasting models show risk at a historical low. This false sense of security prompts participants to increase leverage, thereby accumulating structural fragility for the subsequent market collapse. This mechanism has a deep structural correspondence with Minsky's financial instability hypothesis: low volatility $\rightarrow$ low realized volatility $\rightarrow$ low margin consumption $\rightarrow$ traders increase leverage $\rightarrow$ systemic fragility accumulates $\rightarrow$ eventual collapse, which is precisely the crypto-market mapping of Minsky's "stability breeds instability." The quantitative study of systemic risk in cryptocurrency markets by Franco and Laurini (2025) [64] shows that systemic risk contagion often occurs within hours, and conventional daily risk metrics simply cannot provide a warning. In the FTX collapse of November 2022, BTC fell from about \$21,000 to about \$15,500 (a decline of more than 25%) over the three days from November 6 to November 9, and yet in the days before the event erupted the market still maintained a low volatility level, with no forecasting model having given an adequate warning.

Faced with this intrinsic unpredictability, the design of a risk-management system should acknowledge the limits of models' capability. Effective risk control is not about trying to predict all extreme events but about building systemic resilience to them. Constructing this resilience rests on two layers: the first is the statistical-model layer,

used to optimize decisions under normal market states; the second is the rule-constraint layer, a set of hard risk-control rules that do not depend on model output, ensuring that the system can still maintain basic operation when the model fails.

Through rigorous position-size control, participants can ensure that the maximum loss on any single trade does not exceed a fixed proportion of total capital, for example 2%. This proportion must be adjusted for the leverage actually used in a high-leverage environment: at 10x leverage, a 2% capital loss corresponds to a roughly 0.2% price move, still a reasonable stop-loss range; but at 50x leverage, the same capital loss corresponds to only a 0.04% price move, which can be triggered within seconds even under normal market conditions, rendering the stop-loss rule useless. Through firm stop-loss discipline, a trader can close a position immediately once the loss reaches a preset level, avoiding a further widening of the loss. Through an ample liquidity reserve, exchanges and risk-control systems can maintain operational capacity during extreme events rather than being forced to liquidate at extreme prices. None of these measures aims to predict a black swan; they aim to ensure that, when a black swan inevitably appears, losses are bearable rather than unbearable.

Volatility can be studied and partly predicted, but its inherent randomness cannot be completely eliminated. Understanding the sources, dynamics, and predictability boundaries of volatility can improve the quality of risk-management decisions, but it cannot eliminate all uncertainty. A clear-eyed recognition of the limits of models' capability, and a tail-risk budgeting mechanism based on that recognition, are the prerequisites for volatility forecasting to deliver value in practice.

24.8 Chapter summary

In the perpetual futures ecosystem, which lacks a deep options market, participants face a core challenge: how to sense and forecast volatility risk without the benchmark of implied volatility. This chapter has built a complete closed-loop framework running from knowledge of volatility, to forecasting, to decision-making, turning the theoretical insights of the previous two chapters into operational tools. The starting point of this framework is to identify the set of alternative volatility signals specific to perpetual futures, including the degree of extremity of the funding rate, the spatial distribution of open interest in the liquidation heatmap, leading changes in order book depth, and cross-exchange spread anomalies [65]. Although these signals are limited in any single dimension, a reasonable combination of them can effectively capture volatility risk from different sources.

Based on this signal set, the chapter proposed a source-decomposed volatility forecasting method. Traditional unified modeling tries to capture total volatility with a single econometric model, but often performs poorly in the face of the extreme jumps of liquidation cascades and the periodic pulses of funding settlement [66]. The source-decomposed framework, by contrast, models informational, liquidity, mechanical, and transmission volatility separately and then aggregates them, fully exploiting the differences among the sources in time scale and predictability. Its core advantage is interpretability: when the forecast shows a rise in volatility, the risk manager can accu-

rately judge the driving source (informational, liquidity, mechanical, or transmission) and respond in a targeted way.

The ultimate purpose of moving from signal to forecast is to guide decisions. The chapter embedded the forecast outputs in the micro- and macro-level decision processes of different market participants, forming a three-layer decision architecture. At the micro layer, market makers dynamically adjust their quoting strategy based on real-time identification of the volatility state; at the meso layer, portfolio managers use volatility-adjusted position sizing and the CVaR model to manage directional exposure; at the macro layer, exchanges and protocol designers guard against systemic risk through volatility-sensitive dynamic margin mechanisms and liquidity early-warning systems [60]. The core innovation of this closed-loop framework is that it provides not only a tool for measuring risk but also a set of conditional action rules based on the volatility state.

The framework established in this chapter has three key improvements over volatility analysis in traditional finance. First, it explicitly acknowledges the distinctive phenomenon of mechanical volatility in the perpetual futures market—volatility created out of nothing by liquidation cascades and the funding-settlement mechanism, rather than arising from information arrival or liquidity changes. Second, it exploits the special data advantages of perpetual futures, including real-time liquidation heatmaps, funding-settlement schedules, and order book microstructure—data that are hard to obtain in traditional futures markets. Third, it combines volatility forecasting with the specific incentive structures of market participants rather than remaining at the level of abstract risk measurement.

Different types of market participant draw different tools from this framework. Market makers rely on volatility-state identification to achieve dynamic spread adjustment and strategy-mode switching; their core competency is the real-time discrimination between liquidation-driven mechanical volatility and information-driven structural volatility, enabling a correct stay-or-withdraw decision during a sharp price drop. Directional traders and portfolio managers use source-decomposed forecasts for volatility-adjusted position sizing, proactively reducing the leverage multiple rather than merely shrinking the notional position when volatility is high, and identifying a portfolio's vulnerabilities in advance through stress-test scenario design based on the four-source theory [67]. Protocol designers and exchanges embed volatility forecasts in dynamic margin calibration and tiered liquidity early-warning systems, triggering a degradation mode before systemic risk accumulates. The output of the same volatility-forecasting model must be translated into three different decision signals, which requires the risk-management system to be highly flexible and modular in design.

Having built a complete framework from theory to practice, one must be clear about the epistemological boundary of this system: volatility forecasting is essentially a tool for reducing uncertainty, not a method for eliminating it. Intraday liquidity patterns, the periodic pulse of funding settlement, and the inertia effect of volatility clustering belong to the highly predictable category and usually account for 30% to 50% of total volatility. Sudden information shocks, extreme events, and the nonlinear evolution path after a liquidation cascade begins are intrinsically difficult to predict precisely

[67]. A robust risk-management system must be built on the principle of modeling the predictable part and defending against the unpredictable part—even if the model forecasts that volatility will remain at 20%, the risk manager must still reserve an adequate capital buffer for the possibility that volatility suddenly jumps to 100%. In the perpetual futures market, the best risk managers are not those with the most complex forecasting models but those who maintain the clearest recognition of their own models' limitations and reserve an ample tail-risk budget accordingly.

As the final chapter of Part Eight, this chapter has not only completed a full account of volatility from its sources and dynamics to its forecasting and decision-making but has also laid the micro-level foundation for subsequent parts on market-quality assessment and the economics of regulation. Having understood the endogenous interaction between liquidity and volatility, the following analysis turns to a more macro perspective, exploring how these micro-level mechanisms shape the efficiency of price discovery across the whole market, and under what conditions external regulatory intervention must be introduced to correct market failures. The volatility-analysis framework established in this chapter will be used in subsequent parts to evaluate multiple dimensions of market quality, including the accuracy of price discovery, the reasonableness of transaction costs, and the controllability of systemic risk.

Part IX
Engineering: From Diagnosis to Construction

Core question: Once we understand how this market works, how do we evaluate it, regulate it, improve it, and ultimately build a better version?

A Five-Dimensional Evaluation of Perpetual Futures Market Quality

By early 2025, cryptocurrency derivatives trading had been fundamentally reshaped: perpetual futures accounted for 93% of all cryptocurrency derivatives volume [1]. That dominance is the endpoint of a long climb. Since BitMEX launched the first Bitcoin perpetual futures in 2016, an instrument with no expiry date, anchored to the spot price through the funding rate, has grown from a fringe experiment into core infrastructure for pricing crypto assets worldwide. As volumes have grown exponentially and the participant base has become more complex, however, volume alone can no longer answer a more basic question: does the market's overall quality match its scale? High leverage and around-the-clock trading may impose hidden structural costs that headline volume conceals. This tension frames the central question of the chapter: how can we construct a unified, multidimensional framework for evaluating market quality—one that diagnoses the true health of the perpetual futures market and confronts the systematic trade-offs among its quality dimensions?

Evaluating a trading market's quality means asking how well it satisfies the most fundamental demands of its participants. From the perspective of a perpetual futures trader, these expectations can be summarized as standards across five dimensions: low transaction costs (encompassing not only explicit fees but also the implicit taxes formed by the bid-ask spread, market impact, and funding rate), accurate price discovery (market prices that reflect supply-and-demand information rapidly and without bias), strong resilience (the maintenance of liquidity supply amid extreme volatility), fair trading rules (ordinary participants are not placed at a systematic disadvantage for lacking market-maker privileges), and open market accessibility (the ability to participate in global pricing regardless of geographic location, capital scale, or technical sophistication). Together, these five dimensions constitute the core framework of market quality. The microstructure analyses in Chapters 13 through 24—covering price discovery, arbitrage mechanisms, liquidity supply, and the sources of volatility—all ultimately serve a single macro-level question: how does the perpetual futures market perform overall across these five dimensions? The task of this chapter is to integrate the fragmented conclusions of the preceding chapters into a structured diagnostic report on market quality, a framework that measures both the absolute level of each dimension and the intrinsic conflicts among them. The high-leverage mechanisms introduced to lower

transaction costs, for example, often come at the expense of the market's resilience under extreme conditions, while the strict admission screening implemented in pursuit of absolute fairness inevitably undermines the market's accessibility.

This chapter first measures the five dimensions of transaction costs, price discovery, resilience, fairness, and accessibility (Sections 25.2 through 25.6), and then incorporates three market states—normal, stressed, and crisis—to analyze the time-varying characteristics and state dependence of market quality. On this basis, the chapter constructs an evaluation model that unifies the five dimensions, delivers a structured quality assessment of perpetual futures platforms or specific assets, and explains the systematic compromises that different mechanism designs make among multidimensional quality objectives, thereby laying a diagnostic foundation for the subsequent discussion of regulatory intervention and institutional redesign.

25.1 Theoretical foundations of market quality

25.1.1 The economic meaning of market quality

At its most fundamental level, evaluating market quality examines how well a market's institutions allocate resources efficiently and distribute welfare among participants. A high-quality market should maximize social welfare, an objective that, at the microstructure level, manifests as the unity of investor welfare, market stability, and allocative efficiency. Investor welfare depends on the level of transaction costs, the accuracy of pricing, and the fairness of participation rules. Market stability requires that a trading venue be able to withstand external shocks and the risks of internal positive-feedback loops. Allocative efficiency, in turn, depends on how accurately price signals reflect fundamental information, thereby directing capital toward its highest-value uses.

From the standpoint of social welfare, improvements in market quality translate directly into gains in economic efficiency: lower transaction costs improve the efficiency of capital allocation, greater price-discovery efficiency improves the quality of investment decisions, and stronger market resilience reduces systemic risk. These seemingly microscopic changes in metrics manifest at the macro level as improved allocative efficiency, reduced financial risk, and greater overall economic welfare. Market quality is therefore not only a concern for traders but also a strategic issue that regulators and policymakers must address.

The economic study of market quality can be traced back to the perfect-market benchmark proposed by Stigler (1961) [2]. In this theoretical abstraction, a perfect market is characterized by instantaneous trading, zero transaction costs, and homogeneous participants, with information transmitted through the market without friction. Real financial markets cannot attain this ideal state; the existence of information costs necessarily produces price dispersion and friction. The degree of departure from the perfect-market benchmark constitutes the central yardstick for measuring the loss of market quality. Within this framework, every evolution of market institutions—from manual matching to electronic order books, from centralized clearing to on-chain automated market makers (AMMs)—can be viewed as an attempt to narrow the gap between real and perfect markets.

Stigler's framework provides a systematic method of analysis. By taking the perfect market as a benchmark, we can decompose the defects of any real market into specific sources of cost: transaction costs, information asymmetry, participant heterogeneity, and so on. This decomposition allows us to diagnose exactly where a market's quality problems lie. If a market's bid-ask spread is wide, for example, we can ask further: is it because market makers face high adverse-selection risk (a problem of information asymmetry), because liquidity providers face high funding costs (insufficient market depth), or because the exchange's technical infrastructure is outdated (slow trading)? Different root causes call for different solutions.

Evaluating market quality requires a conceptual expansion from a single efficiency metric to a multidimensional evaluation system. Informational efficiency is an important dimension of market quality, measuring the speed and accuracy with which prices absorb new information. Yet informational efficiency is not the whole of market quality. A market that is highly informationally efficient but has extremely high transaction costs, or that is prone to systemic collapse under extreme conditions, cannot be called high-quality. Evaluating market quality requires jointly considering the efficiency of price discovery, the cost of liquidity provision, and the market's performance under stress. The need for this multidimensional perspective is especially pronounced in perpetual futures markets, because their distinctive mechanism designs—such as high leverage, automatic liquidation, and funding rates—do not exist in traditional financial markets.

The core insight of a multidimensional evaluation framework is to acknowledge the many-sided nature of market quality. A market may excel on some dimensions while exhibiting clear deficiencies on others. Some highly specialized perpetual futures platforms, for example, may be very competitive on transaction costs yet see their liquidity dry up under extreme conditions; conversely, some platforms with abundant liquidity may carry high effective transaction costs because of complex fee structures. This heterogeneity across dimensions means that a simple *ranking* approach is inappropriate. What we need is a framework capable of structured diagnosis across multiple dimensions, not a system that compresses all dimensions into a single score.

25.1.2 Traditional theories of market quality

Modern market microstructure theory provides rigorous analytical tools for quantifying market quality. O'Hara (1995) shifted the research focus from macroeconomic equilibrium to pricing mechanisms at the transaction level; centering on the bid-ask spread and information asymmetry, she revealed how market makers provide liquidity under the constraints of adverse-selection risk and inventory costs [3]. From this perspective, the bid-ask spread is not merely a trader's execution cost but also a structural indicator of the market's degree of information asymmetry and the efficiency of its liquidity supply. The more severe the information asymmetry that market makers face, the higher the spread compensation they demand, which lowers overall market quality.

The insight that information asymmetry is a fundamental source of market friction points directly to one key avenue for improving market quality: reducing the information asymmetry among participants.

As electronic trading became widespread, Harris (2003) proposed a more systematic

multidimensional evaluation framework that decomposes market quality into four core dimensions: liquidity, transaction costs, price discovery, and market integrity [4]. This framework clarified the interactions among these dimensions: liquidity determines the implicit component of transaction costs (market impact), while the efficiency of price discovery is constrained by market integrity and transparency. Building on these theoretical foundations, regulators such as the U.S. Securities and Exchange Commission and the European Securities and Markets Authority (ESMA) established a system of regulatory metrics centered on best execution, order-handling rules, and market-data transparency, translating the academic concept of market quality into operational compliance standards.

Harris's four-dimensional framework provides a direct theoretical anchor for the five-dimensional model of this chapter. While retaining its core dimensions, the chapter makes three key adjustments: it splits *market integrity* into two independent dimensions, *fairness* and *accessibility*, to reflect the sharply distinct constraints on institutional fairness and participation barriers in crypto markets; and it adds a *resilience* dimension to capture the market's capacity to absorb shocks, which the traditional framework did not model explicitly.

The academic literature has developed a variety of single-dimension tools for measuring market quality. The illiquidity ratio proposed by Amihud (2002) captures a market's sensitivity to price impact through the ratio of price change to trading volume and has become one of the most widely used liquidity proxies in empirical research [5]. Such single-dimension metrics, however, cannot capture the multilayered quality characteristics specific to perpetual futures markets. A market with a very low Amihud ratio (that is, superficially abundant liquidity), for example, may prove extremely fragile during a liquidation cascade. The incremental contribution of the five-dimensional model lies in providing a structured diagnostic framework that can identify efficiency advantages and institutional deficiencies at the same time.

The important contribution of the Harris framework lies in making explicit the multidimensionality of market quality and the mutual constraints among its dimensions. A market with abundant liquidity can execute large trades with smaller market impact, thereby lowering transaction costs; but excessive liquidity supply may erode market makers' risk-bearing capacity, so that liquidity dries up rapidly in periods of stress. The efficiency of price discovery depends on participants' ability to acquire and process information, but this also implies the presence of informed traders, whose participation raises the transaction costs of uninformed traders. This trade-off among dimensions is a central difficulty in market design.

The traditional market-quality framework, however, reveals clear limitations when confronted with perpetual futures markets. These classical theories and regulatory metrics embed several structural assumptions that do not hold in crypto-asset markets. The traditional framework presumes that the market has a central clearing counterparty, is regulated within a single jurisdiction, and trades products with standardized expiry dates and delivery mechanisms. The fragmented liquidity of perpetual futures markets, their margin systems without a central clearing house, and their diverse liquidation mechanisms all fall outside the explanatory range of the traditional framework.

Traditional models also fail to adequately account for the systemic risk introduced by high-leverage automatic liquidation, and they do not consider the distinctive features of around-the-clock trading, the funding-rate mechanism, and decentralized architectures.

The failure of these assumptions means that we cannot simply transplant the quality metrics of traditional markets onto perpetual futures markets. The traditional standard of *best execution*, for example, is typically based on the spread and execution speed; but in perpetual futures markets, funding-rate payments can far exceed spread costs and become the primary source of trading cost. Likewise, *market integrity* in traditional markets usually refers to the prevention of manipulation and fraud; but in perpetual futures markets, because of exchanges' proprietary market making and information asymmetry, *fairness* becomes a far more complex and critical problem. It is precisely this inapplicability of the traditional framework that motivates the new five-dimensional model proposed in this section.

25.1.3 The distinctive challenges of perpetual futures

The mechanism innovations of perpetual futures and the distinctive structure of crypto-asset markets pose five new questions for market-quality evaluation that the traditional framework cannot answer.

The first challenge is how to measure market resilience. Traditional financial markets rely on circuit breakers and central clearing counterparties as buffers against systemic risk, but in perpetual futures markets these external protections are typically absent. The market's capacity to repair itself under extreme conditions, the speed at which order-book depth recovers, and the ability to withstand chained liquidations must be measured explicitly as an independent dimension. In the absence of circuit breakers, resilience becomes the key indicator of whether a market can continue to function normally under stress.

The second challenge concerns how to handle institutional noise. Mechanism designs specific to perpetual futures—such as the periodic settlement of the funding rate and the tiered forced liquidation performed by the automatic liquidation engine—introduce non-informational volatility into the price-discovery process. Ruan and Streltsov (2022) show that the funding-rate cycle of perpetual futures produces a systematic intraday pattern in spot-market quality: market makers face higher adverse-selection risk around funding settlement and therefore widen the bid-ask spread [6]. This quality loss, induced by the contract mechanism itself, has no corresponding measurement dimension in traditional evaluation frameworks.

The third challenge is how to evaluate market fairness. Traditional markets are bound by unified regulatory standards, whereas in crypto-asset markets the agreements between exchanges and market makers often lack transparency, and some platforms even face conflicts of interest from proprietary market making. The asymmetric distribution of information privileges and execution latency means that fairness can no longer be assumed as a default premise but must be assessed explicitly through concrete indicators. In perpetual futures markets, certain market makers may obtain special data or priority liquidation rights from the exchange, and these hidden privileges directly affect market fairness.

The fourth challenge is how to compare centralized exchanges (CEXs) and decentralized exchanges (DEXs) within a unified framework. Barbon and Ranaldo (2024) find that CEXs have a cost advantage in small trades, whereas DEXs offer a more competitive execution environment for large trades [7]. Capponi and Jia (2025) further note that the infrastructure of DEXs confronts liquidity providers with a distinctive collective-action dilemma, giving them little incentive to withdraw from the liquidity pool [8]. These two architectures differ fundamentally in their trust assumptions, settlement efficiency, and modes of organizing liquidity, which requires the evaluation framework to be sufficiently inclusive. CEXs rely on the credit of a central counterparty, whereas DEXs rely on the transparent execution of smart contracts; the quality characteristics of the two are entirely different.

The fifth challenge is how to evaluate accessibility. The global nature of perpetual futures and the *permissionless* property of decentralized protocols transform the participation barrier from an exogenous regulatory setting, as in traditional markets, into an endogenous quality variable that directly determines the diversity of participants and the depth of liquidity pools (elaborated in Section 25.6).

25.1.4 The architecture of the five-dimensional model

To address these challenges, this section proposes the five-dimensional model of perpetual futures market quality (5D-MQ). The model decomposes the market quality of perpetual futures into five interrelated dimensions: transaction costs, price discovery, resilience, fairness, and accessibility. Together, these five dimensions constitute a complete evaluation framework capable of a structured diagnosis of how different platforms and different assets perform across various market states.

The five-dimensional model rests on a core recognition: the quality characteristics of perpetual futures markets differ fundamentally from those of traditional markets and require an evaluation framework designed specifically for them. This framework must be able to accommodate the mechanisms specific to perpetual futures (funding rates, automatic liquidation, and the like) while also comparing markets with different architectures (CEX versus DEX). More importantly, it must be able to identify the multiple dimensions of market quality and make explicit the trade-offs among them, thereby offering market participants and regulators a clear diagnosis and a direction for improvement.

Figure 25-1 presents the hierarchical architecture of the five-dimensional model: market quality sits at the center, from which the five first-level dimensions—transaction costs, price discovery, resilience, fairness, and accessibility—radiate outward, and each in turn resolves into several operational second-level indicators. The structure thus offers macro-level generality while grounding itself in concrete measurement indicators at the micro-operational level.

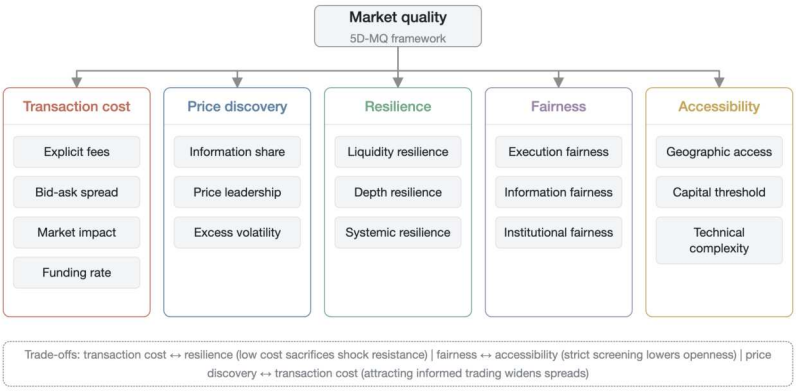

Figure 25-1. Architecture of the five-dimensional model of perpetual futures market quality (5D-MQ) (Data source: author's construction)

The design of the five-dimensional model follows four core principles. The first is mutual exclusivity: each dimension covers an independent facet of market quality. Transaction costs measure the execution friction of entering and exiting the market; price discovery assesses the efficiency with which price signals absorb information; resilience gauges the market's capacity to recover after a shock; fairness examines how equitably the rules treat different participants; and accessibility defines the breadth of the market's openness. This partition avoids overlap and ambiguity among dimensions. Mutual exclusivity matters because it ensures that each dimension has a clear definition and an independent measurement method, avoiding the double-counting or logical confusion that dimensional overlap would cause.

The second is completeness: these five dimensions form a comprehensive mapping of market microstructure and macro-level performance, and omitting any one of them would lead to a biased judgment of market quality. A market with very low transaction costs that is prone to collapse under stress, for example, has a true quality far below what its low-cost metric would imply. Likewise, a market with efficient price discovery that is entirely unfriendly to small traders has a deficiency in the accessibility dimension that offsets its price-discovery advantage.

The third is measurability: each dimension is decomposed into concrete operational indicators. Transaction costs, for example, include not only explicit fees and the bid-ask spread but also market impact and the funding rate, the implicit cost unique to perpetual futures; price discovery is quantified through information share and excess volatility; and resilience is measured through the spread-recovery half-life and the depth-recovery rate. Alexander et al. (2020), analyzing the Ethereum market, demonstrate that perpetual futures dominate price discovery—a leadership metric that is itself an important component of the price-discovery dimension [9].

The fourth is the presence of trade-offs: the five-dimensional model reveals systematic intrinsic conflicts among the dimensions of market quality. Lower transaction costs often come at the expense of market resilience (high leverage, for example, lowers the cost of capital tied up in margin but intensifies liquidation fragility); greater institu-

tional fairness may require stricter identity verification, thereby reducing accessibility; and greater price-discovery efficiency may attract more informed traders, raising market makers' adverse-selection costs and ultimately pushing transaction costs up. The five-dimensional model shows that no market is perfect on all dimensions; the design of market institutions is essentially a matter of weighing trade-offs along the efficient frontier formed by these five dimensions. Recognizing these trade-offs helps make sense of the complexity of market design, because it explains why different markets make different choices and why the *optimal* market design depends on the specific use case and the needs of participants.

The five-dimensional model lays the theoretical foundation for the sections that follow. Sections 25.2 through 25.6 examine, one by one, each dimension's measurement methods, cross-platform comparisons, and evolutionary trends; Section 25.7 analyzes the trade-offs among the dimensions; and Sections 25.8 through 25.10 further explore the state dependence of market quality, cross-platform comparison, and long-term evolution, providing an empirical foundation for the discussion of regulatory economics in Chapter 26 and the thought experiments in Chapter 27.

The five-dimensional model is a diagnostic framework rather than a scoring system (its *non-scoring* stance is detailed in Section 25.1.1). Its diagnostic power lies in its ability to answer concrete questions such as "Why does a given exchange have very low transaction costs yet see its liquidity dry up in periods of stress?" or "Why does a given DEX offer greater fairness but relatively lower accessibility?" Such questions are valuable not only for academic research but also as practical guidance for participants' decisions and regulators' policymaking.

Finally, one intrinsic limitation of the five-dimensional model should be openly acknowledged: the framework embeds an assumption of rational participants—that market participants can correctly assess risk and make decisions in their own interest. In crypto perpetual futures markets, however, the combination of high leverage, around-the-clock trading, and extreme volatility may systematically exploit traders' behavioral biases, including overconfidence, loss aversion, and a propensity to gamble. The five-dimensional model evaluates the operating quality of market institutions, not the behavioral health of participants. This means that a market performing excellently on the five-dimensional metrics may still produce large-scale individual welfare losses because of participants' behavioral irrationality. The absence of this dimension is not a design oversight but reflects a fundamental distinction between assessing institutional quality and assessing participant welfare, the latter of which requires the independent analytical tools of behavioral finance.

25.2 Transaction costs

Transaction costs are the most traditional and most measurable dimension of market quality. In perpetual futures markets, the composition of transaction costs is more complex than in traditional financial markets. Beyond explicit fees and the implicit bid-ask spread, the funding rate constitutes a distinctive holding-period transaction cost. In a one-sided trending market, the cumulative burden of the funding rate can

far exceed the sum of fees and spread, becoming the largest cost a trader faces. This section deconstructs the total transaction cost of perpetual futures across three layers: explicit fees, implicit friction, and the funding-rate burden.

25.2.1 Explicit costs

Fees are the explicit costs a trader must pay to enter and exit the market. Cryptocurrency exchanges generally adopt a two-tier maker-taker fee structure—based on whether an order provides or removes liquidity—combined with a tiered fee schedule keyed to trading volume and asset holdings. The core aim of this design is to incentivize market makers to supply liquidity while charging a premium to traders who actively consume it.

Among the leading centralized exchanges, fee schedules display a high degree of convergence alongside subtle differences. Take Binance's Ethereum perpetual futures: for ordinary users the maker fee is 0.02% and the taker fee is 0.05% [10]. By comparison, OKX charges ordinary users a 0.1% maker fee and a 0.2% taker fee for spot trading, which indicates that explicit transaction costs in the derivatives market are markedly lower than in the spot market [11]. A decentralized exchange such as Hyperliquid establishes a competitive advantage in explicit costs by waiving maker fees entirely and compressing the taker fee to 0.02%. Bybit, a newer centralized derivatives exchange, has a base fee structure close to Binance's but attracts high-frequency traders through a more aggressive rebate program.

There is a marked difference between nominal and effective fee rates. Through tiered fee schedules and market-maker rebate programs, exchanges compress the actual execution rate on the vast majority of trading volume to a small fraction of the nominal rate. Once a trader's monthly volume reaches a certain threshold, the maker fee can fall not merely to zero but into negative territory, becoming a rebate subsidy. When a Binance VIP 3 user reaches $100 million in monthly volume, the maker fee on perpetual futures can fall to 0.012%, roughly three-fifths (about 60%) of the ordinary-user rate [10]. An OKX VIP 9 user can obtain a 0% maker fee, achieving entirely free market making [11]. This structure means that retail traders are, in effect, subsidizing the liquidity-provision costs of high-frequency market makers. Assessing a market's explicit transaction costs through the official fee schedule alone is therefore incomplete; one must compute a weighted-average effective rate that reflects the structural distribution of market participants.

25.2.2 The bid-ask spread and market impact

Explicit fees make up only part of transaction costs; the bid-ask spread and market impact constitute a far larger implicit friction. The bid-ask spread is not a fixed value set by the exchange but compensation that market makers demand for bearing inventory risk, adverse-selection risk, and order-processing costs. The spread directly reflects the market's liquidity depth and degree of information asymmetry.

The quoted spread and the effective spread are two distinct dimensions for measuring this implicit cost. The quoted spread is the difference between the best bid and the best ask on the order book and represents the immediate execution cost of a small market

order. The effective spread accounts for how an order actually fills across multiple price levels and thus more truthfully reflects the real cost borne by large traders [12]. In markets dominated by traditional market makers, the effective spread is typically about half the quoted spread, reflecting limit-order price improvement and participants' adjustments in anticipation of price movements [12]. In the electronic limit order books of crypto perpetual futures, however, the ratio between the effective and quoted spreads varies with the market state, owing to the high proportion of aggressive market orders and market makers' rapid quote withdrawals during volatile periods; under stress, the effective spread may approach or even exceed the quoted spread [7]. In the highly liquid Bitcoin and Ethereum perpetual futures markets, the quoted spread is typically held within an extremely narrow range of 0.5 to 2 basis points [7][13]. For less liquid altcoin contracts, however, the spread can widen to more than 50 basis points, forming a significant implicit barrier to trading.

The market impact generated by large trades is another important component of implicit costs. When the size of a market order exceeds the depth at the best bid and ask, the order eats through successively worse price levels along the order book, so that the actual average execution price departs from the initial quote. This price impact can be decomposed into a permanent information cost that cannot be eliminated and a temporary liquidity cost that can be reduced by improving liquidity. In calm markets, a $1 million Bitcoin market order may generate only about 5 basis points of impact cost [7]; but during periods of extreme volatility or liquidity exhaustion, an order of the same size may trigger more than 100 basis points of impact, giving implicit transaction costs a nonlinear amplification (the specific basis-point figures above are illustrative estimates based on the methodology of [7]). This nonlinearity carries important implications for risk management, because it means that during market stress the real cost a trader faces can be more than 10 times the normal level.

25.2.3 The holding cost of the funding rate

The funding rate is a transaction-cost dimension unique to perpetual futures markets and constitutes the holding cost of a position. In traditional futures markets, the cost of holding a position is chiefly a deterministic interest charge; in perpetual futures, by contrast, longs and shorts must periodically exchange the funding rate in order to keep the contract price anchored to the spot price. This rate is a random variable that fluctuates in real time with market supply and demand, and it can spike to extreme levels under extreme conditions.

In economic terms, the funding rate is the mechanism by which the market prices leverage imbalance. When market sentiment is extremely optimistic and long leverage demand far outstrips short demand, the perpetual futures price develops a positive premium, driving the funding rate positive. Longs must then pay shorts. At the peak of the 2021 bull market, the annualized funding rate on Bitcoin perpetual futures held at a high of 30% to 80% for several weeks at a stretch. This means that even if the underlying asset's price merely churns sideways, long holders suffer significant capital erosion from the heavy funding burden—and the funding rate has been confirmed by empirical research as a risk factor independent of price direction [14].

The way the funding rate is calculated varies across exchanges and continues to evolve. BitMEX first established the model of a fixed base rate plus a premium index, with settlement every 8 hours as the early industry standard. Leading exchanges such as Binance and OKX built on this with more flexible floating-rate models that adjust dynamically to the real-time deviation between the contract price and the spot price. As of early 2025, these platforms had introduced 4-hour or even higher-frequency settlement cycles for some major contracts, while a new generation of platforms such as Hyperliquid was exploring hourly settlement. Higher-frequency settlement reduces the absolute magnitude of any single funding payment but also increases microstructure noise around the settlement points, requiring market makers to rehedge their funding-rate exposure before and after each settlement window.

In bull-market cycles, the funding rate exhibits a marked positive skew, with longs systematically paying this holding tax. Yet this positive skew is not an inherent property of perpetual futures: during the deep bear market of 2022–2023, the funding rate was persistently negative, and shorts instead became the net payers. Over data spanning a full bull-bear cycle, the net positive skew of the funding rate is far smaller than the value observed during a pure bull market, but it remains positive, reflecting the structural feature that long leverage demand dominates over the long run in crypto markets. This is an additional implicit cost of taking a long exposure through perpetual futures rather than spot. For high-frequency traders, the effect of the funding rate is small; but for swing traders or hedging institutions holding for more than a few days, the cumulative funding outlay can far exceed the combined fees and spread of entering and exiting. A trader holding a $1 million Bitcoin long position for 30 days, in an environment where the funding rate is annualized at 30%, would pay about $25,000 in funding costs, equivalent to a 2.5% erosion of capital. This cost level is enough to meaningfully eat into a trading strategy's return. Annualizing the expected funding rate and weighting it by the holding period is therefore a necessary step in accurately assessing the true transaction cost of perpetual futures.

25.2.4 Measuring total transaction cost

A comprehensive assessment of market quality requires integrating explicit fees, implicit friction, and the funding-rate burden into a single total-transaction-cost metric. Total transaction cost equals the sum of fees, half the effective spread, the market-impact cost, and the expected funding-rate holding cost. This composite measure reveals the true cost constraints faced by different trading strategies.

A concrete worked example helps clarify this framework. Suppose a trader opens a $1 million Bitcoin long position on Binance as a taker, holds it for 7 days, and executes both the opening and closing trades with market orders. The total transaction cost should include all the friction of the round trip: the entry taker fee, $0.05\% \times \$1$ million $= \$500$; the entry effective-spread cost, assumed at 5 basis points, or $500; the entry market-impact cost, assumed at 10 basis points in a calm market, or $1,000; the 7-day funding cost, assumed at an annualized 20%, or $20\% \times 7/365 \times \$1$ million $\approx$ $3,800; the exit taker fee, likewise $500; the exit effective-spread cost, $500; and the exit market-impact cost, $1,000. The total cost of a full round trip is therefore about

$7,800, equivalent to a capital cost of 0.78%. This cost level may be acceptable for strategies with short holding periods but constitutes a significant drag on returns for long-term holders. If the trader closes with a limit order rather than a market order, the spread and impact costs on the exit side can be avoided, lowering the total cost to about $6,300 (0.63%)—though at the expense of immediacy in closing the position.

Investors with different trading frequencies and holding periods have sharply different sensitivities to total transaction cost. For high-frequency market makers, fees and the spread are the core consideration, while the funding rate is nearly negligible because holding times are so short. For lower-frequency trend followers, the funding rate is the largest cost item, especially since building a position with the trend often requires paying a steep funding premium. Total transaction cost is also strongly state-dependent. In calm markets, abundant liquidity and low-volatility funding keep total cost at a low level; during market stress, the spread widens sharply, market impact amplifies nonlinearly, and the funding rate produces extreme pulses, so total transaction cost can spike dozens of times over within a short span. More important still, the total-cost formula above treats each cost item as an independent variable to be summed, whereas in real markets these items interact significantly. When the funding rate spikes, market makers widen the bid-ask spread because they bear greater inventory risk and funding-rate exposure; that is, an extreme funding rate indirectly pushes up the other implicit cost items. This interaction means that the true total transaction cost during stress can be higher than the simple sum of the individual costs.

Comparing total transaction cost across assets further confirms the stratification of market quality. Major assets such as Bitcoin and Ethereum enjoy the narrowest spreads, the deepest liquidity, and relatively stable funding rates, and their total transaction cost is the lowest. As market capitalization and liquidity decline, the total transaction cost of altcoin perpetual futures rises along a steep gradient. This cost differential reflects not only how market makers price the risk of different assets differently but also a friction barrier that impedes the efficient allocation of capital across long-tail assets.

25.2.5 Cross-platform comparison and evolution

Applying the total-transaction-cost framework to individual platforms, Figure 25-2 decomposes the total transaction cost of Bitcoin perpetual futures across exchanges under typical market conditions.

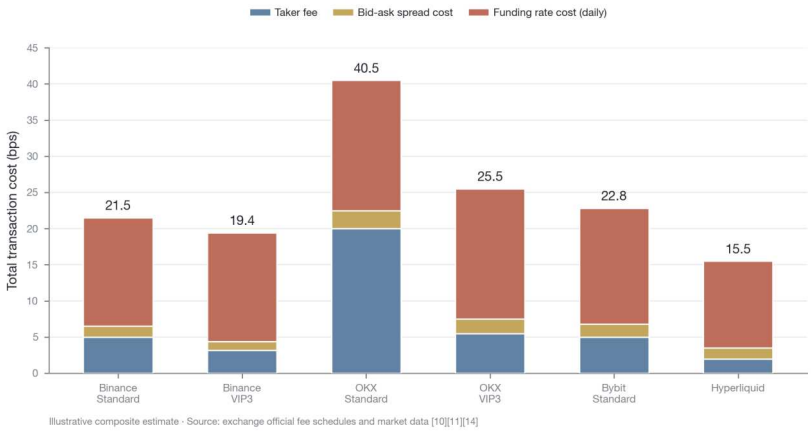

Figure 25-2. Comparison of total transaction cost for Bitcoin perpetual futures across leading exchanges (illustrative composite estimate, not direct measurement; the OKX VIP 3 and Bybit ordinary tiers are representative extensions not discussed in the main text, while the remaining tiers appear in the text; data source: exchanges' official fee schedules and market data [10][11][14])

In cross-platform comparison, ordinary users of centralized exchanges face the highest explicit fee burden, but the exchanges' deep order books effectively lower market-impact costs. The total transaction cost for a Binance ordinary user is about 21.5 basis points, of which the taker fee accounts for 5 basis points, the bid-ask spread cost for 1.5 basis points, and the annualized funding cost for 15 basis points. As the fee tier rises, total transaction cost falls markedly: a Binance VIP 3 user's total cost drops to 19.4 basis points, reflecting the platform's tilt toward high-frequency, large-capital users. Because its spot fees are higher, an OKX ordinary user's total transaction cost reaches 40.5 basis points, roughly twice that of a Binance ordinary user. Through a zero-fee strategy and an innovative liquidity-pool mechanism, the decentralized derivatives platform Hyperliquid compresses total transaction cost to 15.5 basis points, exerting significant competitive pressure on total cost and forcing traditional centralized platforms to reexamine their fee models.

Over the past 10 years, the transaction cost of perpetual futures markets has fallen structurally. From the tens-of-basis-points wide spreads when BitMEX launched the first Bitcoin perpetual futures in 2016, to today's extremely narrow spreads on major assets that approach those of traditional financial markets, this progress is attributable chiefly to three drivers. The first is the full-scale entry of high-frequency market makers and the spread of algorithmic trading, which sharply compressed implicit friction and reduced spreads on major assets from more than 10 basis points to less than 1. The second is fierce competition among exchanges over liquidity and market share, which drove explicit fees steadily downward, from an early 0.1% to today's 0.02%. The third is the maturation of liquidation engines and risk-management mechanisms, which lowered the system's tail-risk premium and markedly reduced funding-rate volatility. Yet the funding rate, as the core mechanism for balancing longs and shorts, still imposes a holding cost that remains a distinctive property setting perpetual futures apart from other financial instruments—and a computational hurdle that traders must clear when assessing the cost of long-term positions. The existence of this cost dimension gives the

total-transaction-cost structure of perpetual futures markets a fundamental difference from that of traditional futures markets and is central to understanding perpetual futures market quality.

25.3 Price discovery

Price-discovery quality measures the efficiency of the market as an information processor—that is, how quickly and accurately prices reflect new information once it arrives. This section treats informational efficiency as a key dimension of market quality, examines how it interacts with the other dimensions, and constructs a multilayered framework for evaluating price-discovery quality. Perpetual futures have become the dominant venue for crypto-asset price discovery, but this leadership is conditional and varies significantly with the type of information shock, the market state, and the asset class.

25.3.1 Measurement methods

When the same asset trades across multiple markets, determining which market leads the price-discovery process is a central question in assessing market quality. The academic literature generally uses two classic econometric methods to quantify the price-discovery contribution of different markets. The first, proposed by Hasbrouck (1995), centers on the concept of the information share. This method assumes an implicit, unobservable common efficient price and defines a given market's information share as its proportional contribution to innovations in that common efficient price [15]. Within this framework, a market that absorbs and reflects new information more quickly has a higher information share, indicating that it dominates price discovery.

The second method derives from Gonzalo and Granger (1995), who proposed a technique for decomposing a price series into permanent and transitory components. This permanent-transitory decomposition is widely used to estimate the price-discovery contributions of multiple cointegrated markets, particularly in analyzing price leadership between futures and spot markets [16]. Unlike the information share, which focuses on the contribution to variance, the Gonzalo-Granger method focuses on measuring the speed at which each market's price adjusts to the common long-term trend. When two markets depart from equilibrium, the market that adjusts more slowly is regarded as the price leader, while the market that adjusts more quickly is the follower.

Applying these traditional methods directly to perpetual futures markets, however, poses particular challenges. The fundamental difference between perpetual futures and traditional futures is their lack of an expiry date, which requires the funding-rate mechanism to anchor them to the spot price [17]. The periodic payment or receipt of the funding rate introduces a distinctive mechanical friction that makes the cointegration relationship between the perpetual futures price and the spot price more complex than in traditional markets. Moreover, the around-the-clock trading and very high microstructure noise of crypto markets require the use of high-frequency data and finer adjustments to model specification when applying these econometric models, so as to accurately separate genuine information shocks from short-term liquidity disturbances.

Notably, the Hasbrouck information share and the Gonzalo-Granger component share can, in practice, produce contradictory rankings of market leadership. This contradiction stems from the two methods' different treatments of microstructure noise: the information share's variance decomposition of price innovations depends on the ordering of the variables, whereas the component share is highly sensitive to the estimation of short-term noise components. Because microstructure noise in perpetual futures markets is far higher than in traditional markets, the choice of method has an especially pronounced effect on the conclusions. The empirical discussion in the remainder of this chapter therefore draws on the results of both methods to strengthen the robustness of its conclusions.

25.3.2 The leadership relationship between perpetual futures and spot

A large body of empirical evidence shows that perpetual futures lead price discovery in the spot market during most periods. Alexander et al. (2020), in their study of the Ethereum market, find that the Ethereum perpetual futures on BitMEX are absolutely dominant across all price-discovery metrics, with an information share far higher than that of the spot exchanges. The study further notes that the introduction of perpetual futures actually improved the pricing efficiency of the spot exchanges [9]. Robertson (2025), analyzing the latest high-frequency data for the Bitcoin market, reaches a similar conclusion, confirming that the futures market holds a systematic lead over the spot market in absorbing information [18]. This leadership stems from the built-in leverage, lower transaction costs, and deeper liquidity that perpetual futures offer—features that make them the preferred venue for informed traders to express their views. The full picture of price discovery, however, should not be confined to a binary comparison between offshore perpetual futures and the spot market. Since the approval of Bitcoin exchange-traded funds (ETFs) in 2024, the open interest of CME Bitcoin futures has grown significantly, and institutional participants increasingly express their pricing views through the CME during U.S. trading hours. In certain periods, the price-discovery contribution of the regulated futures market may exceed that of offshore perpetual futures, forming a tripartite pricing structure of offshore perpetuals, spot, and regulated futures.

Although perpetual futures hold the overall lead, this leadership is markedly conditional. The relative roles of the markets shift depending on the type of information shock. For macroeconomic data releases or market-wide liquidity shocks, perpetual futures typically react fastest, thanks to their high liquidity and leverage. For information specific to a single asset, however—such as a protocol upgrade, a security vulnerability, or a large spot transfer—the spot market sometimes briefly reclaims the lead in price discovery. This division of labor in information processing reflects differences in the composition of participants and their trading motives across markets.

Sharp shifts in the market state likewise reshape the price-discovery hierarchy. During the prolonged 2021 bull market, the leadership of perpetual futures reached its peak: persistently positive funding rates and intense speculative sentiment made the derivatives market the absolute pricing engine. After the series of systemic crises and the deep bear market of 2022, however, the information share of perpetual futures declined some-

what as extensive leverage was liquidated and market-maker capital withdrew. During phases of extreme panic selling, the actual selling pressure of the spot market often becomes the decisive force driving prices, and the leadership of perpetual futures appears more fragile in these stress tests. This state dependence shows that the price leadership of perpetual futures is not a static constant but a variable that evolves dynamically with the market environment.

25.3.3 Cross-asset differences

The price-discovery efficiency of crypto-asset markets varies enormously across assets. Major assets and altcoins exhibit sharply different information-processing capacities. As the assets with the deepest liquidity and the largest market capitalizations, Bitcoin and Ethereum have perpetual futures markets that display high microstructure efficiency. In these two markets, prices integrate new information rapidly, the information share is stable at a high level, and the bid-ask spread is extremely narrow. This efficient price discovery benefits from a mature market-maker ecosystem, broad institutional participation, and highly developed cross-market arbitrage mechanisms.

By contrast, the perpetual futures markets of most altcoins are markedly less efficient. Liquidity in these assets is typically thin, and order-book depth is insufficient to absorb medium-sized trades without generating significant price impact. In such an environment, the price-discovery process is often accompanied by violent volatility and abundant noise. For lack of sufficient arbitrage capital to maintain cross-market price consistency, the prices of altcoin perpetual futures frequently deviate from their spot underlyings for extended periods, resulting in low informational efficiency. This positive-feedback loop between liquidity and price-discovery efficiency allows highly liquid assets to keep improving in efficiency while low-liquidity assets struggle to escape their inefficient state.

The distribution of price-discovery shares across exchanges further reveals the complexity of market structure. The fragmentation of liquidity across platforms disperses pricing power. Leading centralized exchanges, with their vast user bases and deep market-maker resources, typically hold the largest information shares. As decentralized derivatives exchanges have grown, however, this pattern is shifting subtly. Through innovative liquidity-supply mechanisms and permissionless access, decentralized platforms have begun to capture a sizable share of price discovery for particular assets or during particular periods. This multi-centered price-discovery process increases arbitrage opportunities but also introduces cross-platform transmission latency and friction, posing new challenges to the pricing efficiency of the market as a whole.

25.3.4 Excess volatility

In assessing price-discovery quality, relying on the information share and similar metrics alone is often insufficient to capture the full complexity of market microstructure. Excess volatility offers a composite inverse indicator of considerable analytical value. Excess volatility is defined as the difference between a market's actual total volatility and the volatility it ought to exhibit if driven by fundamental information. Operationally, this warranted volatility can be estimated in several ways: one is to use the

Hasbrouck information share to decompose realized volatility into information-driven and noise components; another is to use the degree of departure from a random walk, measured by a variance ratio test over a rolling window, as a proxy [15][18]. High excess volatility means that price movements contain a great deal of non-informational noise, which directly reflects a decline in price-discovery quality. Such noise can mask genuine supply-and-demand signals, raising traders' execution costs and adverse-selection risk.

Several distinctive sources of excess volatility exist in perpetual futures markets. The first is volatility amplification triggered by the liquidation mechanism. When rapid price movements trigger large-scale forced liquidation, the market orders that the system automatically dumps cause a severe chain of price impacts on an already thin order book, producing violent movements that far exceed fundamental value. The second is institutional noise from funding-rate pulses. In a one-sided market, an extreme funding rate forces arbitrageurs to adjust positions frequently, and this non-informational order flow likewise injects additional volatility. In addition, the defensive quote adjustments that market makers make when facing inventory risk increase the random-walk component of prices at the micro level.

Figure 25-3 shows the relationship between excess volatility and the price-discovery efficiency index for different crypto assets across multiple periods.

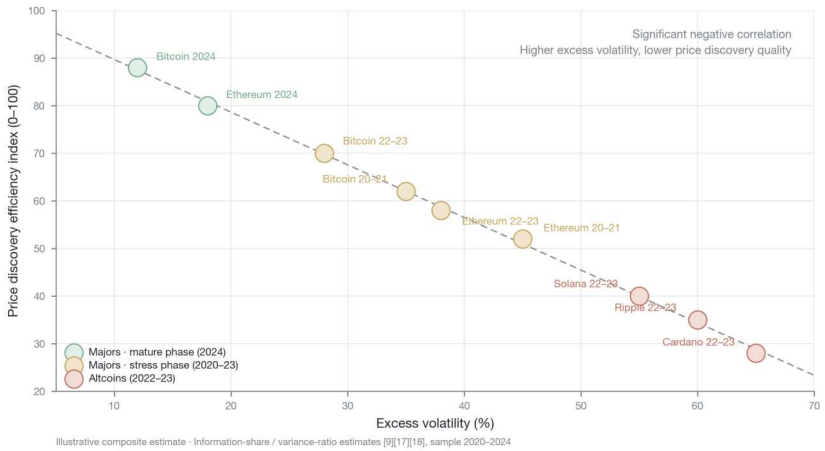

Figure 25-3. The inverse relationship between excess volatility and price-discovery efficiency (illustrative composite estimate, not direct measurement; the two are significantly negatively correlated and are presented qualitatively only, with no precise correlation coefficient reported so as to avoid false precision; based on the information-share and variance-ratio estimates of Alexander et al. [9], He et al. [17], and Robertson [18], with excess volatility defined as the difference between realized volatility and the fundamental volatility weighted by the Hasbrouck information share, sample period 2020–2024)

The scatter plot clearly reveals the significant negative correlation between the two. In more mature market phases, such as 2024, Bitcoin and Ethereum exhibit low excess volatility and high price-discovery efficiency. During the high-stress period of 2022–2023, by contrast, the excess volatility of even major assets rose significantly, accompanied by a decline in efficiency. More strikingly, altcoins such as Solana, Ripple, and Cardano sit systematically in the lower-right region of the chart—the zone of high excess volatility and low price-discovery efficiency. This empirical evidence strongly

supports treating excess volatility as an important dimension for gauging perpetual futures market quality and informational efficiency, providing an intuitive, quantifiable yardstick for comparisons across assets and across cycles.

25.4 Resilience

Resilience is an underrated yet critical dimension of perpetual futures market quality. In day-to-day trading, traders usually attend only to the narrowness of the spread or the depth of the order book, overlooking resilience altogether. Resilience becomes visible only in a crisis, yet the loss from a single failure of resilience can exceed the returns accumulated over years of calm. In a market like crypto—highly leveraged, running around the clock, and lacking a central bank as lender of last resort—understanding and measuring the market's capacity for self-repair is key to assessing systemic risk. This section analyzes resilience across three layers—liquidity resilience, depth resilience, and system resilience—moving from the micro level of spread recovery and order-book reconstruction, to differences in the design of liquidation mechanisms and margin systems, to the resilience function of the funding rate under extreme conditions, and finally to the macro-level systemic risk of cross-exchange contagion.

25.4.1 Definition and measurement framework

In financial microstructure theory, market liquidity is typically decomposed into three interrelated dimensions. Under the classic taxonomy proposed by Kyle, these are tightness, depth, and resilience [19]. Tightness measures the direct cost of trading, usually expressed as the bid-ask spread; depth reflects the market's ability to absorb large orders without causing large price movements; and resilience is defined as the speed at which prices recover from random, uninformative shocks [19]. In perpetual futures markets, resilience is not merely the recovery of price but the self-repair of the entire market structure after extreme stress.

Resilience differs fundamentally from the other dimensions of liquidity. Liquidity is static: it describes how many trading opportunities the market can offer at a given moment. Resilience is dynamic: it concerns the market's ability to replenish liquidity once it has been consumed. A market may exhibit excellent tightness and depth in calm periods yet dry up in an instant when shocked, for lack of resilience. This dynamic property matters especially in crypto markets, because high leverage and programmatic trading tend to amplify local shocks into systemic events.

A comprehensive assessment of perpetual futures market resilience requires a multilayered measurement framework. The first layer is liquidity resilience, concerned mainly with the speed at which the bid-ask spread returns to normal after widening. The second is depth resilience, which measures the time it takes for limit orders to refill the gaps after a large market order has punched through the order book. The third is system resilience, which assesses the ability of an entire exchange to keep functioning normally and to prevent risk from spreading to other markets when confronted with a large-scale liquidation cascade. These three layers are interwoven and together determine a market's survival capacity under extreme conditions.

In analyzing resilience, we must distinguish two conceptually distinct layers: price resilience and system resilience. Price resilience concerns the speed at which an asset's price reverts to fundamentals after a short-term shock, whereas system resilience measures the market's ability to keep its core functions—trade execution, clearing and settlement, and price discovery—uninterrupted when it suffers a severe external shock or internal liquidity exhaustion. For perpetual futures markets, whose underlying assets are themselves extremely volatile, pursuing absolute price stability is neither realistic nor necessary; the core of a resilience assessment should therefore focus on system-level robustness: whether the market can keep operating under stress, not whether the price stays unchanged.

Perpetual futures markets face particular structural challenges in maintaining system resilience. Perpetual futures have no expiry date, which means risk exposure can accumulate indefinitely and the market cannot force a periodic release of accumulated pressure through delivery settlement. These markets generally offer very high leverage multiples, so that small price movements can trigger forced liquidation and, in turn, set off a chain reaction. Empirical observation indicates that when the market's aggregate leverage ratio—defined as the ratio of the notional value of network-wide open interest to total margin deposits—climbs to a high level, systemic fragility rises significantly, and at that point any small negative shock can trigger an uncontainable liquidation cascade [20]. The specific leverage threshold that triggers systemic fragility varies with the measurement approach and sample (illustratively, somewhere around 25%), and there is no single, precise critical value. Actual fragility depends not only on the absolute level of leverage but also on its distribution: high-leverage positions concentrated among a few large holders are far more dangerous than low-leverage positions dispersed across many retail traders, because liquidating the former releases far greater instantaneous selling pressure.

25.4.2 The spread-recovery half-life

The most intuitive expression of liquidity resilience is the spread-recovery half-life. When the market is hit by a large trade or an external news shock, market makers typically withdraw their limit orders quickly to avoid adverse-selection risk, causing the bid-ask spread to widen sharply. The spread-recovery half-life is the time it takes for the spread to fall halfway from its post-shock peak back to its initial normal level [21]. This indicator directly reflects the confidence and speed with which liquidity providers reassess risk and return to the market.

In traditional financial markets, electronic limit order books usually recover quite quickly. Research shows that in mature markets such as the London Stock Exchange, the order book's post-trade recovery half-life is about 20 seconds [21]. In crypto perpetual futures markets, however, the spread-recovery process is often more complex, owing to the widespread use of leverage and the high degree of market fragmentation: under normal conditions the recovery half-life of top exchanges can match or even surpass that of traditional markets, but during periods of stress it may be significantly delayed. Figure 25-4 compares the spread-recovery performance of several major exchanges under both normal and stressed conditions.

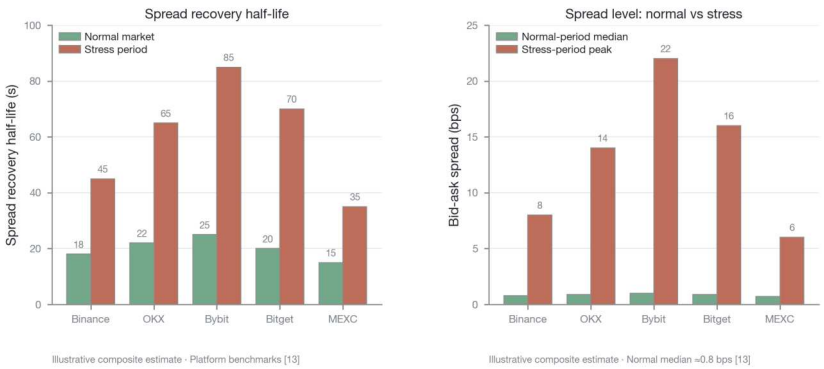

Figure 25-4. Cross-platform comparison of liquidity-resilience indicators (illustrative composite estimate, not direct measurement): the left panel shows the spread-recovery half-life (normal market versus periods of stress), and the right panel shows the median spread in normal periods (≈0.8 basis points) versus the peak spread during stress; recovery diverges markedly under stress and the peak spread widens substantially (data source: commercial-platform review [13] and exchanges' market data)

The cross-platform comparison in the figure clearly shows the differences in resilience across exchanges. Under normal market conditions, the Bitcoin perpetual futures spread on major exchanges is extremely small, with a median typically held at about 0.008% (about 0.8 basis points) [13]. During periods of stress, however, recovery speeds diverge markedly across platforms. Some can restore the spread to normal within 30 to 40 seconds, while others may need more than 1 minute [13]. This difference arises not only from the composition of each platform's market-maker community but, more fundamentally, from the efficiency of each exchange's liquidation engine and the design of its risk-management mechanisms. Platforms with a shorter recovery half-life generally offer traders a more reliable execution environment and thus attract greater liquidity inflows during a crisis.

25.4.3 The speed of order-book reconstruction

Depth resilience concerns the physical process by which the order book rebuilds after a shock. When a large market order sweeps through the order book and consumes liquidity across multiple price levels, it leaves a *hole* in the market. Depth resilience measures the speed at which new limit orders fill these holes and restore the original market depth. This process depends heavily on the behavioral logic of high-frequency traders and market makers.

Figure 25-10 presents the liquidity baseline before a shock: the order-book depth within a $\pm 0.1\%$ price band around the best price under normal market conditions on major exchanges, with most leading platforms in the range of $40 million to $50 million and a few notably higher. It is precisely this baseline that is punched through in an instant under a violent shock, and the speed of its reconstruction determines a platform's depth resilience.

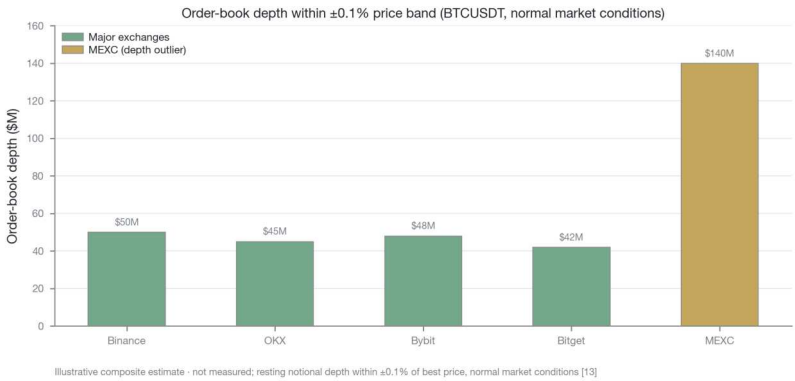

Figure 25-10. Order-book depth of Bitcoin perpetual futures on major exchanges (illustrative composite estimate, not direct measurement; notional resting depth within a ±0.1% price band around the best price, normal market conditions; data source: composite estimate from exchanges' market data [13])

After a shock, market makers face a dilemma. On one hand, the widened spread offers higher market-making profits; on the other, violent price swings entail enormous inventory risk. In crypto markets, market makers often adopt a *retreat-observe-return* strategy. The market crash of March 2020 offers an extreme case of depth-resilience failure. At the time, the Bitcoin price plunged in a short span, triggering a large-scale wave of liquidations [22]. Faced with enormous one-sided selling pressure and a cross-platform spread of more than $500, many market makers simply shut down their trading algorithms and stopped providing liquidity [22].

During that crisis, the order-book depth of one leading derivatives exchange dried up at one point to only about $20 million in buy orders, while the long positions awaiting liquidation reached as much as $200 million [22]. Had all these liquidation orders been dumped at market, the price of Bitcoin might have been driven down to near zero. This total collapse of depth resilience shows that when a market shock exceeds market makers' risk tolerance, the order book's reconstruction mechanism fails entirely. Only after the price stabilized at a new equilibrium, or the exchange intervened (for example, by halting trading), did market makers begin submitting orders again and the order-book depth slowly recover.

25.4.4 The capacity to withstand liquidation cascades

System resilience is the dimension of resilience unique to—and most critical for—perpetual futures markets. It measures the market's survival capacity when confronted with a liquidation cascade. A liquidation cascade is a vicious cycle in which a price decline triggers the liquidation of long positions, the market sell orders generated by those liquidations push the price down further, and the lower price triggers still more liquidations. In crypto markets, which lack circuit breakers and price limits, liquidation cascades are the primary threat leading to systemic collapse.

To withstand liquidation cascades, perpetual futures markets have developed a distinctive set of buffering mechanisms, of which the insurance fund is the most central.

When a liquidated position fills below its bankruptcy price, the resulting shortfall is covered by the insurance fund, protecting the profits of winning traders from being clawed back. The size and burn rate of the insurance fund are important indicators of system resilience. The insurance funds of major exchanges are not a single pool but are established separately by currency and contract type: BTC perpetual futures, ETH perpetual futures, and the various altcoin perpetual futures each have their own independent insurance fund. While this segmented structure provides risk isolation, it also means that the insurance-fund protection for long-tail asset contracts is far weaker than for major assets: in extreme conditions, the insurance fund for a given altcoin contract may already be exhausted and have triggered auto-deleveraging (ADL) while the fund for the BTC contract remains ample. If a single market shock consumes most or all of the insurance fund, the market's system resilience is near its limit. In the extreme, if the insurance fund is exhausted, the exchange must activate the auto-deleveraging mechanism to forcibly close profitable positions, which severely damages the market's credibility and liquidity.

The design of the liquidation mechanism has a profound effect on system resilience. Some early exchanges, for example, accepted only Bitcoin as margin, which meant that when the price fell, long traders faced not only losses on their positions but also a shrinking value of their margin—a nonlinear leverage effect that significantly increased the risk of a liquidation cascade [22]. As the market has evolved, modern exchanges have generally introduced multi-currency blended margin and tiered liquidation mechanisms, which effectively slow the instantaneous impact of liquidations on the market and thereby improve the system's overall resilience.

The architectural choice of the margin system has a decisive effect on the capacity to withstand liquidation cascades. The isolated-margin model isolates the risk of a specific position by allocating independent margin to each contract; its advantage is that it caps the loss from any single bad decision. Isolated margin, however, leaves each position with very little buffer, making it more prone to frequent micro-liquidations during violent volatility and thereby increasing trading friction and short-term volatility at the micro level [23]. The cross-margin model lets a trader use all available balance in the account as shared collateral, which significantly lowers the probability of liquidation under normal market conditions and allows the portfolio to better absorb local shocks [23]. But cross margin proves extremely fragile in extreme tail events: when the market suffers a broad sell-off, the synchronized decline of correlated assets can rapidly exhaust the entire account's margin, causing all positions to be force-liquidated at once and instantly releasing enormous selling pressure into the market. At the system level, when most traders use cross margin, this individually reasonable risk-control choice produces a fallacy of composition in the aggregate: the crash of a single asset liquidates not only that asset's position but also, by extension, all other positions in the same account, spreading a shock originally confined to one market into cross-asset systemic selling pressure.

Tiered liquidation mechanisms and the insurance fund form a second line of defense that buffers the shock of liquidations. Modern liquidation engines have evolved from the early days of simple market-order closeouts into complex multi-stage systems: the first stage attempts to liquidate with limit orders, placing the liquidated position into

the order book to await matching; the second stage, when the limit orders fail to fill, initiates counterparty matching to find market makers willing to take over the position at a discount; and only the final stage executes a market liquidation. Some exchanges have also introduced a liquidation-delegation mechanism that allows third-party market makers to proactively take over liquidated positions at a price better than the bankruptcy price, thereby reducing the impact on the market. Tiered liquidation refines this further by reducing positions gradually in batches according to market depth and price slippage, smoothing the selling pressure to some degree. The insurance fund serves as a pool for absorbing shortfall losses, using the penalties collected in routine liquidations to cover systemic losses in extreme situations; but its size is typically only a small fraction of total open interest [23].

25.4.5 The resilience function of the funding rate

The funding rate is the most central innovation of perpetual futures. It was designed as a price-anchoring mechanism that, through periodic funding exchanges between longs and shorts, forces the perpetual futures price back toward the spot index price. Under normal market conditions, the funding rate serves as an effective corrective mechanism: when the contract price is above spot, longs pay shorts, dampening excessively bullish sentiment, and vice versa. This anchoring mechanism continuously draws arbitrage capital into the market, sustaining pricing efficiency and forming an important micro-foundation of market resilience.

In extreme conditions, however, the funding-rate mechanism may not only fail to perform its resilience function but also exhibit strong procyclicality that amplifies market volatility. When the market swings violently in one direction, speculative order flow tends to overwhelm the capacity of arbitrage capital to absorb it [24]. The funding rate then spikes to extreme levels. Traders holding counter-trend positions must bear not only large paper losses but also steep funding payments. This dual negative effect accelerates the depletion of margin, forcing traders to close early or be force-liquidated, which in turn drives the price still further from fundamentals. The failure of the funding rate's resilience function is not a sudden jump from normal to collapse but a process of gradual exhaustion: during a spell of moderately high funding, arbitrageurs keep stepping in to compress the funding deviation, but their margin buffer is progressively consumed at each settlement cycle. When a truly extreme shock arrives, arbitrage capital has already been significantly weakened, so the corrective mechanism collapses far faster than it would from a fully normal starting state. This path dependence means that after a prolonged one-sided market, the market's resilience to a sudden shock is systematically lower than in its initial state.

Another key condition for the failure of the funding rate's resilience function is the exhaustion of underlying liquidity. When spot-market liquidity dries up, small movements in the index price are amplified, so the basis for calculating the funding rate loses its representativeness. Some exchanges, moreover, set a funding-rate cap to prevent the rate from excessively penalizing one-sided position holders. Under extreme sentiment, when the true degree of market imbalance far exceeds this cap, the funding rate loses its price-anchoring and supply-demand-adjusting functions, causing the perpetual futures

price to diverge from the spot price over a prolonged period and to a severe degree.

25.4.6 Cross-exchange contagion

The crypto-asset market is composed of many mutually independent exchanges, yet they are tightly connected through cross-exchange arbitrageurs, shared market makers, and highly overlapping pools of collateral assets. This network structure means that a crisis at any single node can rapidly evolve into a market-wide systemic crisis, constituting the ultimate test of market resilience.

The mechanism of cross-exchange price contagion works mainly through two channels. The first is the direct transmission of a liquidity shock. When a large exchange suffers a run or a liquidation cascade, asset prices on that platform plunge. Because arbitrage algorithms monitor price differences across platforms at the millisecond level, they quickly sell the same assets on other, still-functioning exchanges to lock in profits, transmitting the price collapse across the entire network in an instant. The second channel is balance-sheet cross-contagion. Many institutional investors hold exposure on multiple platforms at once; when a position on one platform is force-liquidated, they must liquidate healthy positions on other platforms to top up margin, and this cross-platform deleveraging spreads the liquidity crisis to assets and exchanges that were originally unrelated.

Beyond these two channels, the bidirectional contagion between decentralized protocols and centralized exchanges forms a third, increasingly important transmission channel. Large-scale liquidations on centralized exchanges transmit through oracle price feeds to on-chain lending and perpetual futures protocols, triggering on-chain liquidations and imbalances in liquidity pools; conversely, the collapse of an on-chain protocol (such as the Terra-Luna event of 2022) transmits the shock to centralized exchanges through arbitrageurs and shared collateral. A stablecoin depeg constitutes a particularly dangerous, standalone contagion channel: when the peg of USDT or USDC deviates, stablecoin-denominated margin shrinks simultaneously across all exchanges and protocols, triggering liquidations synchronously across venues and protocols, with a contagion reach far exceeding that of a crisis in a single asset or on a single platform.

The collapse of FTX in November 2022 offers a canonical case for studying systemic contagion. As the world's third-largest crypto derivatives exchange at the time, FTX's bankruptcy not only destroyed its native token but also produced a significant downside-risk spillover. Empirical research shows that during the FTX collapse, assets deeply tied to the platform bore the strongest risk contagion, and even the relatively independent Bitcoin and Ethereum underwent violent repricing as overall market liquidity was withdrawn [25]. More strikingly, the FTX crisis left many cross-exchange market makers badly wounded or bankrupt, and the network-wide liquidity baseline fell sharply over the following months, inflicting lasting damage on the market's overall resilience.

Figure 25-5 renders the contagion mechanisms above as a network structure, in which the nodes represent major exchanges and key institutional participants, and the thickness and direction of the edges reflect the intensity and pathways of liquidity-shock and balance-sheet contagion. The key amplifying nodes marked in the figure—large market makers and hedge funds connected to multiple exchanges at once—act as liquidity

bridges in normal times but become accelerators of systemic contagion during a crisis.

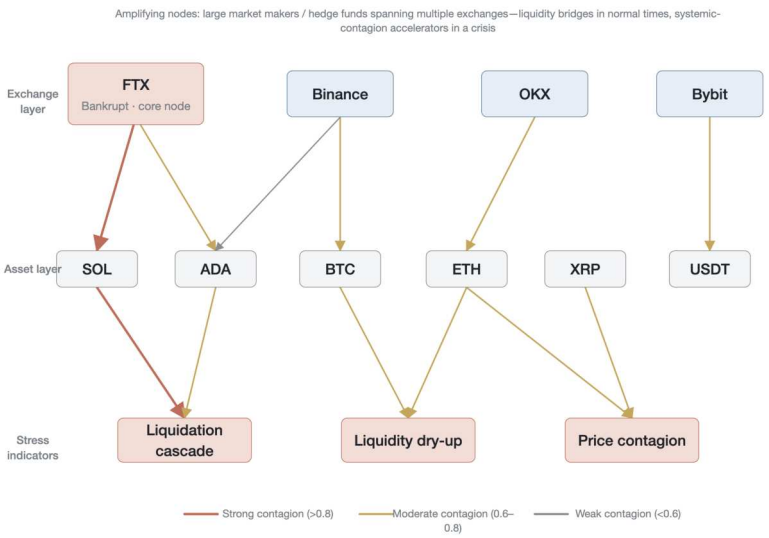

Figure 25-5. Network structure and transmission pathways of cross-exchange stability contagion (a representative reconstruction based on empirical research on the FTX collapse [25] and the October 2025 liquidation cascade [20][26]; edge strengths are qualitative gradations, not measured weights)

Similar network effects have recurred in subsequent episodes of market stress. In the liquidation cascade triggered by a macroeconomic shock in October 2025, for example, an unprecedented scale of liquidations occurred network-wide within about 36 hours (measured as notional value liquidated, not open interest wiped out) [20]. In this crisis, the intensity of cross-asset contagion even exceeded that of previous macro stress tests, demonstrating once again that, absent a network-wide coordination mechanism, the risk controls of individual exchanges cannot halt the spread of a systemic crisis.

25.4.7 Cross-platform comparison and evolution

Although the liquidity of perpetual futures markets has improved significantly over the past few years, resilience has been the slowest to improve. This is because liquidity can be enhanced through short-term incentives such as lower fees or market-maker rebates, whereas strengthening resilience requires systematic institutional reform and long-term investment in infrastructure. Viewed through the lens of historical evolution, the resilience of crypto markets has already undergone several major tests and rounds of evolution.

Comparing several major market crises reveals the trajectory of resilience's evolution clearly. In the crash of March 2020, market structure nearly collapsed entirely: network congestion prevented arbitrageurs from moving funds between exchanges, intensifying local liquidity exhaustion [22]. By the Terra-Luna collapse of May 2022, although the market again experienced violent price swings and large-scale liquidations, the systems of major exchanges did not suffer prolonged outages, and the recovery time for spread and depth had shortened from hours to tens of minutes. In the turmoil triggered by

FTX's bankruptcy in November 2022, although market confidence was badly shaken, the liquidity metrics of the remaining major platforms largely returned to normal within 10 to 20 minutes [27]. Attributing this recovery entirely to a rise in the maturity of market structure, however, calls for caution. The FTX collapse was essentially a credit event rather than a pure liquidity event, and the rapid recovery of liquidity on other platforms stemmed in part from the migration of FTX users' funds and trading activity to surviving platforms—essentially a mechanism of liquidity redistribution rather than the market's own capacity to regenerate liquidity. Distinguishing these two recovery mechanisms is essential to any accurate assessment of market resilience: liquidity redistribution works only when some platforms are in crisis and cannot be relied upon in a market-wide systemic shock.

The improvement of resilience, however, is not without cost; it often requires a trade-off against transaction costs. To maintain higher resilience, an exchange must build a larger insurance fund, implement stricter risk controls, and may impose stricter quoting obligations on market makers. These measures inevitably raise the system's overall friction cost, which is ultimately passed on to traders. Market resilience, moreover, comprises not only the liquidity- and liquidation-level recovery capacity described above but also technical reliability at the operational level. Exchange system outages, API interruptions, DDoS attacks, and security incidents all pose direct threats to market continuity. The 2024 Bybit security incident and the repeated system overloads at centralized exchanges during periods of extreme volatility show that a platform excelling in liquidity resilience but suffering frequent failures of its technical infrastructure will see its effective resilience sharply discounted. Assessing operational resilience should incorporate metrics such as system availability, the frequency of security incidents, and the speed of disaster recovery.

The future design of perpetual futures markets therefore needs to find an optimal balance between extreme liquidity and reliable resilience, so as to ensure that the market maintains its core functions in both normal and stressed states.

25.5 Fairness

Fairness is a dimension often neglected in traditional market-quality evaluation but especially prominent in crypto markets. In traditional financial markets, fairness is usually enforced by regulators through unified rules and severe penalties, so it is treated more as a *precondition* than as a market-quality metric requiring continuous assessment. In perpetual futures markets, however, the absence of a unified global regulatory framework and the fundamental architectural differences between centralized exchanges and decentralized protocols make fairness a highly variable core variable that directly affects participant welfare.

Fairness in perpetual futures markets is not a purely moral question but a profound question of market efficiency. When market rules are not applied equally, or when certain participants obtain systematic information privileges, the resulting unfairness translates directly into transaction costs for other participants. Information privileges and execution inequality amplify the advantage of informed traders, and market mak-

ers, to compensate for the risk of being adversely selected, inevitably widen the bid-ask spread or reduce liquidity supply. Ultimately, this unfairness—produced by institutional design or technical architecture—harms the welfare of all uninformed traders and lowers the overall quality of the market.

25.5.1 A multilayered structure

Market fairness is not a single-dimensional concept but is composed of several interwoven layers. To assess the fairness of perpetual futures markets systematically, we decompose it into three core layers: execution fairness, information fairness, and institutional fairness. These three layers correspond, respectively, to the unequal treatment a trader may encounter in *how they trade*, *on what information they trade*, and *under what rules they trade*.

Figure 25-6 presents the nested relationship among the three layers of execution fairness, information fairness, and institutional fairness, and their transmission paths to market-quality metrics; the three layers rise from the most micro-level execution quality up to the institutional layer that defines the boundaries of the rules of the game. The figure also shows how different architectures perform differently: centralized exchanges face greater challenges at the execution- and information-fairness layers (arising from market-maker privileges and colocation advantages) but can repair them at the institutional layer through internal governance; decentralized exchanges perform excellently at the institutional layer (with rules hardcoded into smart contracts) yet face a novel unfairness threat in maximal extractable value (MEV), which has the dual properties of both information and execution.

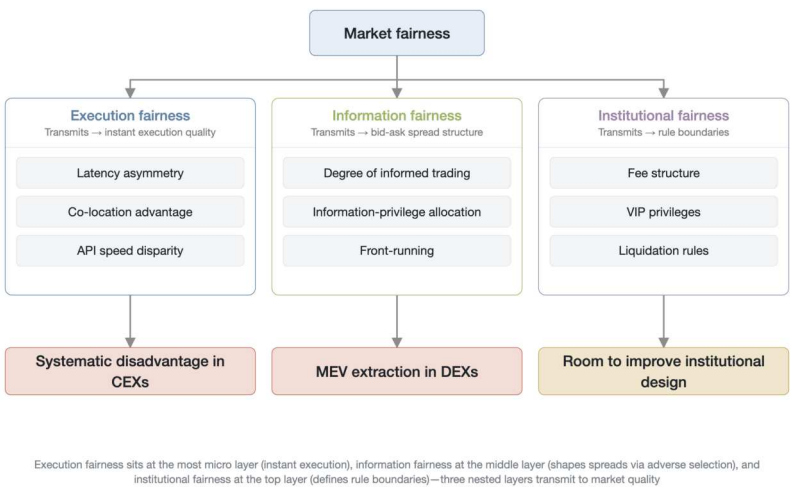

Figure 25-6. The multilayered structure of fairness and its market-impact pathways (author's integrated conceptual illustration, not measured data; theoretical basis: Angel & McCabe, 2013 [28]; Lin et al., 2019 [29])

Execution fairness concerns differences among participants in the speed of order submission and processing. When certain participants obtain a systematic speed advantage through technical means or special channels provided by the exchange, execution fairness is undermined, and the orders of ordinary traders always lag behind those of

high-frequency traders (the mechanism is elaborated in Section 25.5.2).

Information fairness concerns the distribution of market data and order-flow information. In an ideal market, all public information should be available to all participants simultaneously. In real perpetual futures markets, however, the degree of informed trading and the distribution of information privileges vary significantly. Market makers or high-frequency trading firms are often able to obtain deeper order-book data or faster market-data feeds. The classic model of Glosten and Milgrom (1985) shows that, under information asymmetry, a market maker's bid-ask spread is a rational compensation for adverse-selection risk [30]. When information privileges are monopolized by a tiny number of participants, this asymmetry forces other liquidity providers to widen their spreads, raising transaction costs across the whole market.

Institutional fairness is the highest layer of fairness, concerning how equitably an exchange or protocol makes and enforces its rules, and it is also the most destructive source of unfairness—it not only distorts price discovery but can also give rise to conflicts of interest and even a collapse of market trust (the mechanism is elaborated in Section 25.5.3).

25.5.2 Execution fairness

Unfairness at the execution level stems mainly from high-frequency traders' speed advantage in order processing and information acquisition. In perpetual futures markets, price discovery and liquidity supply depend heavily on market makers' continuous quoting. This microstructure, however, also creates room for rent-seeking by participants with ultra-low-latency connections. Angel and McCabe (2013), in examining market fairness in the age of high-frequency trading, note that although high-frequency trading can improve market liquidity in some cases, the microsecond-level speed advantage it relies on essentially constitutes an implicit cost levied on other, slower participants [28].

On centralized exchanges, this execution unfairness typically manifests as differences in physical location and API access. Well-funded trading firms can use server-colocation services to place their trading servers in the same data center as, and as close as possible to, the exchange's matching engine. This shortened physical distance lets them receive price updates earlier than ordinary traders and send orders faster. Exchanges, moreover, often provide dedicated API channels to top market makers, further amplifying this latency asymmetry. When new market information arrives, firms with the speed advantage can cancel stale quotes or establish new positions ahead of ordinary traders; this *front-running* behavior often leaves ordinary traders facing wider slippage or rejected orders.

Beyond a pure speed advantage, market makers also frequently obtain information privileges. On many centralized perpetual futures exchanges, market makers can obtain order-flow information through specific data-sharing agreements that ordinary users cannot see. This privileged data access lets them predict short-term price movements more accurately. Although exchanges typically argue that they provide this data to help market makers manage risk and thus quote more tightly, in practice it creates an unfair information hierarchy. Informed traders use this privileged information to earn excess profits in the market, and those profits are ultimately paid by uninformed

traders (mainly retail) through wider effective spreads and higher slippage.

Under extreme conditions, execution-level unfairness gives rise to more serious problems. When the market swings violently and many positions face liquidation risk, firms that obtain liquidation information in advance and execute faster can establish positions near the liquidation price ahead of time and thus profit when the liquidation cascade unfolds. This behavior not only intensifies the market's excess volatility but also causes those being liquidated to suffer additional losses far exceeding their margin shortfall.

25.5.3 Institutional fairness

Unfairness at the institutional level stems from the deliberate favoritism of those who make the rules. In centralized perpetual futures markets, the exchange is not only the provider of the trading venue but often also the rule-maker, the referee, and even a participant. This multiplicity of roles creates severe conflicts of interest and gives rise to opaque market-maker agreements and extreme institutional favoritism.

The opacity of market-maker agreements is a typical expression of institutional unfairness. To attract liquidity, exchanges generally implement a maker-taker fee structure. Malinova and Park (2015) show that this fee structure can indeed significantly affect market quality and traders' behavioral choices [31]. In crypto markets, however, these agreements are often not disclosed. Top market makers can obtain not only a full rebate of maker fees but even additional cash subsidies or token rewards. These *VIP privileges* let large market makers trade at costs far below those of ordinary participants, giving them a decisive advantage in strategic competition. Although this price discrimination helps sustain nominal liquidity to some degree, it essentially constitutes an asymmetric cost burden on small and medium traders.

A more severe form of institutional unfairness arises from an exchange's proprietary market making and related-party trading. When an exchange operates its own market-making team or is closely tied by interest to a particular hedge fund, fairness is fundamentally compromised. The collapse of the FTX exchange in 2022 offers an extreme case of institutional unfairness. According to the complaint filed by the Commodity Futures Trading Commission (CFTC), FTX's affiliated hedge fund, Alameda Research, not only obtained special trading priority as the platform's principal market maker but also received a systematic exemption from risk controls at the code level [32].

In the FTX case, Alameda was able to bypass the automatic liquidation mechanism and continue trading even when its account balance was negative. This privilege let Alameda draw without limit on other customers' funds for high-risk speculation. Alameda also had faster API access than other institutional clients, letting it stay ahead of the market at the millisecond level [33]. This extreme institutional favoritism was not only unfair to all other traders but also fundamentally undermined the basis of trust in the exchange as a neutral matching engine. When the rule-maker can modify system parameters at will for particular participants, so-called market efficiency and price discovery degenerate into a channel through which internal stakeholders siphon off outside funds.

25.5.4 The fairness of DEXs

In response to the execution and institutional unfairness prevalent on centralized exchanges, decentralized exchanges offer an alternative built on blockchain architecture. One of the core value propositions of a DEX is to fundamentally eliminate human rule-favoritism and secret agreements through the properties of code-is-law and permissionlessness. Under this architecture, the fairness problem shifts from a *game between people and institutions* to a *game between people and code*.

DEXs enjoy a significant structural advantage in institutional fairness. In protocols based on automated market makers or on-chain central limit order books (CLOBs), all trading rules, fee structures, and liquidation parameters are hardcoded into open-source smart contracts. There are no opaque market-maker agreements, no hidden VIP channels, and no risk exemptions for an exchange's proprietary team. All participants—whether an institution with hundreds of millions of dollars in capital or a retail trader with only a few hundred dollars—must follow exactly the same execution logic. This on-chain transparency ensures the absolutely equal application of the rules. McMenamin et al. (2022) note that decentralized architectures have the potential to significantly reduce the value extraction of traditional markets through innovative protocol designs such as frequent batch auctions [34]. Yet *hardcoding* is not absolutely immutable: most DEX protocols adopt an upgradeable-contract model in which core parameters can be adjusted through governance votes or a multisignature wallet, and in practice governance power is often concentrated in the hands of a few large token holders. More critically, the sequencers of today's leading app-chain perpetual futures platforms (Hyperliquid, dYdX v4) are all run centrally by a single entity, which means that the sequencer operator theoretically holds trade-ordering power similar to that of a centralized exchange, including the ability to reorder transactions or selectively censor them. These factors show that although the DEX advantage in institutional fairness is real in terms of rule transparency, it still rests on trust assumptions—regarding how far power is actually dispersed—that are not fully consistent with its decentralization narrative.

The transparency and openness of DEXs, however, also introduce a new type of fairness challenge, the most prominent being the problem of maximal extractable value. In a blockchain network, because all pending transactions are publicly exposed in the mempool and block builders hold the power to decide the order in which transactions are packed, an unfairness arises that has the dual properties of both information and execution. Daian et al. (2019) describe in detail the phenomena of front-running and transaction reordering on DEXs, noting that these cause instability at the consensus level and directly harm the interests of ordinary traders [35].

On perpetual futures DEXs, MEV typically takes the form of a sandwich attack. When a searcher observes in the mempool a large order likely to cause significant price slippage, the searcher pays a higher priority fee to submit a same-direction trade ahead of that order, pushing the price up, and then immediately closes in the opposite direction for a profit once the order executes. This attack forces the victim to fill at a worse price. According to Uniswap's analysis, although this value extraction is a byproduct of blockchain transparency, it is essentially a hidden tax levied on ordinary users by exploiting the power to order transactions [36].

Beyond MEV attacks, liquidity providers on decentralized exchanges face a more insidious structural loss. The loss-versus-rebalancing framework proposed by Milionis et al. (2022) reveals a fundamental fairness defect in automated market makers: when the price on a centralized exchange updates first, informed arbitrageurs can execute trades against the stale quotes on a decentralized exchange, systematically extracting value from liquidity providers [37]. The existence of loss-versus-rebalancing (LVR) shows that even in a decentralized architecture that has eliminated institutional privileges, information asymmetry still imposes a hidden tax on liquidity providers through the channel of cross-market arbitrage—a fairness problem distinct from the market-maker privileges of centralized exchanges but no less deserving of attention.

Fairness on DEXs is further constrained by technical capability and capital scale. Although the rules are equal for everyone, the technically adept who can write complex smart contracts to arbitrage clearly hold an enormous advantage over ordinary users who can only trade manually through a web front end. At the same time, in protocols based on token governance, well-capitalized large holders can change protocol parameters by voting, achieving rule changes that serve their own interests. Thus, although DEXs eliminate the privileges of centralized institutions, they do not achieve absolute fairness; rather, they redefine the sources of advantage under transparent rules.

25.6 Accessibility

Accessibility measures the extent to which a market allows a broad range of participants to enter trading across the geographic, capital, and technical dimensions. In traditional financial markets, eligibility to participate is set in advance by regulatory rules, and the barrier to entry is treated as an exogenous institutional constraint rather than an endogenous variable of market quality. In crypto perpetual futures markets, however, permissionless decentralized architectures coexist with centralized platforms that impose strict identity screening, making accessibility a core quality dimension that directly determines the diversity of participants and the depth of liquidity pools. A market that performs excellently on transaction costs and price discovery but sets high barriers to entry for most potential participants will see its overall quality sharply discounted by the narrowness of its liquidity base.

25.6.1 Definition and measurement framework

Accessibility can be decomposed into three interrelated sub-dimensions. Geographic accessibility measures how open the market is to users in different jurisdictions, including regional bans, tiered Know Your Customer (KYC) screening regimes, and the coverage of fiat on- and off-ramp channels. Capital accessibility concerns the screening effect that minimum deposit thresholds, VIP volume tiers, and margin requirements have on participants of different capital sizes. Technical accessibility assesses the operational complexity users face in wallet setup, gas-fee payment, smart-contract interaction, and cross-chain bridging.

To quantify these three sub-dimensions, the following operational indicators can be constructed: a geographic coverage index (the share of the global active crypto market

represented by the jurisdictions a platform can serve), minimum viable capital (the smallest amount of funds needed to open and maintain a meaningful position on a given platform), and a technical-barrier score (the number of steps and the level of technical knowledge required from wallet creation to completing a first trade) [38][39]. These indicators turn accessibility from a qualitative concept into a quantifiable dimension of market quality.

25.6.2 The entry barriers of CEXs

Centralized exchanges construct an implicit hierarchy of access through a tiered identity-verification system. At the most basic level, KYC screening excludes users who cannot provide valid proof of identity. Geographically, U.S. residents are excluded from the vast majority of offshore perpetual futures platforms, while users in several Asian and African countries face partial or complete service restrictions [38][40]. At the capital level, the VIP tier system constitutes structural discrimination against retail traders: as noted in Section 25.2.1, the $100 million monthly-volume threshold required to reach Binance's VIP 3 tier makes competitive fees structurally unattainable for the vast majority of retail users [10].

Users in developing economies face even harsher friction in fiat on- and off-ramps. The lack of bank-transfer channels, the high fees charged by payment processors, and the exchange-rate losses on local-currency conversion make the real cost of entering the crypto derivatives market from fiat far exceed explicit trading fees [41]. This friction not only limits individual participants' market access but also systematically weakens the ability of particular geographic regions to contribute to the global price-discovery process.

25.6.3 The permissionless access and technical barriers of DEXs

One of the core value propositions of decentralized exchanges is permissionless access: any user holding a digital wallet can participate in trading without identity verification [8][42]. This architecture fundamentally eliminates the geographic restrictions and identity-screening barriers of centralized platforms, achieving the greatest possible openness at the institutional level. Technical barriers, however, largely replace institutional barriers as the main constraint on the accessibility of decentralized markets.

Wallet management, the secure storage of seed phrases, gas-fee optimization, smart-contract risk assessment, and cross-chain asset bridging form a series of operational steps of considerable complexity for non-technical users. Smart-contract security risk deserves particular attention: in interacting with a DEX, non-technical users face not only operational complexity but also the security risk that carelessly authorizing a malicious contract can lead to the theft of their assets. This security barrier partly offsets the permissionless-access advantage of DEXs in practice. On the Ethereum mainnet, gas fees during periods of network congestion can make small trades economically unviable, creating a de facto minimum trade-size threshold. The rise of app-chain architectures exemplified by Hyperliquid and dYdX v4 has significantly eased this technical barrier by migrating trade execution to a dedicated chain and drastically lowering trading fees [43]. While lowering trading fees, however, app-chains also introduce a new barrier:

cross-chain asset bridging. Users must bridge assets from the Ethereum mainnet or another chain to the app-chain, a process that involves trust assumptions about the bridge's security, a wait of several minutes to tens of minutes, and additional bridging fees. For non-technical users, the cognitive complexity and security risk of bridging may be higher than gas-fee optimization itself. Account abstraction and mobile-first interface design have further reduced the complexity of wallet management, so that the user experience of decentralized markets is gradually converging toward that of centralized platforms.

25.6.4 The feedback loop between accessibility and market quality

Accessibility is not an isolated dimension of market quality but forms a deep feedback loop with the other dimensions through the intermediate variable of participant diversity. Broader access means a more diverse body of participants—with different risk preferences, different information sets, and different trading time zones—converging in the same market, which deepens liquidity pools, improves price-discovery efficiency, and strengthens the market's resilience to local shocks. Restricted access, by contrast, concentrates participation among professional institutions; while this may raise execution efficiency in the short run, it also leaves the market overly dependent on a few homogeneous actors for liquidity supply and risk-bearing, so that it proves more fragile in periods of stress.

The marked climb in DEX trading volume during regulatory crackdowns on centralized exchanges provides natural-experiment evidence of accessibility's effect on market quality. When a particular jurisdiction restricts users' access to centralized platforms, trading activity migrates rapidly to permissionless decentralized protocols, revealing participants' strong preference for accessibility [44]. This migration pattern shows that the accessibility constraint is not merely a question of welfare distribution but a structural force shaping the global allocation of liquidity. Section 25.8.1 further examines the regulatory dilemma between consumer protection and market accessibility.

25.6.5 Cross-platform comparison and evolution

On the accessibility dimension, centralized and decentralized exchanges present a complementary pattern of strengths and weaknesses. Through smooth user interfaces, well-developed fiat channels, and professional customer service, centralized exchanges greatly lower the technical barrier, letting users without a technical background participate in trading with ease. Their geographic coverage, however, is strictly limited by regulatory-compliance requirements, and the tiered KYC system, while protecting investors, also constitutes an institutional constraint on global participation. Decentralized exchanges, by contrast, have a structural advantage in geographic accessibility—their permissionless architecture means any internet user can participate—but their higher technical complexity forms a de facto entry barrier at the level of user experience.

These two architectures are undergoing marked convergent evolution. Centralized exchanges have begun to introduce on-chain settlement and non-custodial wallet options, seeking to grant users greater autonomy over their assets within a compliance frame-

work. Decentralized exchanges, through technical innovations such as account abstraction, social login, and mobile-native applications, keep lowering the technical barrier [43][45]. This bidirectional convergence shows that market competition is driving an overall improvement in the accessibility dimension. The focus of future competition will shift from *whether access is possible* to *at what cost access is possible*—that is, how to minimize the combined friction that users face across the geographic, capital, and technical sub-dimensions while maintaining broad access [41].

25.7 Integrated assessment

A single-dimensional market-quality metric is inevitably one-sided. As noted earlier, an extremely narrow bid-ask spread or extremely high informational efficiency alone cannot establish that a market possesses high overall quality. Only by integrating the five dimensions of transaction costs, price discovery, resilience, fairness, and accessibility into a composite index can we capture the full picture of market quality. This integration, however, itself faces the fundamental challenges of weight selection and trade-offs among dimensions. This section sets out in detail the methodology for constructing a five-dimensional market-quality index and applies it to comparative analysis across platforms and across architectures.

25.7.1 Construction methodology

The core objective of the five-dimensional market-quality index is to convert microstructure indicators of different units and properties into comparable, standardized scores. This process requires establishing a unified measurement benchmark while preserving the independent characteristics of each dimension.

Construction of the index begins with the standardization of base indicators. The transaction-cost dimension relies chiefly on the reciprocal of the effective spread and market-impact cost; the price-discovery dimension uses the Hasbrouck information share or the variance-ratio-test score; the resilience dimension is quantified as the spread-recovery half-life and depth-recovery rate after a liquidity shock; the fairness dimension is based on inverse indicators of market-maker-agreement transparency and the probability of informed trading; and the accessibility dimension jointly assesses the minimum capital threshold and the degree of global access (see Section 25.6). These base indicators are mapped onto a 0-to-100 score range through min-max normalization, turning originally incommensurable physical quantities into quality scores on a common scale [7]. Min-max normalization is highly sensitive to extreme values, and extreme values occur frequently in crypto markets—the bid-ask spread of a given altcoin, for example, may suddenly spike to several hundred basis points during a liquidity crisis. In practice, one can use quantile normalization or winsorize extreme values to enhance robustness. Moreover, the choice of reference sample for normalization (whether to benchmark against all assets or only against major assets) fundamentally changes the score ranking of the platforms, so the reference scope must be stated explicitly in any specific application.

Once standardization is complete, computing the composite index confronts the core

difficulty of weight selection. An equal-weighting scheme assumes that the five dimensions contribute identically to overall market quality; this treatment is mathematically simpler but often lacks solid theoretical support in economic terms. A functional-weighting scheme, by contrast, has greater explanatory power. For a high-frequency arbitrageur, for example, the transaction-cost and price-discovery dimensions carry far greater weight than the others, whereas for a long-term institutional investor or a regulator, the resilience and fairness dimensions dominate. The practical application of the five-dimensional index therefore does not pursue a single universal total score but emphasizes a weighted result under a specific evaluation objective.

Although the five-dimensional model offers a more comprehensive evaluative perspective, its limitations must not be ignored. The incommensurability of the dimensions means that a higher score on one dimension cannot fully compensate for a lower score on another. The score gain from lowering transaction costs through extreme leverage, for example, cannot offset the collapse in the resilience score caused by the resulting liquidation cascade. This nonlinear relationship requires that, in applying the five-dimensional index, we not look at the weighted total alone but examine the distribution of scores across dimensions and the trade-offs inherent among them.

25.7.2 A cross-sectional comparison of CEXs

Figure 25-7 uses a heatmap to compare the quality scores of Binance, OKX, Bybit, and the decentralized exemplar Hyperliquid across the five dimensions of transaction costs, price discovery, resilience, fairness, and accessibility. The figure exhibits a striking diagonal pattern of divergence: centralized exchanges lead on the efficiency-oriented dimensions, whereas the decentralized exchange shows an advantage on the fairness and accessibility dimensions.

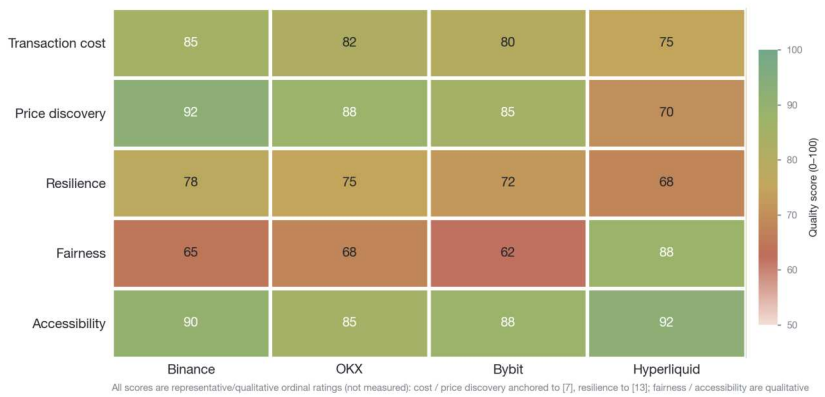

Figure 25-7. Heatmap of five-dimensional market-quality scores for major exchanges (the scores on all five dimensions are representative/qualitative ordinal ratings, not precise direct measurements; the transaction-cost and price-discovery scores are based on the methodology of Barbon and Ranaldo [7], the resilience score is estimated from platforms' publicly disclosed insurance-fund data and spread-recovery speed [13], the fairness score is a qualitative rating based on market-maker-agreement transparency and API-access tiering, and the accessibility score is based on geographic access restrictions and the minimum capital threshold)

On the two *efficiency-oriented dimensions* of transaction costs and price discovery, Binance shows a marked lead. Its deep order-book liquidity and vast trading-volume base keep the bid-ask spread at an extremely low level over the long run while it also dominates the price-discovery process. OKX and Bybit follow close behind on these dimensions, and the gap among the three leading platforms is gradually narrowing, reflecting a homogenization trend driven by market-maker competition and infrastructure upgrades [46].

On the *institutional-safeguard dimensions*, however, the platforms perform with different characteristics. On resilience, leading centralized exchanges, backed by large insurance funds and mature liquidation engines, can restore liquidity relatively quickly when facing medium-sized market shocks. On the fairness dimension, however, centralized exchanges generally score low. This stems mainly from the opacity of their market-maker agreements and the execution privileges enjoyed by VIP clients. Although this institutional design effectively lowers overall transaction costs, it inevitably harms the relative fairness experienced by ordinary traders.

25.7.3 A comparison of CEXs and DEXs

Centralized and decentralized exchanges represent two sharply different paradigms of market architecture, and this underlying architectural difference profoundly shapes their quality characteristics within the five-dimensional model.

Decentralized exchanges hold a structural, absolute advantage in fairness and transparency. On platforms exemplified by Hyperliquid or dYdX, the core logic rests on the enforced execution of on-chain rules. All liquidation parameters, fee structures, and order-matching logic are fully public to every participant, thoroughly eliminating the private market-maker agreements and information privileges prevalent on centralized exchanges [42]. The permissionless nature of the decentralized architecture, moreover, gives it an equally strong performance on the accessibility dimension: any user with a digital wallet can participate in the market without hindrance.

This advantage in fairness and accessibility, however, comes at the expense of some transaction cost and resilience. Decentralized exchanges can often offer competitive execution costs for large trades [7] but still face a cost disadvantage for small trades. For AMM-type decentralized exchanges on the Ethereum mainnet, the fixed gas fee is the main reason small trades are too costly; for app-chain-architecture perpetual futures platforms (such as Hyperliquid and dYdX v4), trades themselves incur no gas fee, and the cost disadvantage for small trades comes mainly from the larger price impact caused by relatively limited liquidity depth rather than from a fixed fee. More critical is the resilience dimension: decentralized platforms face a greater risk of liquidity exhaustion under extreme market stress. When the market swings violently, a decentralized liquidity pool that lacks the backstop of centralized market makers may dry up rapidly, causing the spread to widen sharply and the price-discovery function to stall briefly. This shows that CEXs and DEXs are not simple substitutes in market quality but are highly complementary.

25.7.4 Dynamic evolution

Market quality is not static cross-sectional data but a dynamic process that evolves continually over time. Looking back over the development from 2019 to 2025, the perpetual futures market shows a significant but uneven trajectory of improvement across its dimensions.

Over the past 6 years, the transaction-cost and price-discovery dimensions have improved the fastest. With the full-scale entry of high-frequency trading firms and upgrades in matching-engine technology, the bid-ask spread on major assets has fallen by nearly an order of magnitude [47]. At the same time, the information share of perpetual futures in price discovery has risen steadily, transforming them from an early spot follower into the primary pricing venue. This rapid improvement in the *efficiency-oriented dimensions* is due chiefly to the direct drive of fierce commercial competition and technical innovation.

By contrast, the two *institutional-safeguard dimensions* of resilience and fairness have improved at a relatively slow pace. Although the major platforms have progressively refined their liquidation mechanisms and expanded their insurance funds, momentary liquidity vacuums and liquidation cascades continued to occur frequently during the repeated extreme market shocks of 2022 and 2025 [48]. This shows that technical upgrades alone cannot fundamentally resolve the endogenous fragility produced by high leverage and procyclical mechanisms. Progress on fairness has been equally slow, with market-maker privileges and information asymmetry remaining persistent problems in the market microstructure. The future direction of market-quality improvement will necessarily require a shift from purely technical efficiency competition toward deeper optimization of institutional design and architectural innovation.

25.8 Regulatory implications

Measuring market quality is not merely an academic description of the trading environment but a scientific basis for making regulatory policy. The regulatory frameworks of traditional financial markets are largely built on intervening in specific market-quality defects—for example, improving price-discovery efficiency by requiring disclosure, or strengthening system resilience through capital-adequacy requirements. Transposing this regulatory logic to perpetual futures markets, however, confronts regulators with entirely new challenges. The decentralized character, cross-border nature, and around-the-clock trading of the crypto derivatives market often cause interventions to deviate from their intended effect. More importantly, regulatory intervention itself reshapes the market microstructure, so that resolving a quality problem on one dimension may trigger a deterioration on others. Understanding how each dimension of market quality maps onto regulatory objectives, and the effects of regulatory arbitrage across jurisdictions, is therefore a prerequisite for finding a reasonable balance among efficiency, fairness, and stability.

25.8.1 The correspondence with regulatory objectives

The five dimensions of market quality are not isolated academic metrics; they correspond directly to the core policy objectives of financial regulation. A regulator's intervention in the market is, in essence, a correction and reinforcement of one or more of these dimensions. Figure 25-8 presents, in matrix form, the mapping between the five dimensions of market quality and the main regulatory objectives, and marks the direct strength of each regulatory tool's effect on each dimension along with its potential negative spillovers. From this a key insight emerges: there is almost no regulatory tool that affects only a single dimension. Each intervention, while improving its target dimension, produces positive or negative spillovers onto other dimensions through complex transmission chains—and this multidimensional interconnection is precisely the core difficulty in designing regulatory policy.

Figure 25-8. The mapping between regulatory objectives and market-quality dimensions (a 5×5 qualitative mapping matrix constructed by the author based on Harris [4] and various regulatory frameworks, not direct measurement): the horizontal axis is the five quality dimensions and the vertical axis is the five categories of regulatory objective—competition policy, information regulation, macroprudential regulation, anti-manipulation, and consumer protection; the principal effects lie along the diagonal, and the off-diagonal cells are marked with plus/minus signs for positive and negative spillovers (per Section 25.8.1)

The transaction-cost dimension is directly linked to competition policy. Regulators lower explicit and implicit transaction costs through antitrust measures and by promoting market transparency. In perpetual futures markets, the intensity of competition among market makers and the fee structures of exchanges directly determine investors' transaction costs [17]. Regulatory intervention in transaction costs typically takes the form of requiring exchanges to disclose order-book data and reduce information asymmetry, thereby promoting full competition among market makers. Pushing transaction costs down excessively, however, may squeeze out marginal market makers, concentrating liquidity among a few leading institutions and thereby harming the market's overall resilience.

The price-discovery dimension corresponds to information regulation. A basic objective

of financial regulation is to ensure that market prices reflect all available information accurately and in a timely manner [4]. To this end, regulators typically require issuers to make periodic and ad hoc disclosures and crack down hard on insider trading. In perpetual futures markets, for lack of corporate fundamental information in the traditional sense, price discovery relies more on macroeconomic data, on-chain activity indicators, and the signal transmission of the funding rate. The challenge for regulators is how to define *material nonpublic information* for crypto assets and how to govern the process by which oracle quotes are generated, so as to prevent the price-discovery mechanism from being maliciously distorted.

The resilience dimension is the central concern of systemic-risk regulation. Through macroprudential tools such as capital-adequacy and liquidity-coverage ratios, regulators aim to strengthen financial institutions' ability to withstand external shocks [49]. In perpetual futures markets, for the general absence of a central clearing house's credit guarantee, resilience relies mainly on exchanges' auto-deleveraging mechanisms and insurance funds. The objective of regulatory intervention on this dimension is to prevent a single participant's default from evolving into a systemic liquidation cascade. Requiring exchanges to maintain adequate insurance-fund reserves and to stress-test their risk-management models is a key regulatory means of enhancing market resilience.

The fairness dimension points directly to anti-market-manipulation regulation. A fair market environment requires all participants to enjoy equal opportunity in trade execution and information acquisition. In the crypto derivatives market, latency arbitrage, front-running, and exchanges' VIP privileges for particular market makers constitute the main threats to fairness [50]. Regulators safeguard market fairness by prohibiting specific trading behaviors and requiring exchanges to allocate order flow fairly. Strict fairness regulation, however, may dampen market makers' willingness to provide liquidity, thereby pushing transaction costs up to some degree.

The accessibility dimension is closely tied to consumer protection and access regulation. As analyzed in Section 25.6, regulators decide who may participate in the market through customer-identification and anti-money-laundering (AML) requirements and through assessments of investor suitability [38]. The high leverage of perpetual futures markets makes them enormously attractive to retail investors but also carries a very high risk of liquidation. Regulators face a hard trade-off here: raising the barrier to entry can effectively protect investors who lack the capacity to bear risk, but it also runs counter to the *permissionless* founding ideal of crypto markets and lowers the market's overall accessibility.

25.8.2 The applicability of existing frameworks

Applying traditional securities and derivatives regulatory frameworks directly to perpetual futures markets exposes significant misfits. The traditional framework is built on centralized clearing, clear jurisdictional boundaries, and a standardized product life cycle—assumptions that often do not hold in crypto markets.

The European Union's Markets in Financial Instruments Directive II (MiFID II) is one of the most comprehensive financial-market regulatory frameworks in the world. Under the directive, crypto derivatives may be classified as financial instruments and thus

become subject to complex reporting, transparency, and best-execution requirements [51]. Yet MiFID II was not designed with the features of perpetual futures—no expiry date and a continuous funding rate—in mind. Its pre-trade and post-trade transparency requirements, when applied to the high-frequency, volatile crypto market, may have unintended negative effects on market makers' quoting strategies. MiFID II also relies on clear clearing and settlement infrastructure, which fundamentally conflicts with the logic of many decentralized exchanges that execute automatically through smart contracts. The European Union's Markets in Crypto-Assets Regulation (MiCA), which formally took effect in December 2024, explicitly excludes crypto derivatives from its direct scope, pushing them back under MiFID II for regulation. This classification decision creates a significant regulatory gap: perpetual futures, the most innovative and also the most risky of crypto derivatives, in practice remain subject to a traditional framework that was not designed for them.

The U.S. Regulation National Market System (Reg NMS) aims to enhance the overall efficiency and fairness of the equity market through unified market-data distribution and order-protection rules [52]. Its core order-protection rule requires exchanges to execute orders at the best price available marketwide. Introducing this principle into perpetual futures markets could, in theory, resolve the spread problems caused by liquidity fragmentation. The reality of crypto markets, however, is that exchanges lack a unified clearing system and interoperability protocols, so best execution across platforms faces extremely high technical and fund-transfer costs. Mandating a Reg NMS-like rule would not only be technically difficult to implement but could also trigger severe execution delays that instead harm market quality.

The distinctive features of perpetual futures markets leave large gaps in the traditional regulatory framework. The first is the absence of a regulatory subject under a decentralized architecture. When a trading protocol runs on immutable smart contracts with no clear centralized operating entity, the traditional model of regulation based on institutional licensing becomes difficult to apply. The second is jurisdictional conflict arising from cross-border liquidity. Crypto assets can be transferred worldwide in an instant, so a single jurisdiction's regulatory ban can often only push trading activity toward more lenient jurisdictions rather than eliminate the risk at its root. The third is the new type of risk introduced by the funding-rate mechanism. Traditional regulation lacks tools for assessing this continuous leverage cost and struggles to effectively measure the hidden exploitation it inflicts on investors under extreme conditions.

25.8.3 The design of regulatory tools

Given the limitations of the traditional regulatory framework, regulators need to design more targeted, dynamic tools—tools that anchor directly to specific market-quality indicators rather than relying solely on static compliance checks.

A liquidity-based leverage cap is an important tool for regulating market resilience. Margin requirements in traditional derivatives markets are typically static or adjusted only periodically according to historical volatility. In perpetual futures markets, there is a tight nonlinear relationship between the leverage ratio and liquidity depth [53]. When market depth is insufficient to absorb large-scale liquidation orders, high lever-

age readily triggers a liquidation cascade. Regulators could therefore require exchanges to implement a dynamic leverage cap based on real-time order-book depth: permitting higher leverage in the liquidity-rich normal state to lower transaction costs, and automatically lowering the maximum permitted leverage in a liquidity-exhausted stressed state, thereby enhancing the market's shock-absorbing capacity without entirely sacrificing capital efficiency.

A resilience-based insurance-fund requirement is another key mechanism for guarding against systemic risk. At present, the size of most exchanges' insurance funds is determined by their internal models, without transparency or external oversight. Regulators could introduce a mechanism similar to stress testing in traditional banking, requiring an exchange's insurance fund to be large enough to cover an extreme price shock at a specified confidence level [54]. Such a requirement directly enhances the market's institutional resilience, ensuring that in a black-swan event the profits of winning traders are not subject to a forced clawback because of a counterparty's shortfall.

Market-quality-based regulatory intervention, however, must be wary of unintended consequences. When a jurisdiction imposes strict leverage limits or high capital requirements, the most immediate market reaction is often liquidity migration. Market makers and high-frequency traders quickly move their funds and trading volume to more lightly regulated offshore platforms. This loss of liquidity widens spreads and raises impact costs in the regulated market, ultimately putting it at a disadvantage on the transaction-cost and price-discovery dimensions. The design of regulatory tools must therefore strike a delicate balance between enhancing market safety and preserving market competitiveness.

25.8.4 Regulatory arbitrage and international coordination

The global connectivity of the crypto derivatives market and the fragmentation of national regulatory policies have together given rise to widespread regulatory arbitrage, with a significant effect on global market quality.

Different jurisdictions display sharply different attitudes toward regulating perpetual futures, and those attitudes are themselves evolving rapidly [40]. The U.S. regulatory stance has shifted from aggressive enforcement to cautious openness: between 2022 and 2024, the SEC and CFTC filed suits against numerous crypto exchanges, treated most crypto assets as securities, and cracked down hard on unregistered derivatives platforms; but after a new administration took office in early 2025, the SEC withdrew its suits against some exchanges, and the CFTC began exploring a more inclusive framework for regulating derivatives. This policy shift may significantly improve the accessibility dimension of the U.S. market, but its long-term effect on resilience and fairness remains to be seen. The European Union, for its part, has sought to establish a unified compliance framework through the Markets in Crypto-Assets Regulation, though ambiguity remains in the classification of derivatives. By contrast, some offshore financial centers in Asia and the Caribbean have adopted a more lenient regulatory stance, attracting the registration of many crypto-native exchanges. The direct consequence of these regulatory differences is that global perpetual futures liquidity is highly concentrated on a few offshore platforms.

The effect of regulatory arbitrage on market quality is two-sided. On one hand, it gives participants a channel to escape stringent regulation, letting the perpetual futures market achieve very high accessibility and low transaction costs at low compliance cost. On the other, it severely harms the market's overall fairness and resilience. Offshore platforms often lack rigorous investor-protection mechanisms and transparent market-maker rules, exposing retail investors on these platforms to very high risks of manipulation and systemic collapse. When a crisis strikes an offshore platform, moreover, the absence of a lender of last resort and clear bankruptcy-resolution procedures allows its negative effects to spread rapidly to global markets through the price-transmission mechanism.

International coordination is the fundamental route to resolving regulatory arbitrage, but it faces enormous limits in practice. Although international bodies such as the Financial Stability Board and the International Organization of Securities Commissions have issued high-level recommendations on crypto-asset regulation, a binding, globally unified regulatory framework remains out of reach, owing to fundamental disagreements among countries over financial sovereignty, tolerance for innovation, and philosophies of investor protection [55]. Absent global coordination, a single country's stringent regulation can often only cost its own investors the opportunity to participate in global pricing, without truly eliminating the structural risks inherent in crypto markets. Future regulatory evolution may therefore rely more on bilateral agreements among major economies and on coordinated control over the fiat on- and off-ramp channels for key fiat currencies.

25.9 Technological change and institutional evolution

The evolutionary trajectory of market quality is not linear growth along a single dimension but a complex process in which technical innovation and institutional regulation interact. Technical progress can significantly lower trading friction and improve the efficiency of information processing, but it does not automatically bring an all-around improvement in market quality. On the contrary, the introduction of new technology, while solving old frictions, often creates new structural fragility or fairness imbalances. Assessing the future of market quality turns on discerning whether technical change can reach the fundamental defects of the current market structure and whether institutional evolution can establish a new equilibrium between innovation and stability.

25.9.1 AI market makers

The application of artificial intelligence and machine learning at the microstructure level is reshaping the basic model of liquidity supply. Traditional algorithmic market makers rely on preset parameters and static inventory-control models, whereas AI market makers based on reinforcement learning can dynamically adjust their quoting strategies in response to high-frequency order-flow data [56]. This technical upgrade displays a marked efficiency advantage in normal markets: AI models can predict short-term price direction more accurately, thereby narrowing the bid-ask spread and lowering adverse-selection costs [57]. In inventory management, intelligent algorithms dynamically adjust their position preferences, providing deeper liquidity while maintaining a

lower rate of capital utilization, which directly improves the market's overall trading efficiency [58].

The proliferation of AI market makers, however, also introduces new systemic risk. When most liquidity providers in the market adopt similar machine-learning architectures and training datasets, the problem of strategy homogenization becomes acute. Faced with an extreme shock absent from their training data, homogeneous intelligent algorithms may produce highly correlated order cancellations or aggressive, unidirectional closing of positions [59]. This behavioral pattern drains order-book depth during periods of stress, causing liquidity to dry up in an instant and thereby amplifying local price fluctuations into a systemic liquidity crisis.

The behavioral logic of AI market makers during stress reveals an intrinsic conflict between technical efficiency and market resilience. Although intelligent algorithms can compress transaction costs to extremely low levels in calm periods, their risk-avoidance mechanisms often retreat faster in moments of crisis. This means that a liquidity environment dominated by AI may exhibit a highly fragile character: extremely smooth under normal conditions but highly prone to structural rupture in tail-risk events. Assessing the ultimate effect of AI on market quality must therefore go beyond spread metrics under normal conditions and focus on the willingness to supply liquidity under extreme conditions.

25.9.2 On-chain derivatives

Fully on-chain derivatives protocols represent decentralized finance's (DeFi) latest attempt at complex trading structures. Architectures exemplified by dYdX and Hyperliquid seek to reproduce the execution efficiency of centralized exchanges in a permissionless blockchain environment [43] (this dimension is analyzed systematically in Section 25.6). The core advantage of on-chain derivatives lies in the systematic improvement in market fairness that their transparency brings. On centralized platforms, market makers' privileged agreements and internal liquidation parameters are often hidden from ordinary participants; in an on-chain environment, by contrast, the liquidation logic, funding-rate calculation, and order-matching rules are all executed publicly by smart contracts [8]. This architecture eliminates the space for information privileges and opaque operations, placing all market participants on absolutely equal footing at the level of the rules.

Although fairness improves markedly, on-chain derivatives still face the constraints of physical law in execution efficiency and transaction costs. The consensus mechanism of a blockchain network inevitably introduces a delay in state updates, making on-chain order books less efficient than centralized matching engines at processing high-frequency information [45]. This delay not only widens market makers' adverse-selection risk but also creates room for maximal extractable value. When a trader's intent is exposed before it is packed into a block, arbitrageurs can extract rents through sandwich attacks or front-running, which in effect constitutes a hidden trading tax that erodes the price-discovery quality of on-chain markets.

Whether on-chain derivatives can compete with centralized exchanges on liquidity depth depends on whether their architecture can effectively balance decentralization against

capital efficiency. Current data indicate that although leading on-chain protocols can support the opening of positions on the order of tens of millions of dollars while maintaining reasonable price impact [60], the variability of their liquidity is significantly higher than that of centralized platforms [43]. Under extreme conditions, constrained by the throughput bottleneck of the underlying chain, the on-chain liquidation mechanism may fail because of network congestion, triggering a more severe systemic cascade. The future evolution of on-chain derivatives therefore needs to find a new design space between technical breakthroughs at the consensus level and risk isolation at the application level.

25.9.3 Cross-chain liquidity integration

The proliferation of independent blockchains has made liquidity fragmentation the most severe structural obstacle to crypto-asset market quality. The liquidity of a single asset is dispersed across many independent blockchain networks and protocols, thinning the depth of local markets, enlarging price impact, and thereby pushing up overall transaction costs [61]. This physical isolation impedes the flow of capital to the most efficient trading venues, leaving the price-discovery processes on different chains mutually independent and weakening the pricing efficiency of the global market [62].

The development of cross-chain interoperability protocols offers a technical path out of this predicament. Infrastructure exemplified by LayerZero and Chainlink CCIP establishes standardized cross-chain message-passing mechanisms that let assets and state transfer securely between networks [63]. Such liquidity integration not only lets traders access the globally best quote but also greatly reduces the friction of cross-chain arbitrage. When arbitrageurs can iron out price differences across chains with lower latency and cost, the market's overall informational efficiency improves significantly, and the price-discovery process evolves from a locally fragmented state into a globally coordinated whole [64].

Cross-chain liquidity integration, however, likewise faces serious technical and regulatory challenges. On the technical side, the security model of cross-chain bridges often becomes the weakest link in the entire system; once validator nodes are compromised or a smart contract contains a vulnerability, the integrated liquidity pool faces the risk of devastating asset loss. On the regulatory side, the flow of cross-chain assets blurs jurisdictional boundaries, making anti-money-laundering and compliance monitoring exceptionally difficult. How to build a technical firewall strong enough to withstand systemic contagion, and to meet compliance requirements, while achieving unified liquidity is an obstacle that cross-chain integration must clear on its way to maturity.

25.9.4 Long-term equilibrium

The long-term evolution of market quality can be conceptualized as a dynamic game among competition, innovation, and regulation. Competitive pressure is the most direct force driving improvements in market quality. To compete for market share and liquidity providers, exchanges continually compress fees, optimize matching engines, and offer richer product lines [65]. This commercially driven competition has produced an order-of-magnitude decline in transaction costs over the past 10 years while also

driving continual growth in order-book depth.

Technical innovation, in turn, plays the role of breaking the existing equilibrium. Whether through innovations in the mathematical models of automated market makers or through architectural breakthroughs in cross-chain protocols, innovation provides new tools for resolving old frictions. Yet innovation is often unpredictable: while raising efficiency in one respect, it may harm market fairness or introduce new fragility [66]. Regulatory pressure then becomes the necessary constraint that steers market quality toward the socially optimal direction. Through minimum-capital requirements, mandatory disclosure, and limits on conflicts of interest, the regulatory framework aims to protect participants at an information disadvantage and to guard against the accumulation of systemic risk [67].

Competition, innovation, and regulation together shape the trade-off frontier of market quality. Excessively strict regulation may suppress technical innovation and entrench the competitive advantages of existing oligopolies, impeding further declines in transaction costs; wholly unrestrained competition and innovation, on the other hand, may tilt the market toward an extreme pursuit of efficiency at the expense of fairness and stability. The future of market quality will depend on how these three forces reach a new institutional equilibrium. Only when technical innovation is steered toward resolving fundamental defects, and the regulatory framework can adapt to the features of decentralized architectures, can the perpetual futures market build the deep resilience to withstand extreme shocks while maintaining efficient price discovery.

Figure 25-9 uses a competition-innovation-regulation triangular-game framework to present how these three forces pull differentially on the five dimensions of market quality: the efficiency-oriented dimensions (transaction costs, price discovery) are pulled by the competition-innovation axis and improve rapidly, the institutional-safeguard dimensions (resilience, fairness) strengthen as they draw closer to the regulation vertex, and accessibility occupies a bridging position. The long-term evolution of market quality cannot be dominated by any single force but depends on the equilibrium position of the three forces within a specific institutional environment: when competitive and innovative pressures are too great and regulatory constraints too weak, the efficiency-oriented dimensions are pushed to an extreme and resilience and fairness may deteriorate severely; conversely, excessive regulation may lock the market into a low-efficiency but superficially stable equilibrium.

25.10 Chapter summary

Market quality is a multidimensional, dynamically evolving systemic concept. Traditional market microstructure research has tended to focus on single-dimension analysis—using the bid-ask spread as a proxy for liquidity, for example, or the information share as a measure of price discovery [3]. A single-dimension assessment, however, cannot capture the global characteristics of market structure, especially in an innovative derivatives market like perpetual futures that lacks centralized clearing and permits high leverage. The five-dimensional model constructed in this chapter (transaction costs, price discovery, resilience, fairness, and accessibility) provides a comprehensive evaluation framework that reveals the structural characteristics of the perpetual futures market across its different dimensions.

These five dimensions are not mutually independent but harbor intrinsic tensions: improvements in liquidity often come at the cost of declining resilience—the extremely narrow bid-ask spreads of high-frequency market makers lower transaction costs in normal times, but their rapid order cancellations during extreme volatility also amplify the risk of liquidity exhaustion [68]; and between fairness and efficiency, and between accessibility and fairness, there exist the same systematic trade-offs described in Section 25.1.4. These trade-offs show that no market attains the optimum on all dimensions, and constructing a composite index necessarily involves assigning weights to the different dimensions—an assignment that essentially reflects the value preferences of a particular set of market participants or regulators.

Over the past 10 years of evolution, the improvement in perpetual futures market quality has been markedly asymmetric. As analyzed in Section 25.7.4, the dimensions driven

directly by competition have improved fastest—transaction costs have fallen sharply and the leadership position in price discovery has grown ever firmer [69]—whereas dimensions that require institutional change to support them, such as resilience and fairness, have progressed slowly, and market-maker privileges and information asymmetry still leave ordinary traders at a structural disadvantage [4]. This asymmetric evolution shows that the expansion of market size and the deepening of liquidity cannot automatically eliminate structural defects; improving the institutional-safeguard dimensions must rely on deliberate institutional design and external regulatory intervention.

Assessing market quality is not only a diagnosis of the current state of the market but also an integrative framework for market microstructure research. Liquidity sets the baseline for transaction costs, arbitrage efficiency shapes the boundary of price discovery, the characteristics of volatility reflect the level of market resilience, and governance mechanisms fundamentally define the market's fairness and accessibility. The perpetual futures market's lead on the efficiency-oriented dimensions (transaction costs and price discovery) demonstrates the value of its mechanism innovation, but its persistent lag on the institutional-safeguard dimensions (resilience and fairness) exposes the systemic risk of unconstrained development. As the bridging dimension linking efficiency and institutions, accessibility shows a structural advantage in decentralized architectures but still needs continual improvement in user experience and technical barriers. Chapter 26 will approach, from the standpoint of regulatory economics, how to find the optimal balance between innovation and stability.

The Economics of Regulation Between Innovation and Stability

In the first quarter of 2024, the average weekday trading volume of Bitcoin perpetual futures (measured as a 30-day rolling average) reached $57.7 billion [1]. That figure reflects perpetual futures' roughly 90% share of the crypto-derivatives market by open interest [2], and it has made them a central concern for financial regulators worldwide. Faced with this large-scale market—one that runs around the clock, spans national borders, and has no central clearinghouse—regulators confront a severe classification dilemma. Perpetual futures represent no ownership claim over any entity and therefore fail to satisfy the core "investment contract" element of the Howey test [3], which makes them difficult to classify simply as securities. At the same time, they have no expiration date and no physical-delivery mechanism, which places them outside the definitional framework of traditional commodity futures [4] and likewise challenges the jurisdiction of the Commodity Futures Trading Commission (CFTC).

The difficulty of classification is merely a surface symptom; the deeper predicament lies in the failure of traditional regulatory tools. Historical experience has shown that a simple, blanket ban cannot eliminate market demand and only invites regulatory arbitrage. Indeed, capital flight was among the regulatory motives well before any ban: Chainalysis estimates that from mid-2019 to mid-2020, more than $50 billion in crypto-assets (of which roughly $18 billion was USDT) moved from East Asian addresses to destinations outside the region, forming an important part of the backdrop to China's comprehensive 2021 ban [5]. After the ban took effect, trading activity migrated rapidly to offshore exchanges, while domestic traders continued to participate through technical workarounds. This outcome indicates that the only substantive consequence of prohibition was to strip regulators of all visibility into the market and any capacity to intervene in it, all without reducing systemic risk. Yet the complete absence of regulation carries equally serious consequences. The November 2022 collapse of the FTX exchange exposed a shortfall of roughly $8 billion in customer funds [6], and millions of users suffered substantial asset losses. This episode demonstrates just how severe information asymmetry and agency moral hazard can become in a "free market" that lacks mandatory asset segregation and external audit.

Regulators therefore can neither force perpetual futures into an ill-fitting traditional framework, nor ignore their existence, nor retreat to a posture of laissez-faire. This predicament raises the central question of the chapter: in the specific context of the

perpetual futures market, how should regulation intervene so as to repair the market's defensive deficiencies without destroying its innovative advantages in price discovery and accessibility? Answering this question requires moving beyond a moral or political stance on whether regulation is "good" or "bad" and adopting instead the cost-benefit analytical framework of economics. Regulation is, in essence, a tool for intervening in market failure, and every specific regulatory policy—whether capping leverage, mandating disclosure, or requiring capital segregation—inevitably carries both benefits and costs.

To assess the net effect of these policy tools systematically, this chapter proposes and applies three interrelated analytical frameworks. The five-dimensional regulatory impact matrix evaluates, one by one, the specific effect of each regulatory tool on five dimensions—transaction costs, price discovery, market resilience, fairness, and accessibility—providing a microfoundation for policy comparison. Building on this, the regulatory "impossible trinity" reveals that under a globalized and decentralized technical architecture, no regulatory regime can simultaneously maximize global consistency, innovation-friendliness, and consumer protection, thereby explaining the structural roots of today's fragmented global regulation. That fragmentation, in turn, motivates a paradigm contrast between functional and entity-based regulation, which argues why traditional institution-type regulation is markedly constrained in the face of cross-boundary innovation and prone to regulatory vacuums, and why regulation organized around function and risk characteristics is the more adaptive alternative.

Building on these frameworks, the chapter proceeds to a detailed analysis of the economics of regulation. It first defines four categories of market failure in the perpetual futures market—externalities, information asymmetry, and others—to delineate the legitimate boundaries of regulatory intervention, and it constructs a net-benefit evaluation model that incorporates compliance burdens and innovation suppression. It then sets out an inventory of regulatory targets for perpetual futures, prioritizing systemic risk, market manipulation, consumer protection, and market integrity according to the severity of each risk and the market's capacity for self-repair. On this basis, it dissects the five-dimensional impact of specific regulatory tools such as leverage limits and market-maker obligations, and it examines the economic consequences of the global contest over jurisdiction. Finally, the chapter extends to the regulatory boundaries of decentralized exchanges, exploring the possibility and the technical limits of compliance-by-code. After reading this chapter, readers will be able to step outside the black-and-white debate over regulation, use structured economic tools to assess the true cost of any regulatory proposal, and clearly delineate which market deficiencies can be repaired through legal rules and which must be left to the decentralized engineering discussed in later chapters.

26.1 The legitimacy of regulation

The legitimacy of regulatory intervention rests on market failure: when the market mechanism cannot on its own reach a Pareto-optimal allocation, external intervention may improve aggregate social welfare. In the context of the crypto-derivatives market, not every market deficiency constitutes a failure that warrants regulatory interven-

tion. Some deficiencies can repair themselves through competition among protocols or through underlying technological innovation, whereas excessive regulatory intervention may not only impose high compliance costs but also trigger innovation suppression and regulatory arbitrage. Assessing the soundness of a regulatory policy is therefore, in essence, a complex cost-benefit analysis: intervention is legitimate in the economic sense only when the marginal benefit of repairing a market failure exceeds the sum of the regulatory costs.

26.1.1 Four categories of market failure

In traditional financial theory, market failure is usually grouped into four basic forms: externalities, information asymmetry, undersupply of public goods, and market power [7]. Within the distinctive microstructure of perpetual futures, these four failures display characteristics quite different from those of traditional assets.

Externalities are the most damaging form of failure in the perpetual futures market, typically manifested as the systemic risk arising from liquidation cascades. When a single trader's over-leveraged position is forcibly liquidated, the liquidation engine's dumping of assets onto the market depresses the price, which in turn triggers the liquidation of additional highly leveraged positions [8]. This positive-feedback loop harms not only the liquidated trader but also imposes the negative externality of evaporating liquidity on all market participants. As illustrated by the October 2025 liquidation cascade detailed in Section 26.2.1, this endogenous fragility constitutes the core rationale for regulatory intervention [9].

Information asymmetry is especially pronounced between centralized exchanges and retail traders. Exchanges hold complete data on order flow, liquidation parameters, and asset reserves, whereas ordinary traders are often unable to assess counterparty risk accurately. The collapse of FTX laid bare the extreme consequences of this asymmetry: management's misappropriation of customer assets went undetected by the market for a long period, ultimately producing billions of dollars in customer losses [10]. This collapse of trust, driven by informational opacity, not only destroyed a single platform but also triggered cross-market financial contagion [11].

The undersupply of public goods manifests in the perpetual futures market as a tragedy of the commons in liquidity under extreme conditions. Liquidity is, in essence, a public resource with positive externalities. In calm markets, market makers earn the bid-ask spread by supplying liquidity; but in periods of high volatility or crisis, market makers, out of their own risk-management considerations, often choose to withdraw their quotes. This individually rational risk-averse behavior produces, at the aggregate level, a collectively irrational and sharp decline in liquidity, further exacerbating price volatility and liquidation risk [12].

Market power arises from the monopolistic position of the leading exchanges. In a market where liquidity exhibits strong network effects, trading volume tends to concentrate on a few large platforms. This market concentration allows the leading exchanges to exercise unilateral pricing power when setting market-maker agreements, fee schedules, and listing standards. Moreover, some exchanges combine the dual roles of matching venue and proprietary market maker, a conflict of interest that, absent external

oversight, can readily evolve into an implicit shifting of costs onto ordinary traders.

26.1.2 The boundary of self-repair

Identifying a market failure does not mean that regulation must intervene immediately. In crypto markets, many phenomena regarded as defects are in fact improving on their own through market mechanisms. The central criterion for judging whether regulation is necessary is whether the defect has the potential to correct itself naturally through competition or technological evolution.

Competition constitutes a highly effective self-correcting mechanism. Consider transaction costs: as decentralized derivatives protocols have proliferated and competition among centralized exchanges has intensified, the all-in trading cost of perpetual futures—including explicit fees and implicit slippage—has trended steadily downward. This competition-driven efficiency gain sharply reduces the need for direct price controls on fee rates or market-maker spreads. When the market can maximize welfare on its own through competition, forcible regulatory intervention may instead distort price signals.

Technological innovation likewise performs a regulation-substituting function. Early liquidation mechanisms often used a crude, whole-position approach that readily produced severe price shocks. To attract and retain users, however, many exchanges voluntarily introduced gradual liquidation algorithms and more refined risk engines. This technologically driven improvement in resilience demonstrates that, in certain domains, code and protocol rules can constrain high-risk behavior more effectively than traditional administrative directives. In addition, the maturation of cross-market arbitrage has caused many early pricing anomalies to fade, as arbitrageurs, in pursuing profit maximization, in effect perform the function of correcting price deviations.

Regulatory resources should therefore concentrate on the structural failures that the market cannot resolve on its own. The enforcement of asset segregation and the verification of reserve transparency, for example, cannot be achieved through exchanges' self-disciplinary pledges alone; they require external audit and mandatory legal constraints [13]. Conversely, for the micro-frictions that are naturally easing as competition intensifies or technology iterates, regulatory restraint is often the superior strategy.

26.1.3 The costs of regulation

Every form of regulatory intervention carries non-negligible costs, and in the crypto-derivatives market these costs are exceedingly complex.

Direct compliance costs are the most visible price of regulation. To satisfy the anti-money laundering (AML), know-your-customer (KYC), and periodic audit requirements of different jurisdictions, exchanges must maintain large legal and compliance teams. Research indicates that the average annual federal regulatory compliance cost per employee across all U.S. industries is approximately $12,800, rising to roughly $14,700 for small firms with fewer than 50 employees [14]. In crypto markets, these high operating costs are ultimately passed on to traders through higher fees or wider bid-ask spreads, directly eroding market accessibility and operational efficiency.

Innovation-suppression costs are a hidden but far-reaching negative effect of regulation. Financial innovation is often born in the gray areas of existing regulatory frameworks. Perpetual futures were themselves invented to circumvent the liquidity fragmentation caused by traditional futures delivery. Had this product been brought under a strict traditional-derivatives regime in its infancy, its distinctive funding-rate mechanism might never have been validated and developed. Surveys of regulation-intensive industries such as finance and utilities find that compliance costs can exceed 2.5% of a firm's total payroll, while the aggregate cost of incremental social regulation is estimated at roughly 5% of U.S. GDP [15]. An excessive compliance and regulatory burden can crowd out the resources firms devote to experimentation and R&D, although the net effect of regulation on innovation remains contested in the literature.

Regulatory-arbitrage costs are especially salient in a globalized, decentralized network environment. When a given country or region imposes stringent leverage limits or entry standards, capital and trading activity migrate rapidly to more lightly regulated offshore platforms. When Japan cut the leverage cap on crypto-asset derivatives sharply from 25x to 2x in 2020, for example, it nominally protected domestic investors but in practice drove large trading volumes to overseas exchanges beyond its jurisdiction (Section 26.7.1 documents this trade-off with policy data). Such regulatory arbitrage not only fails to reduce global systemic risk at its root but also strips the strictly regulating jurisdiction of any real pricing power over, or supervisory capacity within, the market.

Moreover, transplanting rules designed for the traditional financial system directly onto crypto architecture generates enormous friction costs. The non-custodial nature of decentralized exchanges and the logic of automatic smart-contract execution conflict fundamentally with the traditional intermediary-based regulatory paradigm. Forcing decentralized protocols to discharge the obligations of a traditional broker is not only technically difficult but may also fundamentally undermine the permissionless nature of decentralized finance.

26.1.4 The net-benefit analysis framework

Building on the preceding analysis, regulatory policy must be formulated on a rigorous cost-benefit framework [16]. The net benefit of a regulatory measure can be formalized as the increase in social welfare from repairing a market failure, minus direct compliance costs, innovation-suppression costs, and the efficiency losses induced by regulatory arbitrage.

Figure 26-1 characterizes the nonlinear relationship between net benefit and regulatory intensity along two dimensions, benefit and cost: the intersection of the two curves marks the critical threshold at which net benefit turns from positive to negative, while the point of maximum vertical distance between them corresponds to the optimal regulatory intensity that maximizes net social welfare.

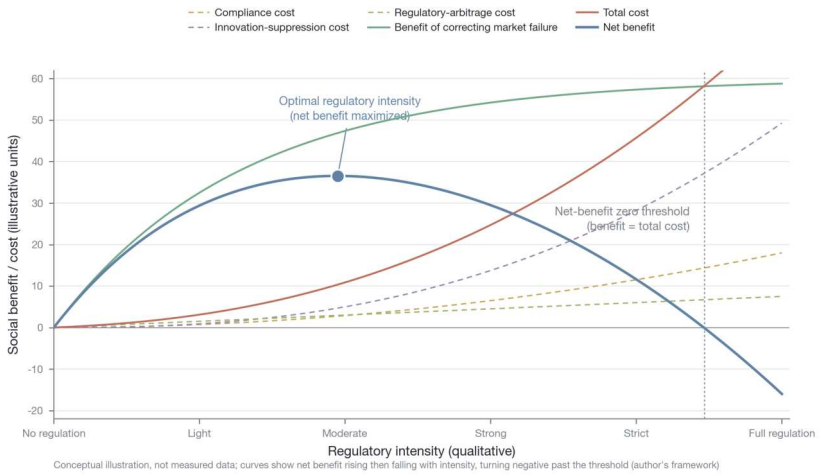

Figure 26-1. The net-benefit analysis framework for regulation

The shapes of the two curves follow from basic regulatory economics. The benefit of repairing market failure rises with regulatory intensity but exhibits pronounced diminishing marginal returns: basic early-stage regulation—such as mandatory disclosure and asset segregation—can sharply reduce systemic risk at relatively low cost. Once regulatory intensity crosses the critical point, however, further intervention such as extreme leverage limits or product bans yields negligible marginal safety benefits, even as compliance and innovation-suppression costs accelerate markedly.

Regulatory-arbitrage costs must be understood along two dimensions. Along the single-jurisdiction regulatory intensity depicted on the horizontal axis of Figure 26-1, arbitrage costs rise monotonically with intensity: the more stringently one jurisdiction regulates, and the larger the rule gap relative to other jurisdictions, the stronger the incentive for capital flight and risk transfer; hence this component is increasing in the figure. Along the dimension of global regulatory coordination, by contrast, arbitrage costs follow an inverted-U shape: under the extreme assumptions of a complete absence of regulation or a perfectly uniform global regime, there is no exploitable rule differential across jurisdictions and thus no room for arbitrage; but in the realistic state where jurisdictions each impose moderate, heterogeneous regulation, the rule differentials across jurisdictions maximize the arbitrage incentive, driving capital flight and risk transfer. This inverted-U shape is a theoretical inference: its peak depends on the degree of rule differential across jurisdictions, and it currently lacks direct empirical calibration.

Regulatory intervention is justified only when the total-benefit curve lies above the total-cost curve—that is, when net benefit is positive. The optimum in the figure indicates the regulatory intensity that maximizes net social welfare. This framework rules out two extreme policy positions: it rejects the complete laissez-faire that ignores the risks of liquidation cascades and asset misappropriation, and it equally rejects the over-regulation that ignores the value of innovation and the native characteristics of crypto. In the regulatory practice of perpetual futures, finding this optimal equilibrium requires policymakers to understand the underlying technical mechanisms thoroughly

and to weigh investor protection against the maintenance of market vitality with care.

26.2 Regulatory targets and prioritization

The scarcity of regulatory resources demands that intervention be selective. Not every deficiency in the perpetual futures market requires regulatory intervention; the core task is to identify the areas where the marginal benefit of intervention is highest and to prioritize among them. In evaluating each market failure, the market's own capacity for repair must be taken into account, because competitive mechanisms and technological evolution can often resolve some problems endogenously. Regulatory intervention is fully justified in the economic sense only when the market mechanism has entirely failed and the negative externality or information asymmetry causes a significant loss of social welfare. This section systematically reviews four potential regulatory targets in the perpetual futures market—systemic risk, market manipulation, consumer protection, and market integrity—and, based on the severity of the market failure, the market's capacity for self-repair, and the net benefit of intervention in each area, provides an operational framework for prioritization.

26.2.1 Systemic risk

Systemic risk is the most prominent source of negative externalities in the perpetual futures market, and its core mechanism is precisely the positive-feedback loop between the forced liquidation of highly leveraged positions and the evaporation of liquidity described in Section 26.1.1. This self-reinforcing liquidation cascade harms not only overleveraged users but, through liquidity evaporation and price contagion, strikes every participant in the ecosystem—including spot holders who never used leverage. The liquidation cascade of October 10–11, 2025 is an instructive case: within 36 hours, roughly $19 billion of open interest was forcibly liquidated. The event was triggered mainly by a macro-policy shock, but the structural accumulation of high leverage was the fundamental reason this shock escalated (base estimates, cross-asset contagion during the episode was roughly $20+) approached 0.90, indicating that the effect of the systemic shock was highly persistent [9].

Individual exchanges lack the economic incentive to unilaterally limit systemic risk—a classic prisoner's dilemma. In a highly competitive environment, exchanges tend to offer very high leverage to attract traders seeking high-risk returns. If one platform unilaterally lowers its leverage cap or tightens margin requirements, its market share will quickly flow to more lightly regulated competitors, whether centralized exchanges in other jurisdictions or permissionless decentralized protocols. This leverage arms race causes systemic risk to accumulate across the entire market, while no individual platform bears the full cost of the systemwide damage caused by a liquidation cascade: the negative externality of excessive leverage is externalized to the whole market, whereas its private benefits (trading fees and funding-rate revenue) are internalized by the exchange. This mismatch between costs and benefits is a clear manifestation of market failure and the fundamental reason regulatory intervention is justified.

Regulatory intervention against systemic risk carries a fairly high marginal benefit, but

the challenges of implementation are not to be underestimated. By imposing a market-wide uniform leverage cap, dynamic margin requirements, and standardized liquidation mechanisms, regulation can effectively interrupt the transmission path of the positive-feedback loop and markedly improve the market's overall resilience. Such intervention, however, also faces complex trade-offs. Strict leverage limits inevitably reduce capital efficiency, raise traders' implicit costs, and may drive high-leverage demand to unregulated offshore markets or decentralized platforms, producing a regulatory-arbitrage effect. The setting of regulatory parameters must therefore strike a delicate balance between reducing systemic risk and maintaining market liquidity, and the effectiveness of regulatory action by a single jurisdiction will be greatly diminished without international coordination.

26.2.2 Market manipulation

Market manipulation systematically undermines market fairness by distorting the price-discovery mechanism and inflating the appearance of liquidity. In the perpetual futures market, manipulation takes more varied forms than in traditional financial markets, and because of the regulatory vacuum, its execution cost is extremely low. One typical pattern is cross-market spot-perpetual manipulation: the manipulator buys the spot asset heavily during periods of concentrated liquidity, pushing up the index price on which the mark price depends and thereby triggering the forced liquidation of a large number of short positions in the contract market; the manipulator then rapidly sells in the opposite direction once the liquidations are complete, profiting from the artificially induced price swing. Empirical research shows that this manipulation pattern leaves identifiable statistical traces in data from major exchanges such as Binance: the price crashes that follow manipulative spikes produce significantly lower subsequent returns, and the position changes of top traders are highly correlated with price movements [17]. This strategy is especially frequent in the less liquid altcoin perpetual futures market, because a thin order book means the manipulator can generate a significant price deviation with relatively little capital.

Wash trading is another pervasive and far-reaching form of manipulation, designed to manufacture a false appearance of market activity through self-trading or offsetting trades between affiliated accounts. A systematic empirical analysis of 29 cryptocurrency exchanges found that wash trading accounts, on average, for more than 70% of the reported volume on unregulated exchanges, with such fictitious volume reaching trillions of dollars annually [18]. Exchanges have strong economic incentives to engage in or tolerate wash trading: inflated volume raises their ranking on third-party data platforms, attracts genuine liquidity providers and institutional clients, and provides stronger bargaining leverage in listing negotiations. The harm of wash trading lies not only in the direct price distortion but, more importantly, in its systematic pollution of the market's information environment. When investors cannot distinguish genuine liquidity from fictitious liquidity, their judgments about market depth and liquidity risk become systematically biased, leading them to make suboptimal investment decisions. Wash trading also provides cover for implicit collusion between market makers and exchanges, making conflicts of interest difficult for outside observers to detect.

Regulators play a critical role in combating market manipulation, but the effectiveness of enforcement depends heavily on their ability to obtain trading data. Although the market's endogenous arbitrage mechanism can dampen price manipulation to some degree, it is often powerless against complex cross-market manipulation and systematic wash trading, because the arbitrageurs themselves may become the injured party of a manipulation strategy. By mandating strict trade surveillance, suspicious-activity reporting regimes, and clear definitions and severe penalties for manipulative conduct, regulation can significantly raise the cost of violations and thereby reduce the frequency of manipulation at the margin. Yet the cross-border nature of crypto markets means that enforcement by a single jurisdiction often runs into the limits of its jurisdictional boundary, which is an important reason the net benefit of regulating market manipulation is partly diluted.

26.2.3 Consumer protection

Consumer protection is fundamentally about correcting the information asymmetry among market participants, and in particular about shielding inexperienced retail traders from the disproportionate harm of complex financial derivatives. The mechanism design of perpetual futures contains several elements that are highly opaque to retail participants: the dynamic adjustment of the funding rate, the calculation of the mark price from a multi-exchange index price, the nonlinear liquidation function, and the operating logic of the insurance fund. Most retail traders do not fully grasp the destructive power of these mechanisms under extreme conditions, especially how the multiplier effect of high leverage and volatility can drive initial margin to zero in a short time. The European Securities and Markets Authority's (ESMA) analysis of the contracts-for-differences (CFDs) market shows that 74% to 89% of retail investor accounts lose money in leveraged trading, with average per-investor losses ranging from €1,600 to €29,000 [19]. Although CFDs and perpetual futures differ structurally—in particular, the B-book market-making structure of CFDs differs from the order-book matching model of perpetual futures, so this figure can be treated as an upper-bound estimate of the retail loss rate—the two are highly similar in their leverage effect and their pattern of retail losses, and this figure provides an important reference benchmark for assessing the consumer-protection needs of the perpetual futures market.

In the regulatory design of consumer protection, there is a fundamental clash of values between libertarianism and paternalism, and this divergence has no objective solution at the economic level. The libertarian view holds that adult investors have the right to bear risk on the basis of their own judgment, including the right to sustain financial losses, and that the regulator's responsibility is limited to ensuring adequate disclosure rather than substituting for the investor's decisions. The economic rationale for this position is that mandatory protective measures generate a paternalism cost: they deprive investors of tools for reasonable risk management with derivatives and may push retail participants toward more lightly regulated offshore platforms, thereby reducing, in substance, the protection they receive. The paternalist view argues that, given retail participants' inherent limitations in cognitive capacity, risk tolerance, and access to information, market outcomes do not truly reflect their preferences, and that mandatory measures must therefore restrict their participation in high-risk trading even at the cost

of their formal freedom to invest. This chapter takes no position, but it notes that this divergence directly shapes the choice of regulatory tools—from mere risk warnings to strict accredited-investor entry standards and tiered leverage regimes.

The behavioral-economics framework of the "nudge" offers a third path beyond this binary opposition [20]. The core idea of a nudge is to guide decision-makers toward better outcomes by altering the choice architecture without prohibiting any option. Applied to the perpetual futures market, regulators can design a set of non-coercive interventions. For example, they can set the default leverage on the trading interface to a low level (such as 5x); users can still raise it manually, but the default effect significantly lowers a novice trader's initial risk exposure. As another example, before a user submits a high-leverage order, they can be required to complete a visual simulation of liquidation risk, so that they intuitively understand the probability distribution of having margin wiped out under extreme conditions. As a further example, a pre-trade cooling-off period can be introduced, imposing a brief delay on newly opened high-leverage positions during periods of extreme volatility to curb emotionally driven impulsive trades. These measures respect the trader's right to autonomous choice while using behavioral intervention to reduce the systematic losses caused by cognitive biases, thereby opening a pragmatic middle ground between libertarianism and paternalism.

The economic trade-offs of implementing consumer protection are especially pronounced, which is the main reason it ranks last in the prioritization. Strengthening disclosure is the lowest-cost intervention and can effectively reduce information asymmetry without directly interfering in market operation, but its actual effect is severely limited by retail participants' attention and comprehension. More aggressive measures—such as sharply limiting retail leverage or outright banning retail participation in certain products—can directly reduce retail financial losses, but they also sharply reduce market accessibility and may drive demand toward regulatory vacuums. Consumer-protection regulation therefore needs to be carefully calibrated between preventing exploitation and preserving market openness, and its net benefit depends to a large extent on the regulator's value preferences rather than on pure economic calculation.

26.2.4 Market integrity

Market integrity is the foundation on which any financial system exists, and its core requirement is the safety of customer assets and the transparency of intermediary operations. If an exchange can arbitrarily misappropriate customer assets without oversight, then any rule design at the trading level and any optimization of market microstructure become meaningless, because users' fundamental interests have already been violated at the most basic level. The collapse of FTX is the definitive cautionary case for the cryptocurrency market. The CFTC's complaint states that the platform entirely failed to implement basic corporate controls, failed to segregate customer assets from its own funds and from the funds of affiliated entities, and failed to keep proper records of intercompany fund flows [21]. The CFTC's 2022 complaint found customer deposit losses at FTX exceeding $8 billion; in August 2024, the Commission further obtained a court-approved monetary-relief judgment of approximately $12.7 billion (about $8.7

billion in restitution to customers and victims and about $4 billion in disgorgement and penalties) [21]. This episode reveals a structural loophole: in the absence of mandatory asset-segregation requirements, the moral hazard of centralized exchanges is systemic rather than incidental.

The proof-of-reserves mechanism that the industry has explored on its own attempts to prove an exchange's asset solvency through cryptographic means, but it has fundamental limitations as a safeguard of market integrity. Proof-of-reserves systems focus mainly on verifying the existence of on-chain assets, yet they often cannot reveal, fully or in real time, an exchange's hidden liabilities and complex off-balance-sheet leverage [22]. Specifically, proof of reserves can show that an exchange controls certain wallet addresses, but it cannot prove that those assets have not been secretly pledged to third-party lenders, nor that the exchange holds no hidden short positions established through derivatives. This incomplete transparency not only fails to prevent the covert misappropriation of assets but may even mislead investors by providing a false sense of security, causing them to form overly optimistic judgments about the exchange's actual solvency. Relying solely on technical means and industry self-discipline therefore cannot fully resolve the moral hazard of centralized intermediaries; it must be supplemented by legally binding external oversight.

Mandatory asset segregation and external audit are the core means of safeguarding market integrity. Regulators must require perpetual futures exchanges to maintain minimum capital to absorb operating losses, to enforce strict physical and legal segregation between customer assets and proprietary assets, and to undergo regular, comprehensive audits by independent third parties, with the audit scope extending to off-chain liabilities and related-party transactions. The compliance cost of this kind of regulatory intervention is relatively manageable—consisting mainly of audit fees and the cost of tied-up capital—but its benefit in averting a multibillion-dollar disaster is enormous. More importantly, safeguarding market integrity has significant positive externalities: when investors have full confidence in an exchange's solvency, the liquidity and participation of the entire market improve.

26.2.5 Prioritization

Based on the net-benefit analysis framework, we can construct a systematic prioritization of the four regulatory areas above. This ranking depends not only on the severity of the market failure but must also weigh the market's capacity for self-repair and the expected net benefit of regulatory intervention. By structuring these dimensions, we can clearly identify the optimal allocation of regulatory resources and provide a theoretical basis for regulators' decisions under resource constraints.

Table 26-1 provides a systematic prioritization of the four regulatory areas along three dimensions: the severity of the market failure, the market's capacity for self-repair, and the net benefit of regulation. Market integrity is placed in the first priority. Its extremely high failure severity has already been demonstrated by the FTX episode discussed above (Section 26.2.4), and the market is entirely unable to guarantee the safe segregation of assets on its own in the absence of external compulsion. Because the compliance cost is relatively low and the intervention effectively prevents catastrophic

outcomes, its net regulatory benefit is extremely high. Moreover, safeguarding market integrity has a foundational status: the other regulatory objectives are meaningful only once the safety of customer assets is assured.

Systemic risk follows in the second priority. Although its severity is slightly lower than that of a market-integrity failure, the market lacks any mechanism to reduce risk on its own because of the prisoner's dilemma created by the leverage arms race. Intervention against systemic risk can significantly improve market resilience and prevent the negative externality of a liquidation cascade from harming innocent participants, so its net benefit is likewise considerable. However, the effectiveness of systemic-risk regulation depends heavily on international coordination, and unilateral action may produce a regulatory-arbitrage effect, which to some extent dilutes its net benefit.

Market manipulation ranks third. Although price distortion and wash trading severely undermine fairness, the presence of arbitrage mechanisms can constrain the space for manipulation to some degree, and as the market matures, the profit margin of some manipulative behavior is narrowing naturally. Regulatory intervention in this area is necessary, but its net benefit is diluted by high enforcement costs owing to the complexity of cross-market and cross-jurisdictional enforcement. Consumer protection is placed fourth. Although retail participants face systematic losses in leveraged trading, the information-asymmetry problem has some room for self-improvement as market education spreads and information transparency increases. More importantly, consumer-protection measures often stand in direct negative trade-off with market accessibility, and their net benefit depends to a large extent on the regulator's value preferences rather than on pure economic calculation.

Regulatory area	Market-failure severity	Capacity for self-repair	Net regulatory benefit	Priority
Market integrity (asset segregation)	Very high (FTX: ~$8 billion in customer losses)	Very low (moral hazard cannot self-eliminate)	Very high	First
Systemic risk (leverage / liquidation)	High (cascade losses can reach tens of billions of dollars)	Low (arms race creates a prisoner's dilemma)	High (subject to international coordination)	Second
Market manipulation (wash trading / cross-market)	Medium to high (wash trading exceeds 70%)	Medium (arbitrage partly corrects; market is maturing)	Medium (enforcement costs are high)	Third
Consumer protection (information asymmetry)	Medium (74–89% of retail accounts lose money; based on ESMA CFD data, an upper-bound estimate for perpetuals)	Medium (information transparency is improving)	Medium (largest trade-off; value-dependent)	Fourth

Table 26-1. Prioritization matrix for regulating the perpetual futures market (Data source: constructed by the author)

This prioritization points to an important economic insight: in regulating the perpetual futures market, basic, innovation-neutral institution-building—such as asset segregation and financial audit—often yields the highest net benefit. Such regulatory measures require neither complex technical knowledge nor fine calibration of market microstructure, and their core logic is entirely consistent with the basic principles of traditional financial regulation. Conversely, the interventions that intuitively attract the most public attention—such as directly limiting retail leverage or banning specific products—have more complex economic consequences, accompanied by the largest unintended side effects and value controversies. A rational regulatory framework should therefore first shore up the foundation of market integrity and then extend gradually to the regulation of systemic risk and market conduct. This inside-out, foundation-to-complexity regulatory path is consistent both with the economic principle of net-benefit maximization and with the historical experience of the evolution of traditional financial regulation.

26.3 The regulatory toolbox

Having identified the failure areas in the perpetual futures market that require regulation and their priorities, the core challenge facing regulators is how to choose the appropriate policy tools. Every regulatory intervention not only generates direct compliance costs but also systematically alters the market's microstructure, thereby profoundly affecting market quality. This section provides an economic evaluation of four categories of core policy in the regulatory toolbox, using the five-dimensional market-quality model introduced in Chapter 25 (transaction costs, price discovery, resilience, fairness, and accessibility) to analyze systematically which dimensions these tools improve and on which dimensions they produce unavoidable side effects.

26.3.1 Leverage limits

Capping the maximum leverage on perpetual futures is the most intuitive response of regulators facing systemic risk. Absent external intervention, the crypto-derivatives market—whether centralized exchanges or decentralized protocols—generally offers extremely high leverage (often as high as 100x to 125x) to attract retail traders seeking high-risk returns [23]. This high-leverage environment, however, greatly increases the probability of liquidation cascades, allowing a single trader's insolvency to spread rapidly to the entire market through the automatic-liquidation mechanism and trigger liquidity evaporation and a price collapse. Regulators therefore generally favor cutting the leverage cap sharply, for example limiting it to the range of 20x to 50x.

Leverage limits have their most pronounced positive effect on market resilience. When the maximum leverage is forcibly reduced, traders must post a higher proportion of initial margin, which directly increases the thickness of a position's buffer. When the market faces sharp volatility, a thicker margin buffer can effectively delay the triggering of liquidation, thereby breaking the vicious circle within the liquidation-price-liquidity positive-feedback loop in which falling prices trigger liquidations and liquidations in turn push prices lower still. This intervention, in essence, provides a public good for

the entire market—systemic resilience against extreme shocks—by weakening individuals' capacity to take on excessive risk. At the same time, leverage limits improve market fairness to some degree, because they protect the retail traders who lack risk-management experience and are prone to the temptation of extreme leverage from severe losses [24].

This improvement in resilience, however, comes at the cost of market accessibility. When leverage is strictly limited, traders with smaller capital must commit more funds to establish a position of the same size, which in effect raises the barrier to market entry and excludes some participants. In addition, transaction costs are affected negatively. Although the explicit fee rate does not change, the reduction in capital efficiency means traders must leave more funds idle as margin, and this opportunity cost constitutes an implicit trading friction. Price discovery, meanwhile, remains relatively neutral in this process, because leverage limits mainly affect position size and do not directly impede the incorporation of new information into prices.

Figure 26-2 uses the leverage cap (2x to 125x) as its parameter axis, with the left and right panels tracking the improvement in market resilience and the loss of accessibility, respectively: when leverage is lowered from 125x to 50x, the resilience gain is substantial while the accessibility loss is limited; compressing it further below 10x flattens the marginal resilience gain but sharply accelerates the deterioration in accessibility, and the sweet spot marked jointly by the two panels (50x) is the core zone of the policy trade-off.

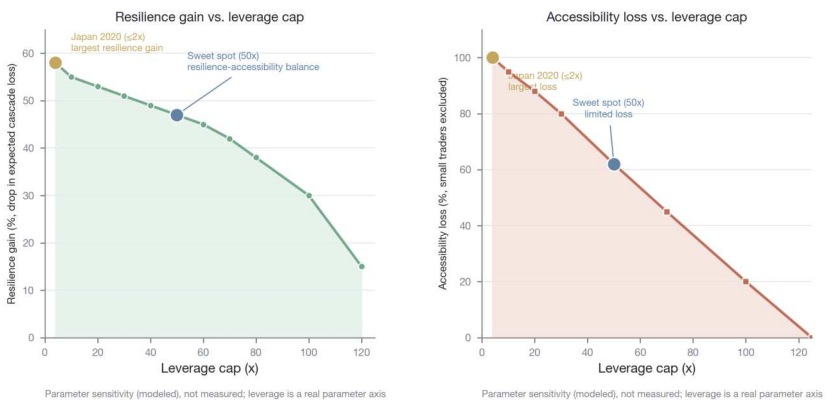

Figure 26-2. Parameter-sensitivity analysis of leverage limits

More complicated still, leverage limits face a serious risk of regulatory arbitrage in implementation. If a strict leverage cap is imposed within a single jurisdiction alone, traders demanding high leverage will quickly move to offshore exchanges or decentralized platforms. Japan's 2020 policy of cutting the leverage cap from 25x to 2x shows that overly stringent limits lead to a large-scale outflow of trading volume, so that the regulator instead loses its capacity to monitor the market (Section 26.7.1 documents this trade-off with policy data from Japan's Financial Services Agency (FSA)) [25]. The net effect of leverage limits therefore depends heavily on how the parameter is set: too loose (such as 100x) fails to guard effectively against liquidation cascades, whereas

too strict (such as 2x) triggers destructive regulatory arbitrage, and a moderate limit of around 50x may be the better compromise between resilience and accessibility.

26.3.2 Disclosure and transparency

Unlike leverage limits, which directly intervene in market trading behavior, disclosure and transparency requirements are a non-intrusive regulatory tool. This kind of policy does not prohibit any particular business model or product structure but instead mandates that exchanges publicly disclose key information about their internal operations, including the state of asset reserves, the summary terms of market-maker agreements, liquidation parameters and mark-price algorithms, and any conflicts of interest arising from proprietary market-making. The core of this regulatory philosophy is that, by eliminating information asymmetry, market participants can price risk on the basis of full information, so that the market mechanism itself spontaneously penalizes platforms that take excessive risk or act in bad faith.

Judged against the same five dimensions, the most direct and significant contribution of disclosure requirements is to improve market fairness. As described in Section 26.1.1, the information gap between exchanges and retail participants leaves ordinary users in a state of blind trust regarding core data such as order flow, liquidation logic, and market-maker privileges [26]. Mandatory disclosure of market-maker agreements and proprietary-trading positions can effectively curb platforms' use of their informational advantage for insider trading or market manipulation, ensuring that all participants stand on an equal footing at the level of the rules. In addition, greater transparency in the liquidation mechanism also helps improve the efficiency of price discovery, because market participants can more accurately anticipate the system's response under extreme conditions and thus make more rational pricing decisions.

The direct impact of disclosure policy on the dimensions of resilience, transaction costs, and accessibility is relatively neutral. It does not directly change the economic cost of trading, nor does it raise the barrier to market entry. In the long run, however, greater transparency can strengthen public trust in the market and reduce participants' concerns about credit risk, and this decline in the trust premium may translate indirectly into lower implicit transaction costs. At the same time, under market stress, a transparent picture of asset reserves can effectively prevent an irrational, panic-driven bank run, providing psychological support for market resilience.

Although disclosure is regarded as the lowest-cost regulatory tool with the smallest side effects, its effectiveness faces one key limitation: the disclosure itself must be truthful and verifiable. The limitations of proof of reserves (see Section 26.2.4—it can prove on-chain assets but cannot reveal off-chain liabilities and off-balance-sheet leverage [22]) are a case in point. Before its collapse, FTX also presented seemingly healthy financial statements to investors and venture-capital firms, but this independently unverified information ultimately proved to be gravely inaccurate. Disclosure therefore translates into effective market transparency only when it is combined with strict external audit and legal liability; otherwise it may merely produce a false sense of security.

26.3.3 Market-maker obligations

Liquidity is the foundation on which the perpetual futures market keeps running, and market makers are the core force supplying it. In an unregulated crypto market, most market makers operate on a voluntary liquidity-provision model that is highly flexible but leads them, when the market suffers an extreme shock, to withdraw en masse out of rational individual risk-management considerations—producing the tragedy of the commons in liquidity described in Section 26.1.1, in which individually rational risk-averse behavior causes liquidity to evaporate instantly at the aggregate level, aggravating one-sided crashes and liquidation cascades [12]. To address this undersupply of a public good, regulators typically introduce a designated-market-maker regime.

The core logic of the designated-market-maker regime is the "parity of rights and obligations." The exchange grants specific market makers privileges such as fee rebates, dedicated API channels, or lower latency; in exchange, these market makers must bear explicit liquidity-provision obligations. These obligations typically include maintaining minimum order depth within a specified price band, adhering to a maximum bid-ask spread, and meeting minimum uptime requirements. More critically, regulation requires that these obligations remain in force even under "abnormal market conditions" and cannot be waived at will simply because volatility has intensified [27].

Market-maker obligations, by contrast, are aimed mainly at improving market resilience. By requiring core liquidity providers to maintain quotes in times of crisis, the market can retain a minimal capacity to absorb selling pressure under extreme conditions, avoiding a disorderly price collapse. At the same time, this regime improves market fairness, because it makes public and standardizes the private incentive agreements that were originally hidden between exchanges and market makers, eliminating opaque interest arrangements.

The introduction of market-maker obligations, however, inevitably has a negative impact on transaction costs. When market makers are compelled to provide liquidity under extreme conditions, they face significant adverse-selection risk and inventory-devaluation risk. To compensate for this potential extreme loss, market makers must widen their bid-ask spreads under normal conditions, passing the cost of bearing the obligation on to ordinary traders. Moreover, the design of this regime faces a difficult balancing challenge: how to define "abnormal market conditions." If the definition is too broad, market makers can easily trigger the exemption clause, rendering the obligation a dead letter; if it is too strict, market makers may, in a genuine systemic crisis, suffer losses beyond their capital capacity and ultimately go bankrupt. Once a core market maker fails, it not only cannot provide liquidity but, as a large defaulting counterparty, further aggravates the market's systemic risk.

26.3.4 Capital requirements and asset segregation

If leverage limits and market-maker obligations address risks at the trading level, then capital requirements and asset segregation strike directly at the core of an exchange's governance structure. The misappropriation of FTX customer assets described in Section 26.2.4 shows that when an exchange's internal governance fails completely, any discussion of liquidation-engine efficiency or order-book depth loses its meaning [28].

In the post-FTX era, therefore, establishing strict capital-adequacy standards and a customer-asset-segregation regime has become the top-priority agenda for regulators worldwide.

Capital-requirement policy stipulates that an exchange must hold a certain proportion of its own funds as a buffer to absorb operating losses, technical failures, or cyberattacks. This is analogous to the Basel Accords framework in traditional banking, which aims to ensure that financial institutions have sufficient solvency when facing unexpected shocks. Asset-segregation requirements are more direct still: they mandate that an exchange strictly separate customers' deposited funds from the platform's own operating funds at the legal and physical levels, and they prohibit the exchange from using customer assets for proprietary trading, staking and lending, or as collateral [29].

Capital requirements and asset segregation deliver their largest gains on the resilience and fairness dimensions. Asset segregation fundamentally cuts off the exchange's path to misappropriating customer funds, eliminating the possibility of a systemic collapse triggered by internal moral hazard on the platform. This not only protects the absolute safety of customer assets but also restores participants' basic trust in centralized trading infrastructure, greatly strengthening the market's resilience against endogenous risk. At the same time, higher capital requirements ensure that an exchange has sufficient own funds to meet its payout obligations under extreme market stress, preserving the fairness of trade settlement.

The distinctive feature of this regulatory intervention is that its enormous benefits come with relatively limited negative side effects, concentrated mainly on accessibility. It does not interfere with traders' leverage choices or change the microstructure of the order book, so it has no direct effect on price discovery or transaction costs. The only dimension that may be slightly affected is market accessibility. Strict capital-adequacy standards and regular external-audit requirements substantially raise the fixed cost of opening and operating a cryptocurrency exchange, which may squeeze some smaller, less well-capitalized platforms out of the market and increase industry concentration. From the perspective of protecting investors, however, eliminating the marginal platforms that cannot provide basic safety guarantees is itself the intended outcome of regulatory selection, and this reduction in accessibility is an acceptable cost in the overall welfare analysis.

26.3.5 The five-dimensional impact matrix

Through the analysis of the four categories of core regulatory tools above, we can clearly see that no single policy can resolve all market failures at once. Every intervention aimed at repairing a specific market failure triggers a chain reaction in the complex market ecosystem, improving certain quality dimensions while inevitably causing friction or loss on others. Table 26-2 compresses these complex trade-offs into a five-dimensional impact matrix of regulatory tools, to facilitate comparison of the net effects of different policies.

Table 26-2 evaluates, one by one, the direction and intensity of the impact of seven categories of regulatory tools along five dimensions: transaction costs, price discovery, resilience, fairness, and accessibility. In the table, an upward arrow (↑) denotes improve-

ment on that dimension, a downward arrow (↓) denotes deterioration, and a rightward arrow (→) denotes roughly no change, with the number of arrows representing the magnitude of the impact. This standardized scoring framework makes horizontal comparison across policies immediately clear and also reveals the unavoidable trade-offs each intervention entails across the dimensions. Of these, the two tools of mandatory KYC/AML and an outright trading ban are not treated separately in the preceding subsections; their five-dimensional scores are based on their typical effects in the discussions of jurisdiction and anti-money laundering (see Sections 26.4.2 and 26.6.2): the former trades accessibility for gains in legitimacy and fairness, while the latter, by driving trading underground, produces negative effects on most dimensions.

Regulatory tool	Transaction costs	Price discovery	Resilience	Fairness	Accessibility	Net assessment
Leverage limit (to 20x)	↑	→	↑↑↑	↑	↓↓	Very large trade-off; highly prone to regulatory arbitrage
Leverage limit (to 50x)	→	→	↑↑	↑	↓	A better compromise; balances resilience and accessibility
Disclosure and external audit	→	↑	→	↑↑	→	Positive net benefit; very low cost; strongly recommended
Market-maker obligations	↑	→	↑	↑	→	Moderate net benefit; highly dependent on the design of exemption clauses
Capital requirements and asset segregation	→	→	↑↑	↑↑	↓	Very high net benefit; a core tool against severe systemic risk
Mandatory KYC/AML	↑	→	→	↑	↓↓	Large trade-off; touches on the decentralization values of crypto markets
Outright trading ban	N/A	N/A	N/A	N/A	↓↓↓	Negative net benefit; drives the market underground; counterproductive

Table 26-2. Five-dimensional market-quality impact matrix of the regulatory toolbox (Data source: constructed by the author)

This matrix distills a core insight of regulatory economics: excellent regulatory design

does not seek perfect improvement on every dimension but instead, on the basis of a deep understanding of a policy's side effects, chooses the tool combination that "maximizes net benefit" or "keeps side effects most manageable." For example, although capital requirements and asset segregation slightly reduce accessibility, their enormous benefit in preventing an FTX-style disaster makes them a primary policy. Conversely, although an extreme leverage limit (such as 2x) can significantly improve resilience in theory, its severe damage to accessibility and the regulatory arbitrage it triggers often make it a failed policy in practice. The core of regulatory design lies in finding, on this multidimensional trade-off frontier, the equilibrium point best suited to the market's current stage of development.

26.4 The jurisdiction problem

The global, decentralized character of perpetual futures raises a question thornier than how to regulate them: who regulates. Regulatory jurisdiction in traditional financial markets rests on the principle of territoriality and on entity registration, and a regulator holds exclusive jurisdiction over financial activity within its sovereign borders. The servers of a perpetual futures trading platform, however, may be deployed across multiple jurisdictions, the core development team may be distributed around the world, and liquidity providers and traders connect from everywhere via the internet. This borderless technical architecture conflicts fundamentally with a legal framework based on sovereign borders. The fragmentation of global regulation is not the incidental result of regulators' lack of willingness to cooperate but reflects a structural contradiction: global consistency, innovation-friendliness, and consumer protection cannot all be achieved at once.

26.4.1 The impossible trinity

The formulation of international financial-regulatory policy is subject to a structural trade-off framework that can be formalized as the regulatory "impossible trinity." This concept derives from the classic macroeconomic theory that a fixed exchange rate, free capital mobility, and independent monetary policy cannot all be achieved simultaneously [30]. This framework is not a strict mathematical impossibility theorem but an analytical tool that reveals the structural tension among policy objectives. In the context of regulating crypto-asset derivatives, the three vertices of the triangle are global consistency, innovation-friendliness, and consumer protection. Global consistency means that countries implement uniform regulatory standards to eliminate cross-border arbitrage space; innovation-friendliness means reserving sufficient room for experimentation for emerging technologies and business models; and consumer protection means reducing retail investors' risk exposure through entry standards, disclosure, and leverage limits. The mutual exclusivity among the three arises from resource constraints and incentive incompatibility: when the international community pursues global consistency and consumer protection at once, it must formulate and enforce strict uniform standards, which inevitably compresses the room for each country to experiment with locally tailored innovation. When global consistency and innovation-friendliness are prioritized together, by contrast, countries can agree only on a low standard, and the strength of consumer

protection is necessarily sacrificed.

Figure 26-3 shows the inherent conflict among these three policy objectives: pursuing global consistency and consumer protection simultaneously requires the enforcement of strict uniform standards, which suppresses early-stage technological innovation in lightly regulated jurisdictions—Europe's mature financial infrastructure can still bear the strict compliance costs, but fintech firms in emerging-market countries may be forced to abandon innovation projects as a result; whereas pursuing global consistency and innovation-friendliness simultaneously can only reach consensus on a loose minimum standard, which cannot provide effective consumer protection and may allow systemic risk and market manipulation to spread.

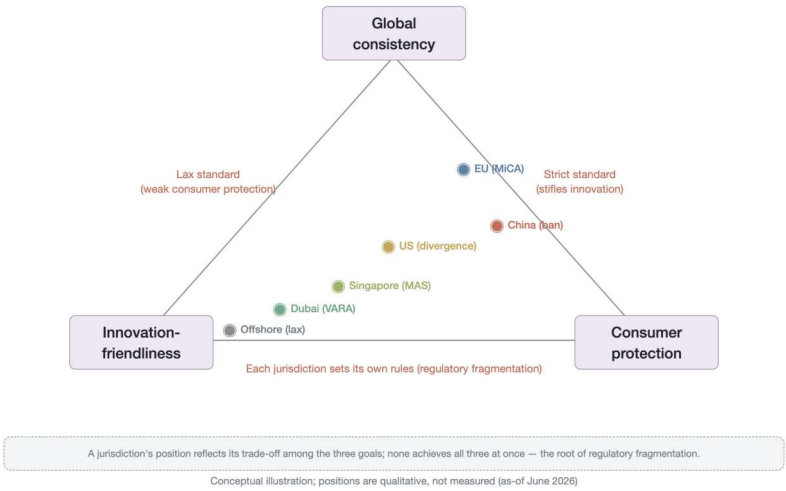

Figure 26-3. The regulatory "impossible trinity"

Faced with this impossible trinity, national regulators can only choose to compromise among the three objectives. The choice in reality is usually to give up global consistency and instead seek a balance between innovation-friendliness and consumer protection according to a country's own economic-development strategy and financial-stability concerns. This policy choice, grounded in sovereign autonomy, directly produces the inconsistency of global rules. The current regulatory fragmentation is therefore an inevitable product of structural constraints, and each country's or region's different position in the triangle reflects its different pricing of the benefits and risks of financial innovation.

From an economic perspective, this trade-off reflects different countries' different valuations of the benefits and risks of innovation. Developed economies generally have stronger financial-regulatory capacity and investor-protection mechanisms and can therefore bear higher innovation risk. By contrast, some developing countries may face more severe financial-stability challenges and therefore tend to adopt a more conservative stance. In addition, each country's industrial policy also influences its regulatory choice. Countries that hope to attract fintech talent and firms may choose

a more relaxed regulatory environment, whereas those that rely mainly on traditional financial institutions may take a more cautious attitude toward emerging technologies.

26.4.2 The global regulatory map

Based on their different trade-offs within the impossible trinity, the world's major economies have taken sharply different policy stances on regulating perpetual futures. This divergence of stances is not a simple binary opposition but forms a continuous spectrum from outright prohibition to active embrace. On this spectrum, the policy choices of different jurisdictions determine not only their share of the global crypto-derivatives market but also significantly affect the geographic distribution of trading activity.

Figure 26-4 depicts the current spectral distribution of global regulation. At the far left of the spectrum are the jurisdictions that adopt outright prohibition. China imposed a strict ban on cryptocurrency trading in 2021, aiming to sever completely the link between crypto-assets and the fiat-currency system in order to guard against capital flight and financial risk. Empirical research shows, however, that the enforcement effect of this extreme policy is limited: trading activity did not disappear but shifted to offshore platforms through intermediaries such as stablecoins, and Chinese investors continue to exert significant influence on Bitcoin price formation [31]. This finding carries an important policy implication: even the strictest regulatory measures cannot fully halt trading activity and may instead cause regulators to lose visibility into and control over that activity.

To the right of the prohibition end are the jurisdictions that impose strict regulation. Japan's FSA strictly limits the leverage cap on crypto-derivatives to 2x, and this extremely conservative consumer-protection measure forces traders seeking high leverage toward unrestricted overseas platforms, thereby weakening the domestic regulator's influence and the competitiveness of Japan's fintech industry (Section 26.7.1 documents this trade-off with FSA policy data).

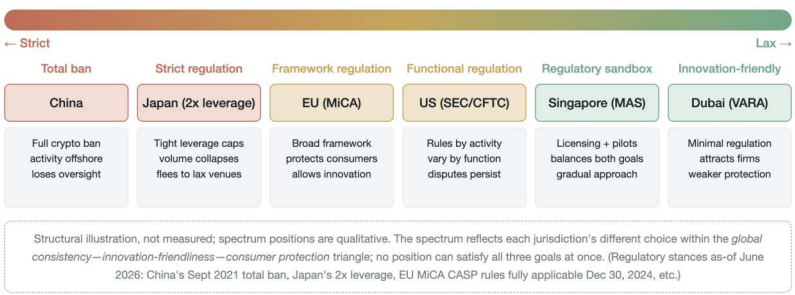

Figure 26-4. The global regulatory map and policy spectrum

The middle of the spectrum comprises the regions that attempt to build comprehensive

frameworks. Through the Markets in Crypto-Assets (MiCA) regulation, the European Union established the world's first cross-national comprehensive regulatory framework; although the regulation targets mainly spot markets and stablecoins, it provides a foundational classification and entry standard for derivatives regulation. The core feature of the MiCA framework is that it establishes uniform EU market-access rules, allowing a crypto-asset service provider licensed in one member state to provide services in other member states. This "single passport" mechanism substantially lowers cross-border compliance costs but also requires all participants to comply with relatively strict consumer-protection standards. The United States, by contrast, is in a state of functional-regulatory divergence: the U.S. Securities and Exchange Commission (SEC) and the CFTC have a long-standing dispute over jurisdiction of crypto-derivatives, and this enforcement-based rather than legislation-based regulatory model brings extremely high uncertainty, which has in effect entrenched the market dominance of offshore exchanges. The U.S. divergence reflects a deeper problem: different regulators may have different classificatory understandings of the same category of financial product, creating opportunities for regulatory arbitrage.

At the right end of the spectrum are the jurisdictions inclined toward innovation-friendliness. The Monetary Authority of Singapore (MAS) combines a regulatory sandbox with a licensing regime, attempting to strike a balance between attracting fintech innovation and guarding against money-laundering risk. The MAS framework allows qualified firms to test new products and services in a restricted environment while maintaining basic consumer protection. The advantage of this approach is that it can provide space for innovation without entirely abandoning regulation. Dubai's Virtual Assets Regulatory Authority (VARA) offers a more light-touch regulatory framework, attracting a large number of crypto firms through clear and flexible rules. VARA's success lies in providing clear legal status and relatively low compliance costs, which has led many global crypto firms to establish regional headquarters in Dubai. At the far right of the spectrum, certain offshore jurisdictions impose almost no substantive regulation on crypto-derivatives; they offer the highest degree of freedom to innovate and the lowest compliance costs but also entirely abandon consumer protection.

26.4.3 The economic consequences of fragmentation

The significant differences in global regulatory policy directly give rise to regulatory arbitrage. Regulatory arbitrage refers to market participants exploiting the inconsistency of rules across jurisdictions to shift business or trading activity to the regions with the lowest compliance costs and the fewest restrictions. In the perpetual futures market, this arbitrage takes three main forms: arbitrage of exchange domicile, circumvention of users' geographic location, and liquidity fragmentation. Arbitrage of exchange domicile means that an exchange chooses to register in the most lightly regulated region and then provides services to users worldwide via the internet. Circumvention of users' geographic location means that users employ technical means such as VPNs to bypass geographic restrictions and access trading platforms banned in their home country. Liquidity fragmentation means that, because of regulatory restrictions, trading liquidity is dispersed across multiple platforms, resulting in insufficient liquidity in the global market.

When a country imposes strict regulation, the direct consequence is often not the elimination of high-risk trading but the loss of jurisdiction over it. The migration of trading volume to offshore platforms after China's 2021 ban, described in Section 26.4.2, is a paradigmatic case of regulatory arbitrage causing a country to lose its regulatory capacity [31]: the effectiveness of regulation depends not only on the strictness of the rules but, more importantly, on their enforceability. This substantive regulatory failure instead increases systemic risk, because regulators cannot obtain trading data or conduct risk monitoring.

A deeper problem triggered by regulatory arbitrage is the loss of global market efficiency. The Financial Stability Board's (FSB) assessment report notes that significant gaps and inconsistencies in the implementation of crypto-asset regulation are undermining the interconnectedness of the global financial system [32]. At the level of micro-market structure, this fragmentation manifests as a pricing-island effect. Because of compliance requirements, fiat on- and off-ramp restrictions, and region-specific trading bans, the funds and positions of cross-market arbitrageurs cannot flow freely between exchanges in different jurisdictions. The blocking of arbitrage paths allows cross-market price differences—which should converge instantly—to persist, reducing the overall efficiency of price discovery in the global market. For example, if the perpetual futures price on a European exchange differs significantly from that on an Asian exchange, traditional arbitrageurs should eliminate the difference by buying in the low-price market and selling in the high-price market. But if the European exchange is prohibited from serving Asian users, or the Asian exchange is prohibited from serving European users, this arbitrage mechanism breaks down and the price difference may persist for a long time.

Moreover, regulatory fragmentation may trigger a race to the bottom. To attract the tax revenue, employment, and technology spillovers that crypto firms bring, some jurisdictions may face political pressure to lower their regulatory thresholds. If this competition evolves into a scramble to relax standards, the level of consumer protection worldwide will decline overall. When large numbers of retail investors conduct high-leverage trading on offshore platforms that lack asset-segregation and disclosure requirements, systemic risk is not reduced by some countries' strict regulation but instead becomes harder to monitor and guard against, because risk concentrates in opaque regions. This phenomenon has precedents in traditional finance as well: in certain historical periods, some countries competed to loosen regulatory standards in order to attract financial institutions, which is thought to have aggravated the subsequent fragility of the financial system.

26.4.4 The path to coordination

Faced with the economic costs of regulatory fragmentation, establishing some form of international coordination mechanism becomes an inevitable choice. Because of the structural constraint of the impossible trinity, however, pursuing a fully unified global regulatory framework is unrealistic in the short term. A more feasible path is to seek a compromise between core consensus and regional differences through bilateral mutual recognition and the setting of minimum standards.

Bilateral mutual-recognition agreements are an effective mechanism for lowering cross-border compliance costs. When the regulatory objectives and rule intensity of two jurisdictions are sufficiently close, they can mutually recognize each other's regulatory licenses. This means that a perpetual futures exchange licensed in one country can legally operate in another without reapplying. This mechanism can locally alleviate liquidity fragmentation without requiring global uniformity. The precondition for implementing bilateral mutual recognition, however, is that both sides must be highly consistent on core issues such as asset segregation, anti-money laundering, and the prevention of market manipulation. Successful examples of such agreements include the financial-services passport regime within the European Union, which allows a financial institution licensed in one member state to provide services in other member states, substantially lowering the cost of cross-border financial services.

At the multilateral level, setting international minimum standards is key to preventing a race to the bottom. In 2023, the International Organization of Securities Commissions (IOSCO) issued policy recommendations for crypto and digital-asset markets, providing benchmark regulatory guidance for its member countries [33]. This minimum-standard model is analogous to the role of the Basel Accords in traditional banking: it requires all participating countries to meet basic requirements on customer-asset protection and conflict-of-interest management but allows each country to add stricter rules on top (such as different leverage caps) according to its national circumstances. The advantage of this approach is that it can maintain a minimum protection standard while allowing each country to innovate according to its own situation.

IOSCO's recommendations cover core areas such as anti-money laundering, know-your-customer, the prevention of market manipulation, and customer-asset protection. Through these minimum standards, the international community can prevent regulatory competition from evolving into a total collapse of consumer protection. At the same time, countries can still maintain differences in leverage limits, product classification, and entry standards to suit their stage of economic development and risk appetite. This approach has already achieved some success in other financial domains; for example, the recommendations of the Financial Action Task Force (FATF) on anti-money laundering have been adopted by most countries.

Although international organizations are actively promoting coordination, the surrender of sovereignty in reality still faces complex political-economy constraints. Global regulatory unification involves not only the alignment of technical standards but also touches on each country's financial sovereignty, tax interests, and industrial policy. Over the next 5 to 10 years, therefore, the most likely regulatory configuration for the perpetual futures market combines a global consensus on bottom-line issues such as anti-money laundering and asset custody with persistent regional differences on dimensions such as leverage limits, product access, and derivatives classification. This hybrid model of core consensus plus regional difference is the most realistic response to the regulatory impossible trinity.

26.5 Functional regulation versus entity-based regulation

The traditional financial-regulatory framework rests mainly on the logic of entity-based regulation. This paradigm assumes that financial activity is tightly bound to specific types of institution, so regulators achieve their objectives by licensing and imposing overall constraints on specific entities such as banks, securities exchanges, or commodity-futures commissions. The emergence of perpetual futures, however, poses a fundamental challenge to this paradigm. As a derivative that occupies a dominant position in the crypto-asset market, perpetual futures operate in a way that crosses the clear boundaries of traditional financial products, so a regulatory method based on entity classification faces significant limitations when confronting this kind of innovative instrument. This predicament has driven an evolution of the regulatory paradigm, prompting academics and policymakers to reexamine the theoretical value and practical potential of functional regulation.

26.5.1 The limits of entity-based regulation

Entity-based regulation works effectively only on the premise that the regulated object can be accurately assigned to a predefined legal and economic category. In the U.S. financial-regulatory system, this classification process usually determines whether a product falls under the jurisdiction of the SEC or the CFTC. For digital assets and their derivatives, this either-or classification framework has produced long-standing jurisdictional disputes and regulatory vacuums.

The legal nature of perpetual futures first faces the challenge of the definition of a security. The Howey test, established by the U.S. Supreme Court in 1946, is the core standard for judging whether a transaction constitutes an investment contract and therefore a security [34], and the SEC adopted this standard in its analytical framework for digital assets [3]. The test requires an investment of money, in a common enterprise, with a reasonable expectation of profits, where the profits derive entirely or predominantly from the efforts of others. As a derivative, perpetual futures anchor their value to the price of an underlying crypto-asset, and traders profit from price movements by going long or short. This mechanism represents no ownership of any issuing entity, and traders' expectation of profit derives from changes in the market price rather than from the operating efforts of a specific management team. Classifying perpetual futures directly as a security under the Howey test framework therefore faces significant legal obstacles.

Having ruled out classification as a security, bringing perpetual futures under the commodity-futures regulatory framework seems the more reasonable path, but this too faces a conflict of technical definition. A traditional futures contract is defined as a standardized agreement to buy or sell a specific quantity of a commodity at a predetermined price on a specific future date. The core innovation of perpetual futures is precisely that they eliminate the expiration date, using the funding-rate mechanism to make the contract price track the spot price closely [13]. This design without a delivery deadline places them, in legal definition, outside the category of traditional futures, so the CFTC faces a challenge of legal interpretation in establishing its jurisdiction. Although the CFTC has recently signaled that it may permit perpetual futures trading

in the United States, this process remains subject to a reinterpretation of the definition of derivatives [35].

This classificatory ambiguity directly leads to the formation of a regulatory vacuum. When a systemically important financial innovation cannot be accommodated by the existing regulatory framework, market participants often exploit the ambiguity for regulatory arbitrage. Capital and trading activity tend to flow to the jurisdictions with the most lenient regulatory requirements or where clear rules have not yet been established. This phenomenon is especially evident in the perpetual futures market, where large trading volumes concentrate on offshore exchanges, leaving the regulators of major economies without effective tools to intervene when facing potential systemic risk and market manipulation. This regulatory failure stems not from regulators' inaction but from the structural limitation of the entity-based regulatory paradigm in the face of cross-boundary financial innovation.

26.5.2 The principle of functional regulation

Faced with the limitations of entity-based regulation, functional regulation offers a more adaptive alternative paradigm. The theoretical basis of functional regulation can be traced to the financial-system design framework of Merton and Bodie [36]. That framework proposes that financial functions are more stable than financial institutions; the form of an institution evolves with changes in technological, political, and cultural norms, but the basic functions that a financial system must perform are enduring. The design and regulation of a financial system should therefore anchor on function rather than on institution.

Applying this theory to regulatory practice, the core logic of functional regulation can be summarized as "same function, same risk, same regulation." In discussing financial-regulatory frameworks, the Bank for International Settlements notes that activity-based or functional regulation is more justified when financial instability originates from a specific activity rather than a specific entity [37]. Under this paradigm, the focus of regulation shifts from "what type of institution is this" to "what economic function is this institution performing." If a decentralized protocol and a centralized exchange both perform the functions of order matching and price discovery, then, for that specific function, they should be subject to the same rules aimed at preventing market manipulation and ensuring transparency, regardless of their legal organizational form.

The economic advantage of functional regulation lies in its ability to effectively eliminate the incentive for regulatory arbitrage. Under entity-based regulation, innovators have a strong incentive to circumvent strict regulatory requirements by changing their organizational form or product name. Functional regulation, by seeing through the appearance of organizational form and imposing constraints directly on the substance of the economic activity, renders such formal circumvention ineffective. Moreover, this paradigm is more friendly to technological innovation. It does not need to create a new legal category for every newly emerging financial instrument or institutional form but instead decomposes the new thing into a combination of known financial functions and applies the corresponding existing rules.

Figure 26-5 contrasts the structural difference between the two regulatory paradigms:

entity-based regulation attempts to force perpetual futures into ill-fitting institutional categories, whereas functional regulation achieves precise rule-matching by decomposing the specific functions they perform.

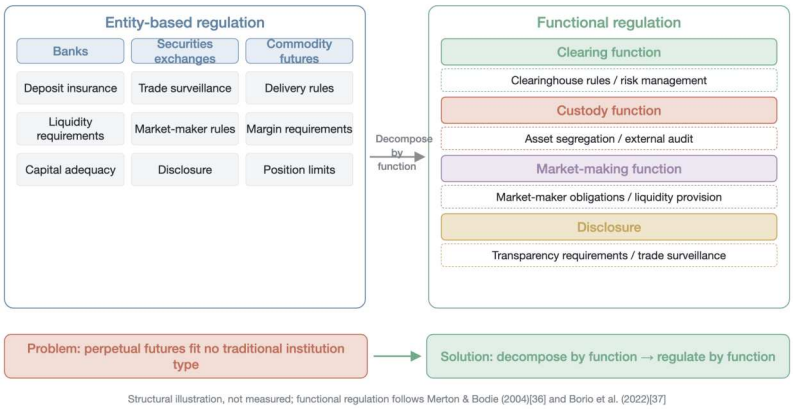

Figure 26-5. Structural comparison of entity-based and functional regulation

26.5.3 The functional decomposition of perpetual futures

Applying the functional-regulation paradigm to the perpetual futures market requires a deep functional decomposition of the platforms that offer perpetual futures trading. Whether a centralized exchange or a decentralized protocol, its operation can be deconstructed into four core financial functions: clearing, custody, market-making, and disclosure. By mapping these functions to their corresponding regulatory objectives, one can build a systematic and highly adaptive regulatory framework.

The clearing function is the primary source of systemic risk in the perpetual futures market. Because of the high leverage inherent in perpetual futures, the design of the liquidation mechanism directly bears on market resilience. Under a functional-regulation framework, any entity or protocol that performs the clearing function must be subject to rules analogous to those of a traditional clearinghouse. These include establishing a robust risk-management framework, setting reasonable initial and maintenance margin requirements, and maintaining an insurance fund sufficient to absorb the bad-debt losses of underwater positions under extreme market conditions. For decentralized exchanges, this means that the liquidation logic in their smart contracts must meet minimum risk-control standards to prevent a liquidation cascade from triggering a broad market collapse.

The custody function concerns the holding and safekeeping of customer assets. The lesson of the FTX episode is that when a trading platform performs both trade-matching and asset-custody functions, the risk of misappropriating customer assets is extremely high. Functional regulation requires strict asset-segregation rules for entities that perform the custody function. This means that customers' margin must be completely separated from the exchange's operating funds at the physical or cryptographic level

and must undergo regular external audit or provide verifiable transparency through cryptographic means such as proof of reserves.

The market-making function directly affects the supply of liquidity in the perpetual futures market but is also prone to conflicts of interest and market manipulation. When the exchange itself or an affiliated entity acts as a major market maker on the platform, the fairness problem comes to the fore. Functional regulation requires imposing explicit market-maker obligations on participants that perform the market-making function, such as maintaining minimum liquidity and limiting spreads under abnormal market conditions. At the same time, a strict firewall must be established to prevent the exchange performing the matching function from using non-public order-flow information to gain an improper advantage for its proprietary market-making business.

The disclosure function is the foundation for mitigating information asymmetry among market participants. Functional regulation requires that platforms offering perpetual futures trading, whatever their architecture, provide the market with sufficient transparency. This includes publishing trading data, disclosing the key terms of market-maker agreements, clarifying the calculation methods of liquidation parameters and the mark price, and providing regular trade-surveillance reports to deter manipulation.

Figure 26-6 systematizes the decomposition of the four functions above into a regulatory mapping, enabling regulators to identify precisely the functional nodes that require intervention rather than imposing homogeneous compliance obligations on an entire platform indiscriminately. For a centralized exchange that bears multiple functions at once, this framework requires the establishment of internal firewalls between the functions; for a decentralized architecture in which the functions are dispersed across different protocols, the compliance obligations can be assigned to the actual performer of each function.

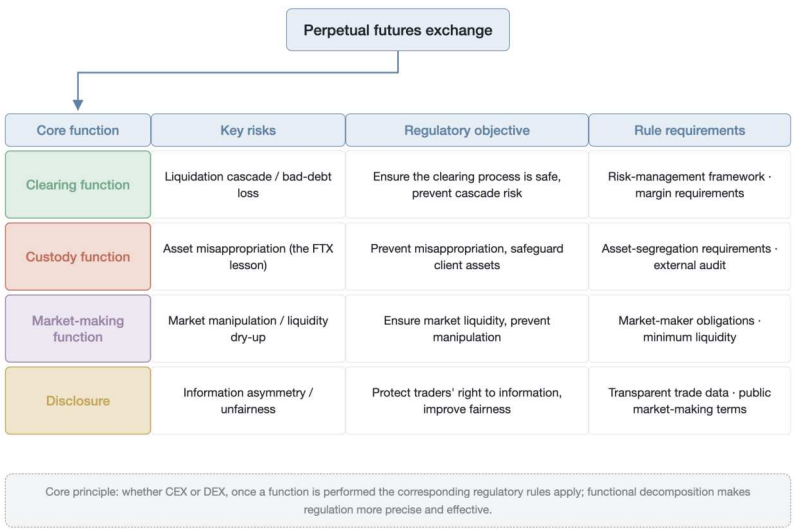

Figure 26-6. Functional decomposition of a perpetual futures exchange and the corresponding regulatory mapping

26.5.4 Implementation challenges

Although functional regulation offers an elegant solution in theory, its actual implementation in the perpetual futures market still faces major challenges. These challenges stem mainly from the special features of crypto-market microstructure and the inherent properties of decentralized technology.

The first is the problem of blurred functional boundaries. In traditional finance, clearing, custody, and trade-matching are usually performed separately by different specialized institutions. In the crypto-asset market, however—especially within centralized exchanges—these functions are highly concentrated in a single entity. This cross-functional coupling makes it exceedingly difficult to apply segregated regulation to a single function. For example, when an exchange controls both the liquidation engine and the market-making funds, requiring it to build an absolute internal firewall often lacks a credible verification mechanism. It is very difficult for regulators to force the separation of these deeply coupled functions without disrupting the exchange's existing business model and efficiency advantages.

The second is the challenge of enforcement difficulty—namely, "who determines that a certain function has been performed" and "against whom is accountability pursued." In the context of decentralized exchanges, this problem is especially acute. A decentralized protocol is, in essence, a set of automatically running smart-contract code that lacks a traditional legal-person entity as a regulatory object. When an automated market maker protocol performs the functions of price discovery and liquidity provision, it is difficult for regulators to determine whether the protocol's original developers, the holders of governance tokens, or the operators of the front-end interface that provides liquidity should bear compliance responsibility. This absence of a responsible subject greatly weakens the deterrent power and enforceability of functional regulation when it confronts a purely on-chain application.

Moreover, the scope of applicability of functional regulation has inherent limits. Although it can effectively handle activities highly similar to traditional financial functions, for mechanisms unique to crypto markets—such as algorithm-based automated liquidation and flash loans—the functional-regulation framework may lack ready-made rules to draw on. This means that regulators must not only decompose functions but also create entirely new regulatory standards for these new functions, which undoubtedly increases the complexity and time cost of regulatory design. Functional regulation is therefore not without limits; it requires continual adjustment and refinement in defining functional boundaries, adapting to cross-boundary coupling, and innovating enforcement means.

26.6 Regulating DeFi perpetual futures

The preceding analysis has systematically evaluated the various regulatory tools aimed at centralized exchanges. Assessing the actual effectiveness of these tools, however, requires considering one key variable: as the principal escape valve for regulatory arbitrage, decentralized exchanges' accessibility directly determines the net effect of regulating the centralized market. If traders can migrate almost frictionlessly to permissionless

decentralized protocols, the actual binding force of the leverage limits or compliance requirements imposed on centralized exchanges is greatly diminished. Understanding the regulatory boundaries of DeFi perpetual futures is therefore a prerequisite for accurately assessing the effectiveness of the entire regulatory toolbox.

Decentralized exchanges pose a fundamental challenge to the traditional regulatory paradigm. When an exchange is no longer an entity operated by a specific company but a set of smart contracts deployed on a blockchain and jointly maintained by nodes worldwide, the traditional "regulate the entity" approach faces the risk of complete failure. This failure stems not from a lack of regulatory will but from the physical limits of the technical architecture: code has no nationality, a smart contract has no legal personality, and a decentralized network has no chief executive who can be subpoenaed. This does not mean, however, that decentralized finance is unregulable; only that the entry point of regulation must shift. This section analyzes how a decentralized architecture dismantles traditional compliance tools and explores how, in an environment without a centralized controller, a new type of regulatory framework can be built through code audits, front-end restrictions, and liquidity-provider obligations.

26.6.1 The spectrum of decentralization

Decentralization is not a black-and-white binary state but a continuous spectrum. In the perpetual futures market, a protocol's degree of decentralization directly determines the difficulty of regulatory intervention. Depending on how many core components run on-chain, existing decentralized perpetual futures exchanges fall into three categories: nominal decentralization, hybrid architecture, and fully on-chain architecture [38].

The nominally decentralized architecture is typified by dYdX v3 (its form before migrating to the v4 standalone chain in 2023). The protocol deploys its smart contracts on an Ethereum layer-2 network, achieving decentralization of asset custody and settlement, but its order book and matching engine still run on centralized servers operated by dYdX Trading [39]. This design guarantees users' control over their assets while providing a trading experience close to that of a centralized exchange. From a regulatory standpoint, this architecture retains a clear operating entity and centralized infrastructure, and regulators can enforce compliance requirements by requiring the operating company to implement geo-blocking or identity verification.

The hybrid architecture is typified by GMX, whose core feature is that it abandons the order-book model in favor of a global liquidity-pool design [40]. In this architecture, users' trades are matched directly against the liquidity pool as counterparty, prices are supplied by a decentralized oracle network, and the liquidation logic is executed entirely and automatically by smart contracts [41]. This design markedly raises the degree of decentralization, with no centralized matching engine and no single controlling entity. The hybrid architecture, however, still depends on an external oracle network to feed in price data, which provides a potential intervention node for regulation.

The fully on-chain architecture represents the current endpoint of decentralized evolution, typified by Hyperliquid and dYdX v4. Such protocols are usually built on a dedicated layer-1 blockchain optimized for trading, integrating the order book, matching engine, oracle, and liquidation mechanism entirely into the consensus layer [39] [42].

In Hyperliquid's design, the validator network is responsible not only for producing blocks but also for maintaining the global order book directly in memory, with all state transitions confirmed through Byzantine fault-tolerant consensus [42]. This architecture greatly reduces reliance on centralized components and approaches end-to-end decentralization. It eliminates a certain class of systemic risk arising from single points of failure but at the same time introduces new risks at the consensus and oracle layers, leaving traditional regulatory tools almost nothing to grip onto.

Figure 26-7 places the three architectures above on a continuous spectrum of decentralization from low to high: the higher the degree of decentralization, the lower the regulatory accessibility, which means that the design of regulatory tools must adjust dynamically to the regulated object's position on the spectrum.

Figure 26-7. The decentralization spectrum of DeFi perpetual futures

26.6.2 The failure of traditional tools

Traditional financial regulation is built on the foundational assumption of "intermediary institutions," achieving its policy objectives by licensing entities such as banks, brokers, and exchanges and imposing obligations on them. When a decentralized exchange eliminates the intermediary through smart contracts, this regulatory toolbox encounters a structural failure.

Licensing requirements are the first line of defense in traditional regulation, but in a fully decentralized protocol this requirement loses its object. A smart contract deployed on a blockchain cannot apply for a business license, and there is no legal-person entity to bear the legal consequences of operating without one [43]. Even if regulators attempt to hold the protocol's developers accountable, the nature of open-source software allows the writing and deployment of code to be carried out completely anonymously. More importantly, once a smart contract is set to be non-upgradeable, even its original developers cannot modify or halt its operation, which makes traditional enforcement means such as "revoking the license" or "forcing a shutdown" physically impossible [44].

AML/KYC rules are another pillar of traditional regulation, but they likewise face an enforcement predicament in a permissionless blockchain network. The essential feature

of a decentralized exchange is that it allows any user holding a crypto wallet to interact directly with the protocol, and this interaction occurs in the underlying blockchain network without passing through any centralized gateway that could perform identity verification [45]. Requiring a smart contract to verify a user's real-world identity before executing a trade is not only technically difficult but also runs counter to the core spirit of blockchain pseudonymity. This architectural feature gives decentralized exchanges a natural capacity to evade traditional identity checks, thereby weakening the global anti-money-laundering system in practice [46].

Asset-segregation requirements are used in traditional regulation to prevent intermediaries from misappropriating customer funds, and this is the core mechanism for guarding against an FTX-like collapse. In a decentralized exchange, however, this problem is largely mitigated by technical means. Users' assets are locked in publicly transparent smart contracts, and their transfer and liquidation follow predetermined mathematical logic, making it difficult for any individual or organization to bypass the code rules and use those funds [47]. On the specific dimension of custodial misappropriation, the determinism of code substitutes to some degree for human trust in an intermediary, but this does not eliminate other, new risks—such as oracle manipulation and the inadequate absorption of liquidated positions (see Section 26.6.4).

Regulatory arbitrage is the inevitable result of the failure of traditional tools. Because blockchain networks transcend geographic borders, the strict regulation imposed by one country can often only drive trading activity to offshore hubs or decentralized networks rather than truly eliminate the risk [48]. When compliance costs make centralized exchanges uncompetitive, users seeking high leverage and permissionless trading migrate naturally to decentralized alternatives. This migration not only causes regulators to lose visibility into the market but may also expose users to informal markets that lack basic protection, producing consequences contrary to the original regulatory intent [45].

26.6.3 New regulatory tools

Faced with the failure of traditional tools, the regulatory paradigm must shift from "regulating the entity" to "regulating the code" and "regulating the access point." This shift has given rise to a set of new regulatory tools adapted to the decentralized architecture, which attempt to achieve public-policy objectives without disrupting the underlying technical logic.

Code-audit requirements are becoming a core pillar of decentralized-finance regulation. Since smart contracts substitute for the functions of traditional financial institutions, reviewing the security and logical correctness of the code is equivalent to reviewing the internal controls of a traditional financial institution. Regulators can require that all smart contracts offering financial services to the public undergo a comprehensive security audit by a certified third-party auditor before deployment [49]. Such an audit must cover not only the security vulnerabilities that guard against hacking but also economic stress tests of the liquidation logic, oracle dependencies, and governance permissions. By establishing a standardized audit framework and an entry regime for audit firms, regulation can significantly improve the market's overall resilience without directly interfering in the operation of the protocol [50].

Front-end regulation represents another pragmatic compromise strategy. Although regulators cannot prevent users from interacting directly with smart contracts on the blockchain, the vast majority of ordinary users still rely on a web-based graphical user interface (the front end) to access these protocols [51]. Regulation can therefore focus on the operators of these front-end interfaces, requiring them to implement geo-blocking based on users' IP addresses or to integrate compliance-screening tools at the front-end level [52]. This "regulate the access point" strategy has already been widely adopted in practice; for example, the front ends of mainstream protocols such as Uniswap actively block access from sanctioned regions. Although advanced users can bypass these restrictions by calling contracts directly or using alternative front ends, front-end regulation effectively raises the barrier to non-compliant participation and brings the vast majority of non-professional users within the scope of protection.

Liquidity-provider obligations are an innovative regulatory idea designed for the features of the decentralized architecture. In protocols that adopt an automated market maker or liquidity-pool model, although traders may be transient and anonymous, the participants who supply large-scale liquidity are often long-lived entities with large amounts of capital [38]. Regulators can shift their approach: rather than attempting to identify every trader, they can impose compliance obligations on liquidity providers above a certain capital scale [53]. For example, they can require institutional-grade liquidity providers to conduct anti-money-laundering screening of the sources of their funds or to follow specific risk-management standards when providing liquidity. Because the on-chain behavior of liquidity providers is continuous and traceable, this strategy of focusing on large participants is far more feasible to enforce than comprehensive surveillance of all users.

26.6.4 Case study: Hyperliquid

Fully on-chain protocols, in responding to extreme market events, have displayed a complex interplay between decentralized governance and the logic of traditional regulation. The JELLY-token manipulation incident on Hyperliquid in March 2025 offers a highly valuable natural experiment for understanding this tension [54].

JELLY is a low-market-cap perpetual futures asset listed for trading on Hyperliquid. Exploiting the asset's scarce spot liquidity, the attacker established a large short position on Hyperliquid and then maliciously ramped up the price in the spot market, attempting to drain the protocol's liquidation fund pool [54]. Because JELLY's price was manipulated upward by more than 400% in a short time, and the order book lacked sufficient liquidity to absorb the forcibly liquidated short position, the position was transferred to the protocol's liquidity-provider vault, driving the vault's unrealized loss to about $13.5 million at one point (about $12 million when the validators intervened) [54][55]. In this moment of crisis, the protocol's built-in auto-deleveraging (ADL) mechanism failed to activate in time because of a flaw in the parameter setting of its trigger condition, and the solvency of the entire protocol faced a severe test [54].

Faced with systemic risk, Hyperliquid did not rely on the intervention of an external regulator but instead activated a decentralized-governance mechanism. The validator network quickly reached consensus and executed an emergency intervention through an

on-chain vote: they overrode the manipulated oracle price, forcibly closed the relevant positions at the reasonable pre-manipulation price, and compensated the affected legitimate long traders from the protocol's reserves (excluding addresses associated with the attack) [54]. At the same time, the validators voted to permanently delist the JELLY contract from the trading platform [56].

This incident reveals the potential and the limits of decentralized autonomy as an endogenous regulatory mechanism. On the one hand, it demonstrated that even without a centralized entity, a decentralized network still has the capacity to act quickly in a crisis, protect the system from malicious attack, and compensate innocent users. This crisis-handling mechanism, driven by validator consensus, in effect partly achieved the market-integrity and majority-user-protection objectives that traditional regulation pursues [57]. On the other hand, this act of intervening in contract execution by modifying the oracle price essentially broke the absolute rigidity of "code is law" and introduced the subjectivity of human judgment.

From the perspective of regulatory economics, the Hyperliquid case shows that decentralized governance is not the opposite of traditional regulation but a complementary institutional arrangement. When a protocol's architecture technically rules out the possibility of external enforcement, cultivating a healthy, fast-responding decentralized-governance mechanism—one that can internalize and enforce the basic principles of maintaining market fairness and stability—will be the most pragmatic choice for regulators confronting the decentralization paradox. Future regulatory frameworks should not seek to destroy this capacity for autonomy but should instead work to set reasonable boundaries and transparency requirements for decentralized governance, so that it can resist risk without degenerating into a tool through which a few validators abuse their power.

26.7 Empirical evidence on regulation

The economic analysis of regulatory intervention cannot remain at the level of theoretical deduction alone. The distinctiveness of the crypto-asset market lies in its high degree of data transparency and the fragmentation of the global regulatory framework, which provide a rich array of natural-experiment scenarios for evaluating the market-quality effects of different regulatory tools. Empirical evidence shows that the impact of regulation on market quality is not a one-way cost or benefit but exhibits pronounced nonlinearity and dimensional differentiation. Every regulatory intervention, while improving certain market-quality dimensions, necessarily comes at the cost of others. This section quantitatively assesses the specific impact of regulatory intervention on the five market-quality dimensions—transaction costs, price discovery, resilience, fairness, and accessibility—by analyzing the leverage limits of Japan and the European Union, exchange compliance requirements, and the enforcement actions of the SEC.

26.7.1 Empirical evidence on leverage limits

Leverage limits are the intuitive tool with which regulators address systemic risk, and their core logic is to interrupt the transmission path of the liquidation cascade by

reducing individual participants' risk exposure. The net effect of leverage limits on market quality, however, depends heavily on the parameter setting and the enforcement environment. Japan's FSA leverage-limit policy of 2020 provides a clear empirical sample of this trade-off. Before the limit was implemented, Japanese crypto-asset trading platforms generally offered leverage as high as 25x, and annual margin-trading volume once reached the scale of $500 billion [58]. In May 2020, the FSA forcibly reduced the maximum leverage on margin trading to 2x, and this policy shock directly reshaped the microstructure of the Japanese crypto market.

Figure 26-8 uses two panels to show the change in market quality before and after Japan's leverage-limit policy. On the accessibility and liquidity dimension, average monthly margin-trading volume collapsed from about $42 billion before the limit to about $5 billion per month by the end of 2020, and market depth shrank significantly; on the fairness and resilience dimension, the overall profitability rate of retained users rose from about 17% to 32%. Two points must be emphasized here. First, this profitability figure is cited by the author from [59], has not yet undergone independent public verification, and should be regarded as cited evidence rather than a verified empirical conclusion. Second, this increase stems mainly from a composition effect—the change in the makeup of market participants after high-risk retail traders exited—rather than from an improvement in the profitability of any individual trader. The essence of this trade-off is that regulation, at the cost of liquidity and retail accessibility, weeded out the most fragile market participants, thereby improving the system's overall resilience and traders' average survival rate.

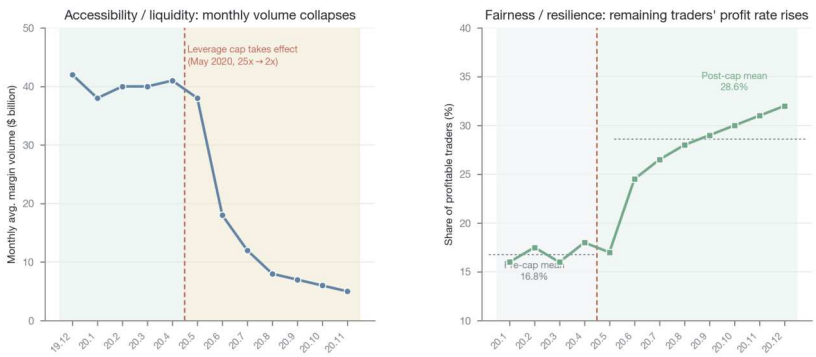

Figure 26-8. Change in market quality before and after Japan's 2020 leverage limit

Similar trade-offs also appeared in the regulatory practice of Europe and South Korea. Through its product-intervention measures for CFDs, ESMA strictly limited retail leverage on crypto-derivatives to 2x, which placed European domestic perpetual futures providers at a significant disadvantage in competing with offshore platforms offering 10x to 100x leverage [60]. South Korea's regulatory path was more aggressive: in September 2025, its Financial Services Commission (FSC) issued guidelines on crypto-asset lending that prohibit leveraged borrowing in excess of collateral value [61]. At

the same time, South Korea's long-standing controls on cross-border capital flows have impeded the free entry and exit of arbitrage capital, isolating the domestic market from the global liquidity pool and producing a structural pricing-island phenomenon, the so-called "kimchi premium" [62]. Together, these natural experiments demonstrate that, absent global coordination, unilateral leverage limits often lead to a geographic reconfiguration of liquidity rather than a fundamental elimination of systemic risk.

26.7.2 The market-quality effects of compliance requirements

An exchange's compliance status and choice of domicile directly determine the strength of the regulatory constraints it faces and, in turn, systematically affect its market-quality performance. In traditional financial-microstructure theory, stricter regulation is generally thought to improve market integrity and reduce adverse-selection costs. In the crypto-asset market, however, the relationship between compliance requirements and liquidity is more complex and dynamic. Jurisdictions that require exchanges to implement strict asset segregation, customer identity verification, and anti-money-laundering procedures often face pressure from the migration of trading volume to more lightly regulated regions.

Empirical research shows that exchanges registered in different jurisdictions exhibit significant divergence in market-quality indicators. Taking global platforms such as Binance and OKX as examples, their liquidity-provision patterns under different regulatory environments reflect the pass-through mechanism of compliance costs [63]. In markets with strict regulatory requirements, market makers face higher costs of tied-up capital and compliance-reporting burdens, and these costs are ultimately internalized as wider bid-ask spreads and thinner order-book depth. Conversely, in more lightly regulated offshore markets, lower entry barriers attract a large number of high-frequency traders and arbitrage capital, forming a highly competitive transaction-cost environment.

This liquidity stratification, driven by regulatory arbitrage, embodies the dual effect of compliance requirements. On the one hand, strict registration requirements and asset-segregation rules significantly improve market resilience and fairness and reduce the tail risk of an FTX-like collapse. On the other hand, high compliance costs constitute a substantive barrier to market entry, causing liquidity to concentrate among the few large compliant institutions that can bear these costs. This regulation-driven market concentration not only weakens competition but may also aggravate the fragility of liquidity supply under extreme market conditions. When compliant market makers retreat in unison during a crisis because of regulatory constraints or capital requirements, liquidity in the compliant market may even dry up faster than in the non-compliant market.

26.7.3 The cost of regulatory uncertainty

In assessing the economic consequences of regulation, one frequently overlooked dimension is the friction cost of regulatory uncertainty itself. When regulatory rules are ambiguous, classification standards unclear, or reliance placed on ex post enforcement rather than ex ante guidance, market participants must pay an additional premium for

the potential compliance risk. The enforcement actions the SEC took against major crypto-asset exchanges in 2023 provide an ideal window for quantifying this cost of regulatory uncertainty.

In June 2023, the SEC sued Binance and Coinbase in quick succession, alleging that they offered securities-trading services without registration. The event study by Saggu et al. shows that this strategy of establishing regulatory boundaries through enforcement caused immediate and far-reaching damage to market liquidity [64]. The event study, based on a full sample of the SEC's series of enforcement actions, finds that in the first three days after the enforcement announcements, the prices of the affected crypto-assets fell by an average of about 5.2%, with the decline widening further to about 17.2% within 30 days. More critically, trading volume dropped sharply, indicating that this was not merely a repricing of prices but a structural withdrawal of liquidity.

The damage that regulatory uncertainty does to market microstructure operates mainly through the defensive retreat of market makers. Facing ambiguous asset-classification standards and potential legal sanctions, the rational choice for compliant market makers is to widen spreads or stop providing liquidity for the relevant assets outright. The research finds that assets with smaller market capitalization and poorer initial liquidity suffered more severely under this regulatory shock, with the widening multiple of their bid-ask spreads significantly higher than that of the leading assets [64]. This liquidity evaporation, triggered by regulatory uncertainty, leaves the market highly fragile when facing an external shock. The empirical results indicate that, for market quality, an unclear regulatory framework may cause greater harm than clear but strict regulatory rules. Under ambiguous rules, the risk aversion of investors and market makers is amplified, leading to the inefficient idling of capital and the stalling of the price-discovery mechanism.

26.7.4 A comprehensive assessment of five-dimensional market quality

Based on the evidence from the preceding empirical research and natural experiments, we can systematically assess the comprehensive impact of the various regulatory tools on crypto-asset market quality. Table 26-3 aggregates the existing empirical findings and maps them onto the five-dimensional market-quality assessment framework proposed in this chapter. This matrix is not only a summary of historical data but also provides an economic benchmark for future regulatory design.

Table 26-3 reveals a core policy dilemma: in the existing regulatory toolbox, no single intervention can produce a purely positive effect across all five market-quality dimensions. Leverage limits greatly strengthen the system's resilience and protect inexperienced retail participants but inevitably harm market accessibility and overall liquidity. Mandatory customer identity verification and anti-money-laundering compliance improve market fairness and legitimacy but likewise come at the cost of accessibility and higher transaction costs. Disclosure and asset-segregation requirements are among the few regulatory tools with a high net benefit: while significantly improving fairness and resilience, they have relatively small negative spillovers to the other dimensions.

Type of regulatory intervention	Transaction costs	Price discovery	Resilience	Fairness	Accessibility	Empirical basis
Strict leverage limit (e.g., reduced to 2x)	Significant increase	Slight weakening	Significant improvement	Significant improvement	Significant decline	Japan FSA data [58][59]
Mandatory asset segregation and audit	Slight increase	Unchanged	Significant improvement	Significant improvement	Unchanged	Post-FTX comparative study [63]
Strict KYC/AML compliance	Significant increase	Unchanged	Unchanged	Significant improvement	Significant decline	Spread comparison between offshore and compliant platforms [63]
Regulatory uncertainty (enforcement actions)	Significant increase	Significant weakening	Significant decline	Unchanged	Slight decline	SEC litigation event study [64]
Isolationist policy (capital controls)	Significant increase	Significant weakening	Slight improvement	Unchanged	Significant decline	South Korea's "kimchi premium" phenomenon [62]

Table 26-3. Summary of the empirical effects of regulatory intervention on five-dimensional market quality (Data source: compiled by the author based on [58][59][62][63][64])

The ultimate lesson of this empirical matrix is that optimal regulatory design does not seek the absolute maximization of any single dimension but instead makes wise trade-offs among the five dimensions that suit specific policy objectives. If the regulator's primary objective is to guard against a systemic collapse, then accepting lower liquidity and higher transaction costs is the price that must be paid. If regulation relies excessively on ex post enforcement or imposes technically incompatible requirements, however, the regulatory uncertainty and friction costs it generates will cause market quality to deteriorate simultaneously across all dimensions. Future regulatory frameworks must therefore move from moral judgment toward cost-benefit analysis grounded in empirical data, seeking room for marginal improvement while acknowledging technical constraints.

26.8 The political economy of regulation

The analytical frameworks of the preceding sections carry an important implicit assumption: that the regulator is a benevolent social planner aiming to maximize social welfare. In reality, however, regulatory rules are not formulated in a vacuum but are the political-economy equilibrium of a game among many interests. The systematic deviation between the theoretical optimum and actual policy is precisely the object of this section's analysis. Understanding the direction of crypto-market regulation cannot proceed from the theoretical model of market failure alone; it must examine who has an incentive to push for regulation, who has an incentive to block it, and who has the ability to exert substantive influence over the rule-making process. At the intersection of decentralized finance and traditional finance, the final form of regulation is often the product of mutual compromise among stakeholders rather than the theoretical optimum in the economic sense. This section applies the theory of regulatory capture to analyze the evolution of the crypto industry's political influence, maps the stakeholders, and explores how the mechanism of regulatory competition among jurisdictions determines the ultimate quality of regulation.

26.8.1 The theory of regulatory capture

The theory of regulatory capture was advanced in 1971 by the Nobel laureate in economics George Stigler; its core thesis is that a regulatory agency will ultimately be controlled by the industry it regulates, causing regulatory rulemaking to favor industry interests over the public interest [65]. Peltzman (1976) developed this theory further, proposing that regulators are not simply captured by a single interest group but instead seek an equilibrium that maximizes political support between producers and consumers—a perspective that provides a theoretical basis for understanding the multi-stakeholder game in Section 26.8.2 [66]. In the evolution of the crypto market, this theory has attracted a growing body of empirical observation consistent with its predictions. As industry capital has accumulated, crypto firms have shifted from initially evading regulation to actively shaping regulatory rules.

The crypto industry's influence over the political process is most directly reflected in the exponential growth of its lobbying spending. Before 2020, the industry's lobbying spending in Washington was almost negligible. As the market grew and compliance pressure mounted, however, industry resources began to tilt on a large scale toward the political arena. In 2022, the crypto industry's federal lobbying spending reached $21.6 million, 2.6 times that of 2021 and 8.6 times that of 2020 [67]. By 2023, despite multiple major industry crises, this figure still set a new record of nearly $25 million, with Coinbase and the Blockchain Association among the largest spenders [68].

Figure 26-9 tracks the exponential growth of the crypto industry's federal lobbying spending from 2018 to 2024. Even amid multiple major industry crises in 2022 (the Terra/Luna collapse and the FTX bankruptcy), lobbying spending rose rather than fell—a sign that in a crisis industry participants step up their investment in the regulatory agenda, competing for a voice while the rules are being rewritten.

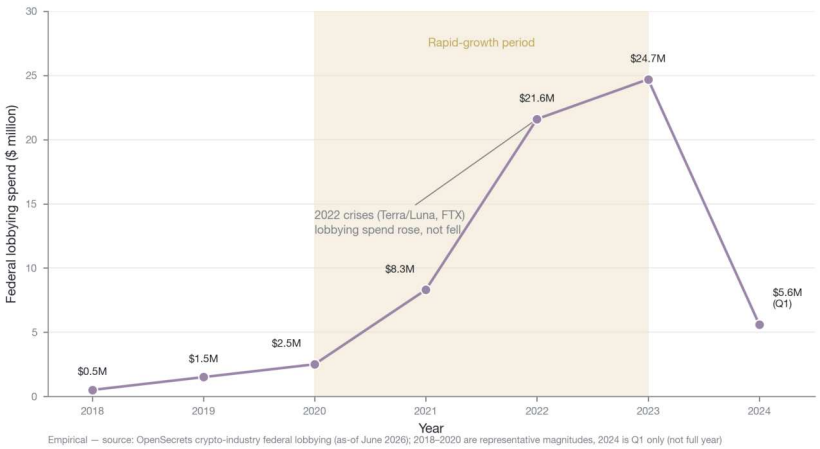

Figure 26-9. Annual trend of the crypto industry's federal lobbying spending

FTX and its founder, Sam Bankman-Fried, offer a classic instance of regulatory capture in the crypto domain. Before the company's collapse, Bankman-Fried was one of the largest donors in U.S. politics and, through his team, established direct contact with financial regulators at the highest level, seeking to advance the Digital Commodities Consumer Protection Act, which would have favored his platform [69]. This influence rested on more than capital alone; it also ran through the subtler "revolving door" effect, whereby crypto firms hired former regulatory officials and government staff at high salaries to work for their new employers using the connections and rule knowledge they had accumulated within the system.

This deep political engagement has produced an endogenous bias in regulatory policy. When the regulated hold an informational and resource advantage, they can steer legislators' attention toward specific types of risk while obscuring other risks that might touch their core business model. The observed regulatory framework therefore often reflects the strategic intentions of the dominant firms within the industry rather than an objective outcome based on a systemic risk assessment.

26.8.2 Stakeholder analysis

The driving force behind the evolution of crypto regulation originates in the ongoing game among different interest groups. In this complex ecosystem, the motives and strategies of each party determine the resistance to, and the direction of, policy progress.

The forces pushing for strict regulation consist mainly of traditional financial institutions, consumer-protection advocates, and victim groups. Traditional financial institutions play a dual role in this game: on the one hand, they view unregulated crypto platforms as a threat of unfair competition and demand that regulators apply the principle of "same business, same risk, same rules" to eliminate the space for regulatory arbitrage; on the other hand, they also hope that a clear compliance framework will remove the compliance barriers to their own entry into this emerging market. Consumer-protection advocates and the retail groups that suffered losses in market collapses constitute the social pressure pushing for regulation, demanding strict asset segregation, leverage limits,

and disclosure requirements to prevent a recurrence of an FTX-like episode.

The forces that block or seek to weaken regulation are led by crypto-native firms, industry lobbying groups, and advocates of technological innovation. The strategy of this camp is not to resist regulation outright but to advocate a "tailored," light-touch regulatory framework. They emphasize the special nature of decentralized technology, arguing that imposing traditional financial regulations designed for intermediaries on smart contracts would suppress innovation and force the industry to move overseas. Offshore jurisdictions, as this camp's implicit allies, attract capital and talent by offering a relaxed regulatory environment, which in effect raises the cost to major economies of imposing strict unilateral regulation.

Between these two opposing forces, institutional investors and large asset managers constitute a key middle force. This group manages vast amounts of capital and is eager to include crypto-assets in its portfolios but, constrained by its own compliance requirements, must operate in a regulated environment. It therefore neither wishes to see over-regulation that could shrink the market nor accepts complete laissez-faire that lacks basic property-rights protection. This demand for "moderate compliance" often becomes the decisive factor in bringing a pragmatic regulatory framework into being.

26.8.3 Regulatory competition

Because of crypto-assets' borderless nature and digital liquidity, regulatory jurisdiction faces a significant arbitrage challenge. Capital and business can cross borders easily, which puts countries and regions in direct competition over crypto-regulatory rules [70]. This competitive mechanism has a significant impact on the quality of global regulation.

In the initial stage of competition, the market widely feared a "race to the bottom." Under this pattern, in order to attract crypto firms and gain tax revenue and employment, some jurisdictions might competitively lower their compliance thresholds and relax their consumer-protection and anti-money-laundering requirements. This regulatory arbitrage not only weakens the overall safety of the global financial system but may also force countries that originally held to high standards to compromise under the pressure of capital outflow.

As the market matures and institutional investors enter, however, a "race to the top" has begun to emerge. After a series of trust crises at offshore platforms, high-quality crypto firms and large institutional investors increasingly prefer to operate in jurisdictions with a clear, rigorous, yet adaptive regulatory framework. This compliance premium has prompted financial centers such as Dubai, Singapore, and Hong Kong to compete in establishing comprehensive and clear virtual-asset regulatory regimes [71].

These emerging crypto hubs have not chosen to abandon regulation but instead compete by offering regulatory certainty. Hong Kong, for example, implemented a new licensing regime for virtual-asset trading platforms in 2023, setting extremely high requirements on asset segregation, conflict-of-interest management, and cybersecurity [72]. This competitive pattern shows that, in a crypto market with severe information asymmetry, high-quality regulation has itself become a competitive advantage: it provides reputational endorsement for the firms within a jurisdiction and lowers the

friction costs of connecting with the traditional financial system.

26.8.4 Factors affecting regulatory quality

Having identified the political-economy drivers of regulation, the core question turns to how to assess and improve the actual effectiveness of regulatory intervention. The effectiveness of regulation is not simply equivalent to the strictness of the rules but depends on a series of determinants of institutional design and enforcement capacity.

The independence and technical capacity of the regulator are the foremost factors determining regulatory quality. In a domain as highly complex and rapidly iterating as crypto, if a regulator lacks sufficient resources and expertise to understand the underlying technical mechanisms, it can easily fall into the trap of "formal compliance"—in which firms superficially meet all reporting requirements but systemic risk is not, in fact, effectively controlled. At the same time, an agency's independence determines whether it can resist the regulatory-capture pressures described above and maintain an objective balance between industry interests and the public interest.

The paradigm choice in regulatory design directly affects the adaptability of the rules. Rules-based regulation often struggles to keep pace with the innovation of smart contracts and decentralized finance and readily leads to obsolete rules or new arbitrage space. By contrast, a principles-based regulatory framework, combined with the concept of functional regulation, can better see through the technological surface and strike at the essence of financial risk. This design allows regulators to remain flexible about the technical implementation path while holding to core bottom lines (such as customer-asset segregation).

In addition, the degree of international coordination determines the size of the space for regulatory arbitrage. Absent a globally unified standard, any unilateral high-quality regulation may see its effect significantly reduced by business migration. Effective regulation must not only balance the interests of all parties domestically but also build a minimum international consensus on guarding against core risks. Only when improving regulatory quality no longer comes at the cost of a jurisdiction's competitiveness can the crypto market truly escape the prisoner's dilemma of regulatory arbitrage and achieve a long-term equilibrium between innovation and stability.

26.9 Chapter summary

Through the analytical framework of regulatory economics, this chapter has systematically answered the core questions of why to regulate, what to regulate, how to regulate, and who should regulate, and it has proposed an optimal regulatory framework based on net-benefit maximization.

The legitimacy of regulatory intervention rests on market failure, not on the market itself. The externalities, information asymmetry, undersupply of public goods, and market power in the perpetual futures market constitute four main categories of failure, but failure alone does not automatically constitute a sufficient condition for intervention—competitive mechanisms and technological innovation can repair some defects on their own, and intervention is economically justified only when the expected benefits of

regulation exceed costs such as the compliance burden, innovation suppression, and regulatory arbitrage [73]. Four conclusions can be drawn on this basis. First, asset segregation is the single tool with the highest net benefit: FTX's roughly $8 billion in customer-asset losses exposed the risk of misappropriation, and mandatory asset segregation combined with regular external audit can significantly improve resilience and fairness at relatively low compliance cost, which is why it ranks first in priority [10]. Second, functional regulation is superior to entity-based regulation: the cross-boundary nature of perpetual futures makes them hard to classify simply as a security or a commodity, whereas the functional principle of same activity, same risk, same regulation shifts the focus from institution type to specific economic function and better adapts to the rapid iteration of financial innovation [37]. Third, the cost of regulatory fragmentation may exceed that of regulation itself: the fundamental contradiction between a globalized market and fragmented sovereign jurisdiction produces, through the impossible trinity, a fragmented global regulatory map that pushes trading activity toward arbitrage space. Fourth, regulatory quality matters more than regulatory strength: disclosure and transparency requirements are the lowest-cost tools with the smallest side effects, and a well-designed framework should give priority to transparency mechanisms that promote market self-discipline.

At the practical level, an optimal regulatory framework should focus on guarding against tail risk and protecting market integrity, allocating regulatory resources first to areas such as asset segregation, reserve audit, and anti-manipulation. For centralized exchanges, compliance is no longer merely a passive cost of responding to external pressure but a strategic asset for building core competitiveness. For investors, understanding the boundaries of regulation's capability is a prerequisite for managing one's own risk, and investors need to develop the ability to assess counterparty risk independently.

Regulation plays a critical role in improving the defensive deficiencies of the perpetual futures market, but the boundary of its capability is equally clear. Legal and administrative means can mandate disclosure, set leverage caps, and regulate market-maker behavior, but they cannot change the physical mechanism of the liquidation cascade, nor can they eliminate the inherent trade-offs in a decentralized architecture. These domains that regulation cannot reach are precisely the space in which technical solutions come into play. Smart-contract audits, on-chain transparency mechanisms, and automated risk-control protocols are building an entirely new paradigm of embedded compliance [74], in which rules are hard-coded into the protocol's execution logic, thereby lowering the friction cost of compliance. Technology is not a substitute for regulation but its necessary complement. Having understood the economic logic of regulation and its limitations, the next chapter turns to a thought experiment, exploring the potential and the boundaries of perpetual futures as a universal pricing infrastructure.

A Thought Experiment on Perpetual Futures Reshaping Global Asset Pricing

177 years ago, the birth of the standardized delivery futures contract shifted pricing power over agricultural commodities from a fragmented network of spot markets to a centralized exchange. 177 years later, perpetual futures — synthetic derivatives with no expiration date — have become the highest-volume financial product in crypto markets, with average daily notional turnover reaching the scale of hundreds of billions of dollars. For the major crypto assets, perpetual futures are already the dominant force in price discovery. Now consider a counterfactual history: what if, in 1848, the Chicago Board of Trade had launched not delivery futures but perpetual futures on grain? How would history have differed? With no expiration date, farmers and buyers would no longer be troubled by the roll costs of quarterly contracts; with around-the-clock trading, participants across the world's time zones could trade at any moment; with a funding rate mechanism, the perpetual price would be automatically anchored to spot without the complex logistics of physical delivery; and with global access, anyone in the world with a communications connection could take part. In 1848 there was no internet, no blockchain, and no global communications network, so perpetual futures were technically impossible. Today, however, all of these technological preconditions are in place [1].

The previous two chapters diagnosed the current state of the perpetual futures market. Chapter 25 used a five-dimensional model of market quality to characterize its asymmetric profile — strong on offense but weak on defense — and Chapter 26 analyzed the extent to which regulation can repair these defensive deficiencies. The central question of this chapter is the following: if we set these constraints aside for the moment, and if the defensive deficiencies are progressively repaired while the offensive advantages are fully released, where does the ultimate potential of perpetual futures as a financial instrument lie? Can it transcend crypto-native assets to become a general-purpose global pricing infrastructure? When perpetual futures on any asset can be traded by anyone, anywhere, at any moment, what happens to global asset pricing? The core mechanism of perpetual futures, funding rate anchoring, does not depend on any special properties of the underlying asset; it is a general-purpose mechanism for generating synthetic exposure [2]. In his theory of macro markets, Robert Shiller argued that derivatives markets should be created for all important economic variables so that risk can be shared more

efficiently [3]. Perpetual futures may be precisely the suitable mechanism for realizing this vision, because they are a low-friction instrument for synthetic exposure. When a faster, more continuous, and more accessible pricing venue emerges, the pricing power of incumbent venues comes under structural pressure to migrate. The speed and limits of this migration depend on the new venue's ability to close the trust gap and on the progress of institutional recognition.

This chapter explores the possibilities and boundaries of perpetual futures as a general-purpose pricing layer through three progressively more ambitious thought experiments. The first examines the world's largest market, foreign exchange, and considers how foreign exchange perpetual futures could address structural inefficiencies such as fragmented trading sessions, settlement delays, and access barriers, while confronting the ultimate obstacles of central bank monetary policy transmission and anti-money-laundering compliance. The second turns to equity indices, analyzing the potential of index perpetual futures as a permissionless alternative to exchange-traded funds, and building a scenario-analysis framework to examine the price-transmission thresholds at which single-stock perpetual futures move from insignificance to systemic influence. The third examines the technical feasibility and institutional obstacles of turning commodities and emerging assets into perpetual futures — from crude oil and gold to carbon credits and real estate indices, and ultimately to prediction markets as the limiting form. Through these thought experiments, we sketch four stages in the migration of pricing power: from the establishment of pricing power over crypto-native assets, to shadow pricing of traditional assets, to institutional recognition, and finally to the integration of infrastructure.

After reading this chapter, the reader will understand that funding rate anchoring, as a general-purpose mechanism for generating synthetic exposure, applies in principle to any underlying asset; will grasp the "faster, cheaper, more accessible" logic of pricing-power migration; and will see clearly the feasibility, advantages, and obstacles of an Everything Perpetual, along with the real-world boundaries drawn by its threefold technical, institutional, and fundamental constraints. This provides the analytical foundation for the subsequent parts of the book, which take up decentralized engineering and autonomous finance.

27.1 The universality of the perpetual futures mechanism

Before developing the analysis, a methodological note about this chapter's framework is in order. There are two parallel paths for extending perpetual futures to traditional assets. The first is the centralized exchange (CEX) path: regulated centralized order-book exchanges extend the range of underlyings for perpetual futures from crypto assets to traditional assets. Examples include the tokenized equity spot products (xStocks) listed on Kraken and the tokenized equity perpetual futures that some platforms are now launching. The second is the decentralized exchange (DEX) path: permissionless on-chain protocols offer perpetual futures trading on synthetic assets through automated market makers or on-chain order books, as Hyperliquid does. The two paths share the same core principles of mechanism design — funding rate anchoring, margin management, and liquidation logic — but their execution-layer trade-offs differ sharply.

The CEX path sacrifices open access in exchange for regulatory compliance, high execution speed, and deep liquidity; the DEX path sacrifices execution efficiency in exchange for permissionless global access and censorship resistance. This chapter uses the CEX order book as its primary analytical framework, because the overwhelming majority of current perpetual futures volume occurs on centralized exchanges (for the specific share, see Section 27.1.5), and because the CEX path is the more likely near-term form for turning traditional assets into perpetual futures. The DEX path is discussed throughout as a point of comparison and complement, especially in the analysis of access barriers and regulatory constraints.

In the evolution of financial infrastructure, a tool built for one narrow purpose can end up reshaping the structure of an entire market. Perpetual futures are just such an instrument, one with systemic potential. This section steps outside the specific context of crypto assets and returns to first principles to examine the core mechanism of perpetual futures: funding rate anchoring. Through this abstraction, we can see that the funding rate is essentially a general-purpose mechanism for generating synthetic exposure, one that does not depend on any special properties of the underlying asset. In principle, so long as a reliable price oracle for the underlying asset exists, this mechanism can create perpetual futures for any asset, thereby building a general-purpose pricing infrastructure that spans everything.

27.1.1 The funding rate anchoring mechanism

When we return to first principles to examine the funding rate mechanism, we must set aside for the moment the specific context of crypto assets such as Bitcoin. The core function of the funding rate is to anchor the contract price firmly to some reference price in the absence of an expiration date and without physical delivery. This anchoring is achieved through periodic funding payments between longs and shorts: when the contract price exceeds the reference price, longs pay shorts; in the opposite case, shorts pay longs. This arbitrage incentive forces the contract price back toward the reference price [1].

In practice, the funding rate typically consists of two components. The standard formula can be expressed as $F = \text{clamp}(\text{Premium}, -d, d) + \text{clamp}(\text{Interest Rate}, -d, d)$, where the interest rate component reflects the lending spread between the quote currency and the base currency, the premium component measures the deviation between the perpetual futures' mark price and the spot index price, and the clamp function restricts the rate to within upper and lower bounds of $\pm d$ to prevent extreme swings. Centralized exchanges differ in how they implement this framework. Binance uses a volume-weighted average price method to compute the index price and settles the funding rate every 8 hours; Bybit uses a fair mark price method, smoothing the mark price through a moving-average basis; and some exchanges have raised the settlement frequency to every hour or even to continuous settlement. The theoretical analysis of Ackerer, Hugonnier, and Jermann (2025) shows that, under no-arbitrage conditions, the perpetual futures price equals the risk-neutral expectation of the spot price sampled at a random time that reflects the strength of funding rate anchoring; as the anchoring strength approaches infinity, the perpetual price converges monotonically to the spot

price, and under a particular funding rate specification the two are identical [1].

This reference price is not limited to the spot price of a crypto asset. It can be any price indicator that is observable and verifiable in public markets — the euro-dollar exchange rate, the level of the S&P 500 index, or the spot price of West Texas Intermediate crude oil, for example. So long as this reference price can be reliably obtained and transmitted to the trading system, the funding rate mechanism can operate effectively. The physical properties, trading conventions, and storage costs of the underlying asset have no material bearing on the intrinsic logic of the mechanism.

The funding rate is to perpetual futures what the interest rate is to a currency swap. In both cases it is a general-purpose tool for anchoring prices, and its effectiveness does not depend on the specific object being anchored. Just as a currency swap can be applied to any two liquid fiat currencies, the funding rate mechanism of perpetual futures can be applied to any underlying asset with reliable price discovery. The simplicity and mathematical generality of this mechanism give it the potential for universality across asset classes.

27.1.2 Applicability across asset classes

If the funding rate mechanism is so broadly applicable, why are perpetual futures today confined almost entirely to crypto-asset markets? The answer lies not in any technical limitation of the mechanism itself but in a combination of historical path dependence and the prevailing regulatory environment.

Historically, the perpetual futures instrument was launched for Bitcoin by the crypto derivatives platform BitMEX in May 2016 and rapidly scaled into widespread use [2]. The crypto community was the first to adopt this convenient, roll-free instrument, and over the following years developed it into the highest-volume product in the ecosystem. This history has created a strong cognitive inertia, so that market participants often equate perpetual futures with crypto-native products.

From the standpoint of the regulatory environment, traditional asset classes such as equities, foreign exchange, and commodities all sit within highly mature and stringent regulatory frameworks. Introducing a new kind of derivative — one with no expiration date, high leverage, and no guarantee from a central counterparty — into these traditional markets faces high compliance barriers. Crypto markets, by contrast, occupied a regulatory gray zone in their early years, and this relatively permissive environment supplied the conditions necessary for the rapid iteration and development of perpetual futures.

From a pure mechanism-design perspective, however, no economic or engineering reason restricts perpetual futures to serving crypto assets alone. Indeed, some cutting-edge decentralized exchanges have begun to offer perpetual futures on foreign exchange, equities, and commodities. Although trading in these non-crypto perpetual futures remains small in scale, their existence already demonstrates the technical feasibility of extending the funding rate mechanism to traditional asset classes. This indicates that, once the regulatory environment evolves or the technical architecture can satisfy compliance requirements, no fundamental technical obstacle stands in the way of perpetual futures

expanding across asset classes.

27.1.3 The economics of synthetic exposure

Another key dimension for understanding the universality of perpetual futures is the economics of synthetic exposure. In financial markets, capturing the return from an asset's price movements does not always require holding the asset physically. Owning the asset and owning a contract — that is, obtaining synthetic exposure — differ markedly in their economic consequences and in their trading friction.

Holding a physical asset typically requires purchase, custody, and safekeeping, a complex chain that necessarily involves settlement delays, delivery logistics, and possible restrictions on cross-border capital flows. Holding a contract, by contrast, requires the trader only to post a certain proportion of margin to obtain price exposure identical to that of holding the underlying asset. The advantages of this synthetic exposure are systemic: it achieves zero settlement delay and zero delivery cost, removes the geographic barriers to cross-border transactions, builds in leverage, and makes shorting as simple and direct as going long.

Among all instruments that provide synthetic exposure, perpetual futures represent the lowest-friction form. Traditional futures also provide synthetic exposure, but their inherent expiration date requires traders to roll their contracts periodically, and this roll cost constitutes a persistent trading friction. Exchange-traded funds (ETFs) likewise provide exposure, but they rely on an in-kind or cash creation-and-redemption mechanism, involve a complex system of authorized participants, and are confined to specific trading sessions. Perpetual futures eliminate these frictions: no expiration date means no roll cost, no delivery means no logistical friction, and the automatic anchoring of the funding rate ensures effective price tracking.

Within the spectrum of synthetic-exposure instruments, the contract for difference (CFD) closely resembles perpetual futures in functional terms: both have no expiration date, and both support leveraged, two-way trading. The two differ in one important respect at the level of market microstructure, however. A CFD is made by a broker acting as the sole counterparty, so that a trader's gain is the broker's loss; this concentrates counterparty risk in a single entity and gives the broker a structural incentive to manipulate quotes. Perpetual futures, by contrast, are traded through order-book matching on a centralized exchange or through an automated market maker on a decentralized exchange, so that counterparty risk is dispersed across the liquidation engine and the insurance fund system. In regulatory terms, CFDs are constrained by the retail-derivatives rules of particular jurisdictions — the United States prohibits retail CFD trading outright, and the European Union imposes strict leverage caps through MiFID II — whereas crypto perpetual futures have in practice achieved global access through on-chain protocols. The marginal innovation of perpetual futures relative to CFDs lies in two dimensions: the funding rate mechanism provides transparent, verifiable price anchoring (a CFD's quotes are determined entirely within the broker), and the decentralized implementation path removes the concentration of credit risk in a single counterparty.

In a 1993 book, the economist Robert Shiller set out a grand vision of macro markets.

He argued that liquid derivatives markets should be created for all important economic variables — gross domestic product, real estate prices, and national income among them — so that these major risks bearing on human welfare could be diversified and managed more effectively [3]. Given the financial technology of the time, this vision faced enormous implementation costs. Yet perpetual futures, a synthetic-exposure instrument superior to traditional alternatives in both flexibility and friction cost, fit Shiller's macro-markets vision more closely than any other existing synthetic-exposure mechanism.

27.1.4 The concept of an Everything Perpetual

Building on the preceding analysis of the universality of the funding rate mechanism and the economics of synthetic exposure, we can construct a thought experiment about a general-purpose pricing layer. At the heart of this thought experiment is a construct that we call the "Everything Perpetual" (a term coined by the author).

Imagine a unified global trading infrastructure on which perpetual futures on Bitcoin against the dollar, the euro against the dollar, the S&P 500 index, gold, and even carbon-emission metrics all trade simultaneously. All of these contracts, spanning different asset classes, share the same stablecoin margin system, the same unified clearing mechanism, and the same governance framework. On a single seamless interface, a trader can switch in an instant from long gold to short euro to long an equity index. All of this trading proceeds continuously, around the clock, is open without distinction to every participant worldwide, and settles instantly.

This construct qualifies as a pricing infrastructure, rather than merely an efficient trading platform, because once enough participants trade on the system, the prices it generates are positioned to become one of the important reference prices for global markets. Just as the futures prices of the Chicago Mercantile Exchange have long been regarded as benchmark prices for global commodities, this Everything Perpetual platform would establish pricing power across asset classes.

There is a fundamental difference from a traditional commodity exchange, however: this perpetual-futures-based general-purpose pricing layer is permissionless. Anyone, anywhere, with an internet connection and a digital wallet can take part in this global pricing process. This means that the billions of unbanked people excluded from the traditional financial system would, for the first time, gain a channel to participate in the pricing of core global assets and to manage their own economic risks. This is the central proposition of the chapter's thought experiment, and it concerns not only gains in financial efficiency but also the reconstruction of financial power.

27.1.5 The order-book microstructure of centralized exchanges

In practice, the principal vehicle for perpetual futures is the order-book matching system of centralized exchanges. Understanding this microstructure is essential for assessing the pricing efficiency of perpetual futures.

At the level of fee structure, mainstream centralized exchanges generally adopt a maker-taker fee model. The maker, who provides liquidity to the order book, typically enjoys

a lower fee or even a negative rate as an incentive, while the taker, who consumes liquidity, bears a higher fee. The economic logic of this asymmetric pricing structure is to use differentiated incentives to elicit a continuous supply of limit orders, thereby maintaining the depth of the order book and the tightness of the spread.

At the level of risk management, centralized exchanges build a multi-layered defense system to preserve the solvency of the system. The insurance fund, accumulated from liquidation gains and platform revenue, absorbs the shortfall when a liquidated position cannot be filled at the bankruptcy price or better. When the insurance fund is insufficient to cover the losses, the auto-deleveraging (ADL) mechanism ranks counterparties by profit and forcibly closes out the most profitable counterparty positions against the bankrupt position. Some exchanges also retain a socialized-loss fallback, allocating the residual loss pro rata across all profitable accounts. Together, these mechanisms form the solvency-assurance chain for perpetual futures on centralized exchanges.

Centralized exchanges also maintain a multi-tiered price system to balance different risk-management needs. The last traded price reflects the actual price of the most recent match in the order book. The mark price, typically computed as a weighted combination of the spot index price and a decaying basis, is used for profit-and-loss calculation and for triggering liquidations; its purpose is to filter out the price spikes caused by short-term manipulation. The index price aggregates a weighted average across multiple spot exchanges and serves as the anchoring benchmark for the funding rate calculation. Binance uses a volume-weighted average price method to compute the index price, whereas Bybit uses a fair mark price method, and the two methods perform differently under extreme market conditions. These design choices give the perpetual futures of centralized exchanges a marked competitive advantage in liquidity depth, execution speed, and risk-control maturity, making them the dominant form in the current perpetual futures market. As of 2025, centralized exchanges accounted for more than 90% of total perpetual futures volume (by notional turnover) [4].

27.2 The historical logic of pricing-power migration

The migration of pricing power is not a theoretical hypothesis but an objective phenomenon that recurs throughout financial history. In every major shift in market structure, pricing power moves from the old trading venue to the new one. This migration typically follows a similar logical pattern, and understanding this historical regularity is important for assessing whether perpetual futures have the potential to take over global asset pricing.

27.2.1 Three migrations of pricing power

Looking back over the development of modern financial markets, we can clearly identify three consequential migrations of pricing power.

The first migration occurred in the mid-to-late nineteenth century and marked the movement of pricing power from fragmented spot markets to a centralized futures exchange. The Chicago Board of Trade was founded in 1848 and initially traded forward (or “to-arrive”) contracts; its truly landmark innovation came around 1865, when it

transformed forward contracts into standardized delivery futures — unifying quantity, quality, delivery location, and delivery date, and introducing margin and formal settlement rules [5]. Before this, pricing power over agricultural commodities was dispersed across countless local spot-trading networks, and information asymmetry produced violent price swings. The advent of the Chicago Board of Trade allowed farmers and buyers to lock in future buying and selling prices in advance, giving them certainty. This standardized and centralized trading model sharply reduced information costs and price uncertainty, so that the exchange's futures prices quickly became the reference prices for the global grain market, completing the first major migration of pricing power.

The second migration took place between the 1990s and the 2010s and was characterized by the movement of pricing power from traditional open-outcry floor trading to electronic trading systems. As computing technology and communications networks spread, electronic matching platforms — exemplified by the Chicago Mercantile Exchange's Globex system and Nasdaq — gradually displaced the traditional trading floor [6]. This migration greatly increased trading speed, compressing execution time from seconds to milliseconds; it also sharply reduced the high costs of manual matching and broke the constraints of physical space, allowing investors worldwide to participate more easily in market pricing.

The third migration occurred mainly from the early 2000s into the 2020s and manifested as the movement of pricing power from traditional delivery futures to exchange-traded funds. For certain assets, particularly equity indices and gold, the trading volume of exchange-traded funds gradually surpassed that of the corresponding futures contracts (such as the Chicago Mercantile Exchange's E-mini futures on the S&P 500), making ETFs the primary tool through which retail investors and some institutional investors obtain market exposure [7][8]. The success of exchange-traded funds rests on their minimalist user experience: investors need not manage complex futures accounts and margin, and can participate simply through an ordinary securities account. Moreover, the total holding cost of an exchange-traded fund is typically lower than the roll cost of a futures contract, which further accelerated this migration.

27.2.2 The drivers of migration

The three migrations of pricing power follow a common driving logic that can be distilled into four core elements: faster (lower trading latency and higher-frequency information processing), cheaper (lower total transaction and access costs), more accessible (a broader range of participants and a lower barrier to entry), and more trustworthy (regulatory protection, depth of institutional participation, and legal certainty). In all three historical migrations, the new venue was no weaker than the old on the trustworthiness dimension, so that dimension did not become a constraint; yet it is precisely the principal weakness of perpetual futures relative to traditional markets. From standardized futures lowering search costs, to electronic matching compressing execution time to milliseconds, to exchange-traded funds turning complex exposure into a product accessible through an ordinary securities account, each migration was the result of the new venue accumulating sufficient advantage along these three dimensions. Throughout this

process, resistance from incumbents delayed but could not reverse the migration; once the efficiency advantage of the new venue is sufficiently pronounced, the migration of pricing power tends ultimately to occur. Section 27.7 further analyzes how this driving logic acts specifically on the extension of perpetual futures to traditional assets.

27.2.3 The candidacy of perpetual futures

Assessed against this framework, perpetual futures hold a structural advantage on two dimensions: faster (around-the-clock continuous trading, which eliminates the price vacuum of non-trading hours) and more accessible (permissionless global access with a very low barrier to entry). On the cheaper dimension, they hold an advantage in some asset classes because they eliminate roll costs and delivery logistics. Their principal weakness lies in the trustworthy dimension: the institutional accumulation of traditional markets in regulatory protection, depth of institutional participation, and legal certainty constitutes a trust gap that perpetual futures must close. The speed at which this gap narrows will directly determine the course of pricing-power migration, and Section 27.7 develops a detailed analysis through a four-stage model.

27.3 Thought experiment I: foreign exchange perpetual futures

Foreign exchange is the largest financial market in the world, and its depth of liquidity and breadth of trading form a cornerstone of the modern international financial system. According to the Bank for International Settlements (BIS), average daily turnover in the global foreign exchange market reached about $9.6 trillion in April 2025, roughly 28% higher than in the same period of 2022 [9]. Despite its vast scale, however, this market still exhibits pronounced structural inefficiencies. This section takes foreign exchange perpetual futures as the starting point for a thought experiment, examining which problems the perpetual futures mechanism can solve when applied to the world's largest financial market, and which insurmountable institutional obstacles it would face.

27.3.1 Structural inefficiencies of the foreign exchange market

The foreign exchange market is nominally a market that operates around the clock, yet its internal structure is markedly fragmented. The first issue is the uneven distribution of liquidity across trading sessions. Liquidity is heavily concentrated in the overlapping London and New York sessions, while the Asian session is relatively thin. More critical still, during the non-trading hours of the weekend the market loses its price-discovery function entirely. When a geopolitical event or major macroeconomic data release occurs over the weekend, participants must wait for the "open" on Sunday evening or Monday morning before they can trade. This "weekend gap" constitutes a serious information-transmission delay and a structural inefficiency.

The second issue is the systemic risk created by settlement delay. The standard settlement cycle for traditional foreign exchange transactions is typically 2 days, which means that after reaching an agreement the two parties must bear 2 days of settlement

risk exposure. In a market with daily volume in the trillions of dollars, this delay accumulates enormous systemic risk. Although some traditional financial markets have recently begun to shorten their settlement cycles — the U.S. equity market, for example, has shortened its cycle from 2 days to 1 day [10] — the complex network of the global foreign exchange market makes universal instant settlement a formidable challenge.

The final issue is access barriers and execution costs. For retail investors and small and medium-sized enterprises, the barrier to direct participation in the core foreign exchange market is extremely high. They can generally trade only through brokers or commercial banks, and in this "last mile" they face wide bid-ask spreads and suboptimal execution quality, bearing a disproportionate share of transaction costs.

27.3.2 The design of foreign exchange perpetual futures

If we introduce the perpetual futures mechanism into the foreign exchange market — designing, say, a euro-dollar perpetual futures contract — its core architecture would display characteristics quite different from those of traditional foreign exchange derivatives. The contract could be denominated and settled in a stablecoin, with its price anchored to the spot euro-dollar exchange rate through the funding rate mechanism. An oracle network would obtain and transmit the spot price in real time, while the funding rate could settle at an hourly or even continuous frequency.

Compared with the traditional foreign exchange futures offered by the Chicago Mercantile Exchange, foreign exchange perpetual futures eliminate the constraint of an expiration date and thus dispense with the roll operations traders must perform at expiry and the costs that accompany them. More importantly, they achieve genuine around-the-clock continuous trading and eliminate the weekend gap. At the same time, a stablecoin settlement mechanism built on a blockchain network achieves instant delivery, replacing the 2-day settlement delay of traditional markets.

From the standpoint of pricing theory, the pricing of traditional foreign exchange forwards rests on covered interest rate parity. Within the perpetual futures framework, the funding rate should, in long-run equilibrium, converge toward the risk-free interest rate differential between the two underlying currencies. This prediction is empirically testable, and it shows that the funding rate mechanism does more than anchor prices: it intrinsically reflects differences in macroeconomic variables.

27.3.3 Potential advantages

The core structural advantage of foreign exchange perpetual futures lies in their capacity for around-the-clock continuous pricing. In today's highly interconnected world, geopolitical risks and sudden events are not confined to the business hours of a traditional exchange. If foreign exchange perpetual futures achieved around-the-clock trading, a sudden event on a Friday evening could be absorbed by the market and reflected in prices within minutes, rather than waiting for an open more than 40 hours later. Such a mechanism would produce a structural leap in informational efficiency.

The instant settlement mechanism likewise has significant practical value. Instant settlement via stablecoins eliminates the 2-day settlement risk exposure, which matters

greatly for the risk management of multinational corporations and large financial institutions. It reduces counterparty risk and substantially improves capital efficiency.

Moreover, undifferentiated global access gives foreign exchange perpetual futures an important dimension of financial inclusion. Around the world, billions of people live in countries or regions with strict foreign exchange controls, and they cannot freely convert into strong currencies through legal channels to protect their assets. Foreign exchange perpetual futures running on a decentralized network can provide these populations with a tool for obtaining synthetic foreign exchange exposure. The core value of such a tool lies not in speculation but in giving ordinary people a way to hedge against depreciation of their home currency, which carries considerable social value.

27.3.4 Core obstacles

Although foreign exchange perpetual futures hold clear advantages in mechanism design, their broad adoption faces powerful resistance from sovereign states and the existing financial system. The foremost obstacle is the monetary policy transmission mechanism of central banks. Central banks rely on their intervention in, and influence over, the foreign exchange market to implement monetary policy and safeguard domestic economic stability [11]. A globally mobile perpetual futures market controlled by no single jurisdiction could weaken the transmission of central bank monetary policy. Sovereign states will not lightly relinquish control over the pricing power of their currencies or over the foreign exchange market.

Anti-money-laundering compliance is another formidable obstacle. The foreign exchange market has always been a high-risk arena for cross-border capital flows and money laundering. A permissionless, decentralized foreign exchange perpetual futures platform faces enormous technical and institutional challenges in implementing adequate know-your-customer (KYC) and anti-money-laundering (AML) procedures. Regulators take a cautious stance toward financial infrastructure that cannot trace the source of funds or the identity of traders [12].

The settlement needs of the real economy also mean that perpetual futures cannot fully replace the spot market. Multinational enterprises making international trade payments require genuine transfers of currency, whereas perpetual futures can offer only a synthetic derivative of price exposure and cannot meet the need for physical delivery. The contract market and the spot market are therefore bound to coexist over the long run, with the former relying on the latter for its price anchor.

Finally, the reliability of the oracle constitutes a single point of risk at the technical level. Trading volume in the foreign exchange market is extremely large, and even a tiny deviation in an oracle's quote could be exploited by high-frequency traders, producing large arbitrage losses. Whether current oracle infrastructure possesses the stability and manipulation resistance required to support a foreign exchange derivatives market on the order of trillions of dollars remains an open question in urgent need of verification.

27.3.5 Feasibility assessment

Taking the preceding analysis together, foreign exchange perpetual futures are more likely in the near term to serve as a complement to the existing traditional foreign exchange market than as its replacement. They can play a distinctive role in filling the weekend pricing vacuum and lowering the barrier to entry for retail investors. For ordinary people in emerging markets, they offer a practical tool for hedging the risk of home-currency depreciation.

Over the longer term, if oracle technology achieves a fundamental breakthrough and the regulatory framework for decentralized finance becomes progressively clearer and widely accepted, foreign exchange perpetual futures could divert a portion of the speculative trading volume of traditional markets. Yet because the central position of central banks and sovereign governments in the monetary system is a cornerstone of the modern state, foreign exchange perpetual futures cannot fully replace the traditional foreign exchange market. The migration of pricing power will be a gradual and constrained process, finding its ultimate equilibrium in the interplay between technological innovation and institutional constraint.

27.4 Thought experiment II: equity index perpetual futures

The success of exchange-traded funds demonstrates substantial latent demand for simplified ways of obtaining asset exposure. Along this trajectory, equity index perpetual futures can reasonably be understood as the ETF's next evolutionary form. They build an around-the-clock, global, and permissionless trading environment. Inevitably, however, this innovative mechanism must confront the institutional advantages that ETFs have accumulated over time, as well as the challenge of winning regulators' acceptance.

27.4.1 The success and limits of the ETF

Since the first ETF tracking the S&P 500 index (SPY) appeared in 1993, ETFs have become one of the most successful products in the democratization of finance. By the end of 2025, global ETF assets under management approached $20 trillion (of which U.S.-listed ETFs accounted for about $13 trillion), and U.S.-listed ETFs attracted about $1.5 trillion of net inflows in 2025 alone, a record high [7]. This product structure allows ordinary investors to obtain broad market exposure at very low cost.

Despite this enormous success, the ETF mechanism retains inherent structural limits. The first is the rigidity of the trading session. SPY, for example, trades mainly during New York's regular session, from 9:30 a.m. to 4:00 p.m. Eastern Time. Participants in other time zones must passively adapt to this window, and Asian investors cannot directly participate in the pricing and trading of SPY during their own regular working hours [13]. The second is geographic and institutional barriers. Non-U.S. residents who wish to buy U.S.-listed ETFs generally must open a securities account across borders, facing burdensome compliance review and obstacles to moving funds internationally.

A more fundamental limit lies in the ETF's liquidity-creation mechanism. The arbitrage anchoring of an ETF depends heavily on the creation-and-redemption mechanism

operated by authorized participants. In the primary market, these large financial institutions swap a basket of underlying securities for ETF shares, keeping the ETF's market price closely aligned with its net asset value [14]. During extreme market volatility, however, authorized participants may withdraw from market-making because of evaporating liquidity or risk considerations, causing the ETF to trade at a large premium or discount — a phenomenon analyzed in detail in Chapter 18 of this book.

27.4.2 The design of index perpetual futures

To break through these limits, on-chain equity index perpetual futures offer a wholly new mechanism design. Consider the SPX perpetual futures tracking the S&P 500 index: their core architecture typically uses a stablecoin (such as USDC) as the unit of denomination and settlement. The contract involves no actual delivery of the underlying stocks; instead, an oracle system continuously obtains the latest level of the S&P 500 index as the reference benchmark. On this basis, the funding rate mechanism substitutes for the arbitrage behavior of authorized participants, automatically anchoring the perpetual futures' trading price to the spot index price through funding exchanges between longs and shorts [15].

To display the structural differences of this design more clearly, Table 27-1 systematically compares the traditional SPY ETF with an idealized SPX perpetual futures contract across 10 core dimensions. This multidimensional comparison helps identify the dimensions on which perpetual futures hold a structural advantage and those on which they carry an inherent institutional weakness.

Comparison dimension	SPY ETF (traditional finance)	SPX perpetual futures (on-chain finance)
Trading session	New York regular session (6.5 hours per day)	Around the clock, uninterrupted (24/7)
Global access	Geographic barriers; requires a U.S. securities account	Permissionless; requires only a crypto wallet (decentralized version)
Access to leverage	Depends on broker financing; constrained by regulatory margin requirements	Built into the protocol; typically 1x to 20x or higher
Shorting mechanism	Requires borrowing shares, with high costs and limited supply	Open a short directly, with no additional friction cost
Settlement cycle	Delayed settlement (T+1)	Instant settlement via smart contract
Holding cost	Fixed annual management fee (about 0.09%)	Dynamic funding rate (potentially much higher than the management fee)
Price anchoring	In-kind creation and redemption by authorized participants	Algorithmically driven funding rate arbitrage
Regulatory protection	Strictly regulated by the U.S. Securities and Exchange Commission (SEC)	Regulation absent or in a gray zone
Oracle dependence	No external price feed required	Core mechanism; highly dependent on oracle accuracy
Ownership attributes	Includes voting and dividend rights of the constituent stocks	Pure price exposure, with no corporate governance rights

Table 27-1. Comparison of the core mechanisms of the SPY ETF and SPX perpetual futures (Data source: CoinDesk reporting on Kraken's tokenized equity perpetuals [15]; Schwab Asset Management report on the ETF creation-and-redemption mechanism [14]). Note: the comparison of 6.5 hours with 24/7 is a coarse-grained contrast along the trading-session dimension; assessing the actual execution cost of arbitrage across U.S. cash equities, futures, and ETFs would also require incorporating the pre-market and after-hours sessions, the CME's near-around-the-clock trading, and the authorized-participant creation-and-redemption mechanism discussed in Chapter 18

As shown in Table 27-1, SPX perpetual futures hold a structural advantage over the SPY ETF on five dimensions: trading session, global access, access to leverage, ease of shorting, and settlement speed. These advantages are not marginal improvements but stem from a fundamental difference in the underlying architecture: the synthetic-exposure mechanism eliminates the frictions of physical delivery and intermediary institutions. Yet the table also clearly reveals the institutional weaknesses of perpetual futures: the absence of regulatory protection means that investors lack legal recourse in a dispute; the loss of ownership attributes means that they cannot replace the ETF's function as a tool for long-term value investing; and the uncertainty of holding cost (a dynamic funding rate can, under extreme market conditions, far exceed an ETF's fixed management fee) adds further unpredictability to long-term holding strategies. This asymmetric profile of "strong on offense, weak on defense" runs throughout the comparison between perpetual futures and traditional financial products.

27.4.3 Potential advantages

The clearest near-term value of index perpetual futures is filling the Asian-session pricing vacuum. In the current market structure, after the U.S. equity market closes, for more than 10 hours global investors have no effective venue to price their views on changes in the U.S. macroeconomy or in corporate fundamentals. If a major geopolitical event or an emergency statement by the Federal Reserve (Fed) occurs during this window, traditional markets must wait for the New York open to release the accumulated pricing pressure. The around-the-clock nature of SPX perpetual futures can effectively fill this vacuum, so that information enters the price-discovery process the instant it arises [16].

Moreover, this mechanism greatly extends the boundaries of financial inclusion. Billions of people worldwide are constrained by local financial infrastructure and cannot easily buy U.S. ETFs. Through the SPX perpetual futures of a decentralized exchange, these groups need only an internet connection and a digital wallet to gain exposure to the world's most important equity market, which democratizes global capital allocation to a degree.

At the level of market microstructure, perpetual futures markedly reduce the friction cost of expressing a bearish view. In the traditional equity market, shorting requires locating a supply of shares and paying high borrowing fees, and this asymmetric transaction cost means that negative information often fails to be reflected promptly and fully in asset prices. The symmetric design of perpetual futures makes shorting as convenient as going long, which helps improve the price-discovery efficiency of the market as a whole.

27.4.4 Core obstacles

For all the ingenuity of their mechanism design, index perpetual futures still face insurmountable obstacles in real-world adoption. The first is the regulatory challenge. The core duties of securities regulators are investor protection and the maintenance of orderly markets, and they are highly unlikely to embrace, in the near term, an S&P 500 derivative that sits outside the traditional compliance framework. Although a decentralized exchange can, through its technical architecture, evade some direct jurisdiction, doing so also means transferring all compliance risk and counterparty risk entirely onto ordinary users [15].

The reliability of the oracle system constitutes another key technical bottleneck. During the regular U.S. equity session, perpetual futures can easily obtain real-time index quotes from data sources such as Bloomberg or Reuters. But during the long non-trading hours, the spot market ceases to operate, and the oracle can rely only on the relatively thin after-hours session or on E-mini futures prices as a reference [17]. This fragility of the data source makes perpetual futures highly susceptible to malicious manipulation during non-trading hours, and a tiny oracle deviation, amplified by leverage, could trigger a catastrophic liquidation cascade.

Another core tension is that index perpetual futures are, in essence, decoupled to some degree from the real economy. They provide pure synthetic price exposure and confer no

ownership whatsoever in the underlying listed companies. This means that a holder of perpetual futures can neither exercise shareholder voting rights nor participate directly in corporate dividends. In terms of financial function, they are not fully equivalent to an ETF that represents ownership of real assets, and this limits their potential to become the preferred tool for long-term value investing.

27.4.5 Near-term value

Weighing their advantages and obstacles together, we can reach a relatively conservative judgment: even if index perpetual futures cannot fully replace the traditional ETF in the foreseeable future, the single function of filling the Asian-session pricing vacuum is enough to establish their distinctive value in the modern financial ecosystem. They can be positioned precisely as an extension of, and complement to, the traditional ETF in trading session and geographic reach.

This convergence and complementarity has in fact already begun to take place in the market. In early 2026, leading platforms including Kraken began launching regulated tokenized equity perpetual futures, supporting 24/7 trading of major indices including the S&P 500 [15]. At the same time, oracle infrastructure such as Chainlink launched U.S. equity data streams covering the full trading day on weekdays (24/5, including the pre-market, after-hours, and overnight sessions), providing continuous pricing support for on-chain derivatives — though continuous pricing over the weekend remains an unresolved gap [17]. Although overall trading volume still appears negligible compared with traditional markets, the completion of this proof of concept marks a key step in the penetration of crypto-native mechanisms into the pricing power of traditional financial assets.

27.5 Scenario analysis: price transmission in TSLA perpetual futures

In the evolution of financial infrastructure, the process by which a new market moves from the periphery to the core is not a linear, gradual progression but often exhibits pronounced phase-transition characteristics. When a new derivatives market attempts to contest pricing power over an asset, it must cross a series of thresholds in liquidity and informational efficiency. This section builds a conceptual scenario-analysis framework, taking Tesla, Inc. (ticker: TSLA) as the benchmark asset, to examine how a hypothetical "TSLA perpetual futures" market might, under varying conditions, progressively acquire and even come to dominate global pricing power over the asset. This thought experiment is not only a test of the theoretical framework developed above but also an attempt to answer a central question: what scale must permissionless on-chain perpetual futures reach before they materially affect the price-discovery process of traditional financial markets, forcing institutional traders to incorporate on-chain price signals into their decision-making framework?

27.5.1 The traditional pricing ecosystem of TSLA

The subjects of the previous two thought experiments — the foreign exchange market and equity indices — are macro-level asset classes whose pricing is dominated by the aggregation of many constituents. This section shifts the analytical granularity down from the index level to the level of a single stock. We choose an individual stock rather than an index because individual stocks have higher volatility, more pronounced information asymmetry, and fiercer contests between institutions and retail investors, which makes for a more extreme test of pricing-power migration. If perpetual futures can capture a material contribution to price discovery in the demanding case of a single stock, their prospects at the index level become more certain.

The choice of Tesla as the subject of the scenario analysis is not random. In contemporary financial markets, TSLA has a set of distinctive microstructure characteristics that make it a suitable subject for testing the pricing-power-migration hypothesis. As the world's most valuable automaker, TSLA has a highly complex and active pricing ecosystem. As of March 2026, Tesla's market capitalization stood at around $1.48 trillion, and its stock exhibited very high liquidity, with average daily volume steady at around 65 million shares and average daily turnover exceeding $25 billion [18]. Such a vast liquidity pool means that any new market seeking to challenge its pricing power must possess extremely deep market thickness.

More critically, in traditional markets TSLA displays a dual character of high volatility and high information sensitivity. Its 5-year monthly beta is as high as 1.93, and its implied volatility has long held at around 45% [18]. In the options market, TSLA is one of the most actively traded single-stock options in the world, with open interest in call options alone remaining above 3.9 million contracts year-round [18]. This microstructure, driven jointly by a vast retail base and high-frequency quantitative institutions, makes TSLA's price-discovery process highly dependent on the capacity to process information instantly.

Yet although TSLA enjoys near-perfect pricing efficiency during the regular session (9:30 a.m. to 4:00 p.m. Eastern Time), the after-hours and weekend periods expose the inherent flaws of the traditional market structure. During the after-hours session, TSLA's volume typically plunges to around 1.5 million shares, less than 3% of the regular session [19]. This evaporation of liquidity causes the after-hours spread to widen markedly, and the price's response to information becomes extremely fragile and prone to overshooting. When a major event — such as an Elon Musk tweet or a sudden geopolitical event — occurs during non-trading hours, traditional markets can absorb the information only through the extremely thin after-hours session or by waiting for the open on the next trading day, producing a large "time gap" and arbitrage opportunity. It is precisely this session-based pricing vacuum that offers around-the-clock (24/7) perpetual futures a structural opening into the global pricing system.

Before constructing the TSLA scenario analysis, empirical data from the Bitcoin perpetual futures market provide a useful reference anchor. Using the information-share method of Hasbrouck (1995), the empirical study of Alexander and Heck (2020) shows that unregulated crypto derivatives markets (perpetual futures and futures) already command about half of the information share in Bitcoin price discovery and domi-

nate the price-discovery process [20][21]; the study by De Blasis and Webb (2022) of arbitrage and spillover effects between quarterly and perpetual contracts on crypto exchanges likewise confirms the dominant role of derivatives markets in pricing [22]. As of 2025, according to CoinGlass data, the average daily volume of Bitcoin perpetual futures accounted for more than 60% of Bitcoin's total market volume (spot and derivatives combined), making perpetual futures the dominant venue for pricing crypto assets [4]. This "already-realized first stage" provides an empirical reference for the TSLA scenario analysis that follows: the trajectory by which Bitcoin perpetual futures grew from a marginal tool into the dominant force in price discovery can serve as a lower-bound estimate of the potential development path for perpetual futures on traditional assets. Bitcoin, however, as a digitally native asset, owes the success of its perpetual futures to special conditions — no need for physical delivery, and little competition from traditional alternatives — so extrapolating directly to traditional equities such as TSLA still calls for caution.

27.5.2 The price-transmission model

To assess systematically the potential influence of TSLA perpetual futures on the spot market, we construct a conceptual price-transmission framework. A caveat is essential here: the functional forms, thresholds, and PTI values given in the following model and in the subsequent figures are all illustrative estimates intended to organize thinking and to display orders of magnitude and nonlinear shapes; they are neither a directly runnable quantitative model nor to be read as precise forecasts or statistical estimates. In market microstructure theory, the contribution to price discovery of two parallel markets is usually measured through the information-share model proposed by Hasbrouck (1995) or the Gonzalo-Granger component-share model [21]. Drawing on this methodological framework, we define the "price transmission intensity" (PTI) as the weight of the perpetual futures market in the total price-discovery process, ranging from zero (completely passive acceptance of the spot price) to one (complete dominance of the spot price); intuitively, PTI measures the "share of voice" the new venue holds in price movements.

Price transmission intensity is not determined by a single variable but is a nonlinear function of the interaction of several market-microstructure parameters. In our model, the core variables that determine PTI span four dimensions. The first is relative liquidity depth — the ratio of the bid-ask depth of the perpetual futures market to that of the traditional spot and options markets. Only when the depth of the perpetual market is sufficient to absorb institutional-sized orders without producing a destructive price impact will market makers in traditional markets have an incentive to arbitrage across markets. The second is the difference in information-processing speed, which reflects the time lag between the two markets in completing a price update after receiving new information. The block-confirmation time and oracle latency of on-chain perpetual futures must be low enough to gain an edge in the competition over information.

The third determinant is the sensitivity of the funding rate. The funding rate is the sole mechanism by which perpetual futures anchor to the spot price, and its speed of response to price deviations and the severity of its penalty directly determine the

direction in which arbitrage capital flows. If the funding rate adjusts too sluggishly, the perpetual futures will devolve into a freestanding speculative casino; if it adjusts too violently, it will trigger frequent liquidation cascades. The last determinant is cross-market arbitrage friction, which includes trading fees, delays in transferring funds, compliance costs, and the friction of on-chain and off-chain fiat channels. This friction coefficient constitutes the physical resistance to price transmission, and only when the price difference between the perpetual futures and spot exceeds this friction threshold is the price-transmission mechanism truly activated.

By feeding these four variables into a nonlinear dynamical system, we can simulate how, as the perpetual futures market grows in scale, its pricing power penetrates the traditional TSLA spot market. This process is not a smooth linear rise but undergoes abrupt shifts at particular parameter thresholds, displaying clear stage-wise leaps.

27.5.3 A five-stage scenario simulation

Building on the model framework above, we simulate the development trajectory of TSLA perpetual futures as five progressive stages, each representing a paradigm shift in the transmission of pricing power.

The first stage is the "shadow market" stage. Here, TSLA perpetual futures have a daily volume of less than 1% of the spot market (about $250 million). The perpetual market is at this point entirely a dependency of the traditional market, its price passively supplied by an oracle. Because liquidity is thin, any medium-sized order pushes the perpetual price sharply away from the spot price, after which a high funding rate forcibly pulls it back. At this stage, price transmission intensity is close to zero; the market lies outside the monitoring field of traditional financial institutions and has not yet drawn the attention of institutional traders. It exists only as a marginal tool for high-leverage speculation by crypto-native users.

The second stage is the "extreme-conditions buffer" stage. When the daily volume of perpetual futures reaches 5% to 10% of spot (about $1.2 billion to $2.5 billion), the market structure begins to change subtly. During the regular session, the perpetual market remains a price taker. When the market experiences extreme volatility, however — say, an earnings shock that drives the spot price limit-down — some of the panicked selling that cannot be closed out in the traditional market spills over into the perpetual market. The depth of the perpetual futures is not yet sufficient to reverse the spot trend, but the additional liquidity pool it provides begins to serve as a buffer. Market makers start to run algorithms for rough statistical arbitrage between the two markets, and under extreme conditions PTI leaps briefly to around 10%.

The third stage is the "non-trading-hours dominator" stage, and it marks the first critical threshold in pricing-power migration. As perpetual futures volume reaches 20% of spot (about $5 billion), their around-the-clock trading advantage begins to show. If a major sudden event involving TSLA occurs over the weekend or after hours, the traditional market cannot respond because it is closed, while the perpetual market immediately begins price discovery. Because the perpetual market now has considerable depth, the price it forms is no longer noise but embodies a genuine market consensus. When Nasdaq opens on Monday, the spot price gaps up or down directly to meet the

price the perpetual market formed over the weekend. At this stage, the perpetual market's PTI during non-trading hours is as high as 80% or more, though during the regular session it still takes second place.

The fourth stage is the "arbitrage engine" stage. When the perpetual market reaches 50% of spot (about $12.5 billion), it has grown too large for the traditional market to ignore. Large quantitative funds and high-frequency trading firms begin to make it part of their core strategies. At this stage, the funding rate of the perpetual futures is no longer merely an anchoring mechanism but becomes a leading indicator for predicting the short-term direction of spot. If the perpetual price stays persistently above spot, large arbitrage capital buys TSLA in the spot market while shorting in the perpetual market, and this arbitrage transmits the perpetual market's long sentiment directly to the spot market, pushing the spot price up. At this point, PTI during the regular session holds steady at 30% to 40%, and the perpetual market has become an indispensable engine in TSLA's global pricing system.

The fifth stage is the "pricing-power reversal" stage. In the limiting scenario of the simulation, TSLA perpetual futures volume exceeds the combined total of the spot and traditional options markets (what follows is an extrapolation of the model's limiting scenario, not a forecast about TSLA). This typically occurs after compliance channels are fully opened and traditional institutional capital connects seamlessly to on-chain infrastructure. At this stage, the perpetual market — by virtue of zero settlement delay, no physical-delivery friction, and undifferentiated global access — becomes the venue with the deepest liquidity and the fastest response to information. The traditional spot market is instead reduced to a "derivative," its price passively following the movements of the perpetual market. Market makers set their spot-market quotes primarily by reference to the real-time order book of the on-chain perpetual futures. At this point, PTI exceeds 60%, and pricing power reverses in the sense of the model, just as delivery futures once wrested pricing power over agricultural commodities from fragmented spot markets.

Figure 27-1 plots the PTI trajectory of these five stages as an S-shaped curve against the perpetual futures' share of trading volume. Its core message is that pricing-power migration is not a linear, quantitative process but exhibits phase-transition behavior at two critical thresholds, 20% and 50%: before a threshold, the marginal contribution of incremental liquidity is extremely limited, but once it is crossed, a positive feedback loop drives PTI to leap rapidly toward saturation.

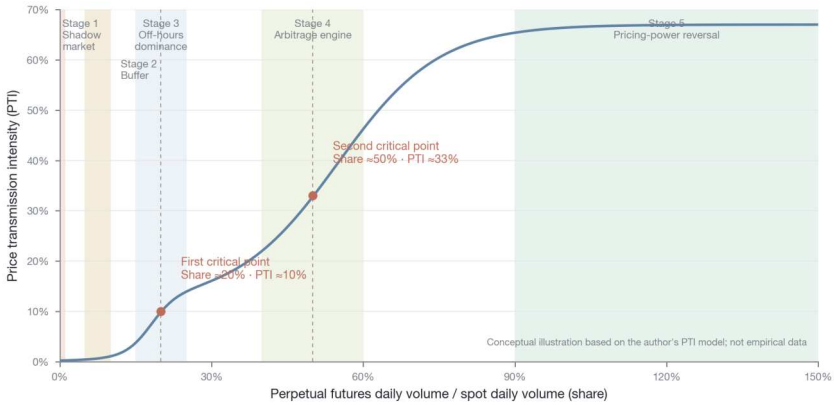

Figure 27-1. The five-stage evolution of PTI as a function of the perpetual futures' share of trading volume (conceptual illustration, not a forecast and not empirical: the curve is an extrapolation of the author's PTI model, using the double-logistic function $\mathrm{PTI}(x) = 0.12{\cdot}\sigma(40(x - 0.18)) + 0.55{\cdot}\sigma(10(x - 0.55))$, where σ is the logistic function; the horizontal axis is the model's independent variable, namely the perpetual-to-spot daily volume ratio, not a time axis; the two critical points at 20% and 50% and the individual PTI values are illustrative parameter choices, not statistical estimates; the PTI concept draws on the information-share method of Hasbrouck 1995 [21], which provides the measurement framework but is not the calibration source for this figure's thresholds)

27.5.4 Sensitivity analysis

In the evolution across these five stages, the weight of each variable is not constant. A sensitivity analysis reveals the key bottlenecks that determine whether a threshold can be crossed.

The first is sensitivity to oracle latency. The model shows that when the perpetual futures' oracle update frequency is slower than one second, its PTI ceiling during the regular session is locked at 15%, because on Nasdaq the reaction time of high-frequency trading firms is measured in microseconds. If an on-chain oracle needs several seconds to reflect a change in the spot price, the perpetual market will remain at a disadvantage in passive arbitrage and become a venue from which high-frequency traders systematically extract value [23]. Only when oracle latency falls to the hundred-millisecond level, with very high manipulation resistance, does the perpetual market gain the physical basis to contest pricing power during the regular session.

The second is the nonlinear effect of the friction coefficient. The simulation finds a clear convex relationship between cross-market arbitrage friction and price transmission intensity. When the all-in cost of moving funds across the on-chain and off-chain boundary — including slippage, gas fees, and losses on fiat on- and off-ramps — exceeds 0.5%, price transmission is significantly suppressed. When this friction coefficient falls below 0.1% through improvements in infrastructure (such as the spread of stablecoin settlement and the establishment of institutional-grade clearing networks), however, PTI grows rapidly. This shows that pricing-power migration is not a linear quantitative change but depends on a threshold effect that takes hold once infrastructural resistance falls below a particular level.

The last is sensitivity to the funding rate cycle. The traditional funding rate mechanism, which settles once every 8 hours, proves too sluggish for a high-volatility asset. The model indicates that shortening the funding rate settlement cycle of TSLA perpetual futures to hourly or even continuous settlement would improve its price-anchoring efficiency by more than 40%. Tighter anchoring means smaller price deviations, which attracts more slippage-sensitive institutional capital and forms a virtuous circle of rising liquidity and improving pricing efficiency.

Figure 27-2 presents, in two panels, the sensitivity of PTI to two bottleneck variables: (a) before oracle latency falls to the hundred-millisecond level, the regular-session PTI ceiling is locked at 15%; and (b) once cross-market friction falls below 0.1%, PTI grows rapidly. Together, the two panels reveal the same regularity: the bottleneck in pricing-power migration is not liquidity itself but the quality of the infrastructure connecting the two markets.

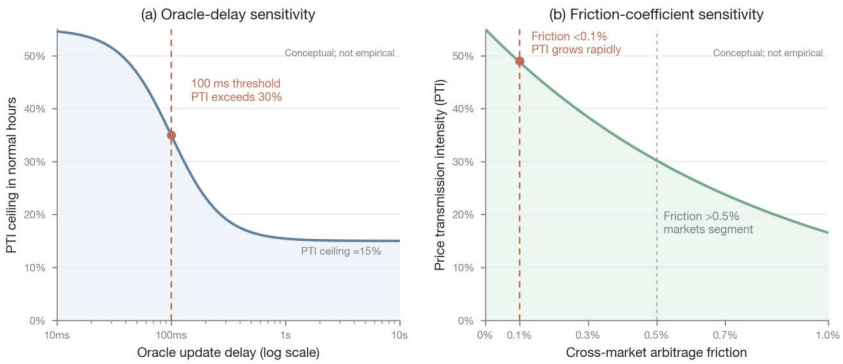

Figure 27-2. Sensitivity curves of PTI to oracle latency and the friction coefficient (conceptual and parameter-sensitivity modeling illustration, not empirical: all are extrapolations of the author's model; (a) oracle-latency model: PTI = $0.15 + 0.40 \cdot \sigma(4.5(2 - \log_{10}(\text{latency})))$; (b) friction-coefficient model: PTI = $0.55 \cdot \exp(-120 \cdot \text{friction coefficient})$, with the friction coefficient entered as a decimal and calibrated to the thresholds in the text as 0.1% → 0.49, 0.3% → 0.38, 0.5% → 0.30, 1% → 0.16)

27.5.5 Summary of the thresholds

Combining the scenario simulation with the sensitivity analysis, we can clearly delineate the quantitative thresholds at which TSLA perpetual futures acquire pricing power. The first threshold is the "non-trading-hours dominance threshold": the perpetual market's daily volume reaches 20% of spot (about $5 billion), and cross-market friction is below 0.3%. Crossing this threshold means that perpetual futures have formally filled a structural gap in the traditional financial market and begin to demonstrate irreplaceable informational value.

The second threshold is the "regular-session competition threshold," which requires the perpetual market's daily volume to reach 50% of spot and oracle latency to fall below 100 milliseconds. Crossing this threshold means that perpetual futures have gained the ability to compete with Nasdaq in price discovery during the regular session and have become a central hub for global arbitrage capital.

The third threshold is the "pricing-power reversal threshold," which requires not only

that perpetual volume surpass spot but also that a widely accepted institutional trust be established, so that traditional asset managers can lawfully use the on-chain perpetual price as a benchmark reference.

These quantitative thresholds reveal an important economic implication: for permissionless financial infrastructure to reshape global asset pricing, it cannot rely on the sophistication of its ideas alone but must meet extremely high engineering standards on the hard metrics of microstructure — liquidity thickness, latency, and friction cost. The migration of pricing power is a strict competition on efficiency, and only when the new system is superior to the old on every dimension can it complete the final substitution.

27.5.6 Case simulation: price transmission of an after-hours event

To make the abstract model above more concrete, we simulate a specific scenario. At 9:00 p.m. on a Friday (Nasdaq has closed, and the after-hours session has ended as well), Elon Musk posts on social media a major tweet announcing a breakthrough in Tesla's autonomous-driving technology. Empirical research shows that Musk's tweets tend to produce measurable abnormal returns in TSLA's stock price within minutes to hours of posting, often accompanied by increased trading activity and volatility [24][25].

Under the traditional market structure, the weekend closure means this major positive news cannot be translated into price immediately. Millions of retail and institutional investors can only crowd in together at the Monday morning open, causing the opening price to show a violent upward gap. This pricing vacuum not only reduces the market's informational efficiency but also forces investors to bear a full 2 days of overnight risk.

Now introduce a TSLA perpetual futures market in the "third stage" (non-trading-hours dominator). After the tweet is posted, algorithmic trading bots instantly detect the shift in sentiment, and a flood of buy orders pours within milliseconds into the around-the-clock on-chain perpetual futures order book. Because the spot market is closed and the oracle price is frozen at Friday's close, the perpetual price rapidly unmoors to the upside, standing about 5% above the spot close within the first 10 minutes. The large basis forces longs to pay shorts an extremely high funding rate, while shorts, tempted by that funding rate, supply liquidity. Over the roughly 60 hours of the weekend that follow, the perpetual market, through ample turnover, independently completes the pricing of this information without a spot anchor, ultimately reaching a new equilibrium at a level 8% above the original close.

When Nasdaq opens at 9:30 a.m. on Monday, market makers in the traditional market no longer need to guess blindly at the opening price. They refer directly to the equilibrium price the on-chain perpetual futures formed over the weekend and use it as the benchmark for setting the spot open. In this specific event, TSLA perpetual futures took on the function of price discovery during non-trading hours; they did not replace the spot market but performed the spot market's work of absorbing information during the closure. This price-transmission path clearly demonstrates how, when the mechanistic advantages of perpetual futures are fully released, they can seamlessly embed in and optimize the pricing network for global assets.

Figure 27-3 uses three liquidity conditions — shadow market, non-trading-hours dominator, and pricing-power reversal — to simulate the evolution of the TSLA perpetual futures price from Friday's close to Monday's open (a 72-hour window) in the scenario above, along with the corresponding implied funding rate dynamics. Its core regularity is that the deeper the liquidity, the faster weekend price discovery converges: the first stage barely responds to the event, whereas the fifth stage converges to a new equilibrium within hours of the event.

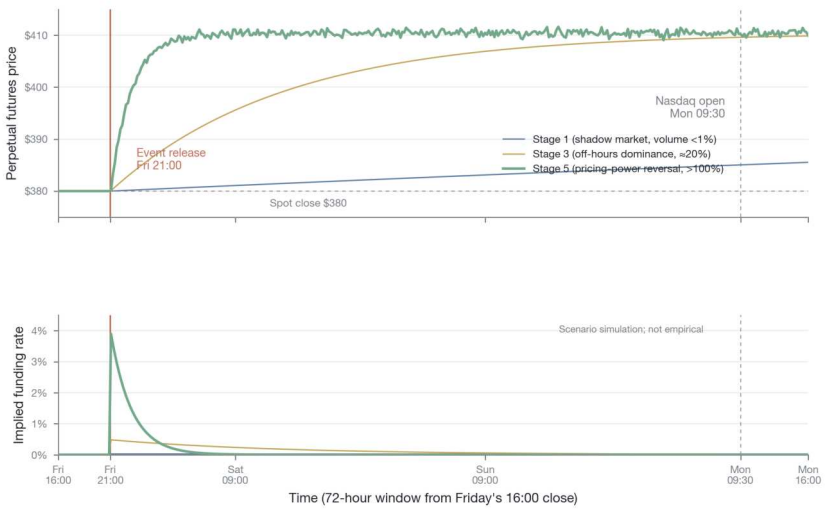

Figure 27-3. TSLA weekend-event simulation: the price-transmission trajectories and funding rate dynamics of perpetual futures at different stages (scenario simulation, not empirical: built by the author on the exponential-convergence model $P(t) = P_0 + \Delta P \cdot (1 - \exp(-\lambda \cdot t))$, with price convergence timed from the event at 9:00 p.m. on Friday; the total shock magnitude of +8% is a scenario shock assumption set by the author, not a point estimate from any study; Dam 2023 [24] supports only the directional conclusion that Musk's Tesla-related tweets produce measurable abnormal returns, not the +8% magnitude; the calibration parameters are TSLA's average daily volume of about $25 billion, a representative magnitude as of March 2026 [18], and an after-hours volume share of about 3% [19])

Figure 27-4 uses a stacked bar chart to quantify the information-incorporation efficiency of the five stages: the green bars represent the price gain already absorbed over the weekend, and the red bars represent the residual gap remaining at Monday's open. Efficiency rises from 17% in the first stage to 97% in the third, exhibiting the same nonlinear leap as Figure 27-1. This shows that when perpetual futures volume reaches 20% of spot (the third-stage threshold), the problem of the weekend pricing vacuum has, in substance, been solved.

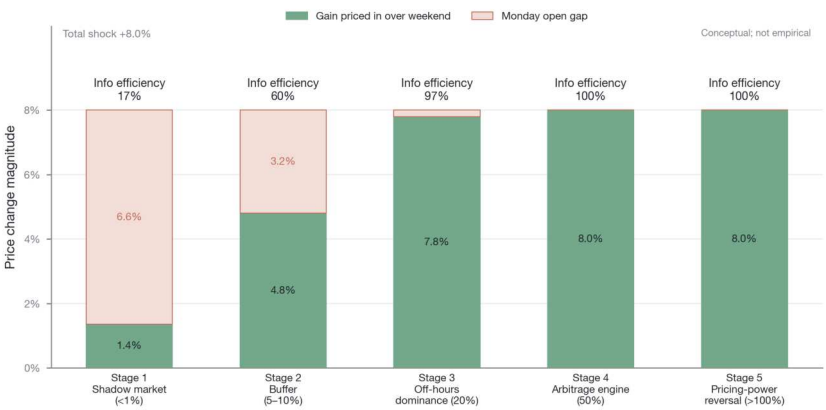

Figure 27-4. The five-stage information-incorporation efficiency of TSLA perpetual futures and the Monday-open gap (conceptual illustration, not empirical: built by the author on the exponential-convergence model $\eta = 1 - \exp(-\lambda \cdot T)$, with five-stage information efficiency of 17% → 60% → 97% → 100% → 100%, derived from the share of the total shock already incorporated at each stage and internally consistent, with an effective convergence window of T = 60.5 hours timed from the event at 9:00 p.m. on Friday to the Monday open; the total shock magnitude of +8% is the author's scenario assumption; the λ values are illustrative choices reflecting the liquidity depth of each stage; Dam 2023 [24] supports only the direction and not the 8% magnitude, and Hasbrouck 1995 [21] is the conceptual anchor for the information-share method — neither is a source of point estimates)

27.6 Thought experiment III: commodities and emerging assets

The pricing mechanism of perpetual futures shows potential not only in crypto assets, foreign exchange, and equity indices; its properties of no expiration date and synthetic exposure also offer a wholly new pricing perspective for commodities and emerging asset classes. This section extends the boundaries of the thought experiment further, examining how perpetual futures could reshape the pricing logic of non-traditional underlying assets — from crude oil and gold to carbon credits, real estate indices, and even prediction markets. The traditional derivatives markets in these areas often suffer from fragmented liquidity, an excessively high barrier to entry, or the outright absence of any effective pricing mechanism, and the introduction of perpetual futures may be not only a complement to existing markets but also a creator of entirely new liquidity.

27.6.1 Crude oil, gold, and agricultural commodities

In the traditional financial system, commodity futures markets are the central hub of price discovery. Take crude oil: the West Texas Intermediate crude oil futures and options of the Chicago Mercantile Exchange together have average daily volume exceeding 1 million contracts and combined open interest of about 4 million contracts, forming the benchmark for global energy pricing [26]. The gold market is likewise vast: open interest in the gold futures of the New York Mercantile Exchange has long held at roughly 400,000 to 550,000 contracts (with a peak of about 900,000 contracts

on a combined-options basis and an all-time record of about 800,000 contracts) [27]. For these highly mature markets, the incremental value of perpetual futures is not to replace the existing liquidity pool but to eliminate the friction costs inherent in traditional delivery futures.

The principal drawback of traditional commodity futures is the roll cost. Because a futures contract has a fixed expiration date, an investor who does not wish to take physical delivery — a commodity index fund or a retail speculator, for instance — must close the position before expiry and buy a forward contract. This periodic roll not only incurs high trading fees but also exposes the investor to the implicit losses of the term structure (such as contango or backwardation). Perpetual futures anchor automatically to the spot price through the funding rate mechanism, eliminating the explicit roll operation and its trading friction (the holding cost is instead expressed as the funding rate). A trader can hold synthetic exposure to crude oil or gold indefinitely, without attending to a complex delivery calendar. Decentralized derivatives platforms such as Hyperliquid have recently reported record-high open interest in their crude oil and gold perpetual futures, providing preliminary confirmation of genuine demand for roll-free commodity exposure [28].

Commodity perpetual futures nonetheless face an insurmountable physical constraint: the need for physical delivery (this is one of the four ultimate constraints on the "Everything Perpetual," discussed in full in Section 27.8.2). Although synthetic exposure holds advantages for price speculation and risk hedging, it can never replace the movement of supply chains in the physical world. In crude oil and gold, therefore, perpetual futures are more likely to evolve into a parallel, "purely financialized" pricing layer that coexists over the long run with the traditional futures markets that bear the function of physical delivery.

Unlike crude oil and gold, the traditional futures markets for agricultural commodities and metals are often characterized by insufficient liquidity. Research shows significant differences in liquidity cost across agricultural futures contracts, with trading volume and the delivery period the key factors affecting liquidity [29]. For many farmers in developing countries, participating in the agricultural futures markets of Chicago or Dalian entails extremely high barriers to opening an account, moving funds across borders, and managing margin. Here, the global access and very low barrier of perpetual futures reveal enormous potential for financial inclusion. Through a smartphone and a crypto wallet, a coffee farmer in South America or a cocoa grower in Africa could use agricultural perpetual futures directly to lock in a future selling price and hedge the risk of price fluctuations. This is the closest realization of the vision Robert Shiller depicted in Macro Markets: enabling groups once excluded from the modern financial system to effectively manage the economic risks they face.

27.6.2 Carbon credits and real estate indices

As the thought experiment extends outward, we enter areas where traditional derivatives markets are weaker still. The carbon-credit market is an important global mechanism for addressing climate change, but the liquidity of the current voluntary carbon market is highly fragmented. Although trading volume in compliance carbon markets

continues to grow, the voluntary carbon market still faces problems such as opaque pricing and high transaction costs, with significant price differences between different types of carbon credits (such as forestry carbon sinks and industrial emissions reduction) [30]. The introduction of carbon-credit perpetual futures could provide this fragmented market with a unified global pricing venue. By indexing carbon credits of a particular standard and issuing perpetual futures on that index as the underlying asset, global capital could participate seamlessly in the pricing of carbon emissions, substantially improving the liquidity and price-discovery efficiency of the carbon market.

Real estate is another quintessential "non-traditional" underlying asset. Housing is not only the principal store of wealth for most households but also one of the most broadly influential variables in the macroeconomy. Real estate, however, is extremely illiquid and difficult to short. The Chicago Mercantile Exchange once launched futures based on the S&P CoreLogic Case-Shiller Home Price Index, but because of the high barrier to entry and insufficient willingness among market makers, its volume has always remained extremely low [31]. Although the Real Estate Index of the Shenzhen Stock Exchange in China reflects the performance of the relevant listed companies, it cannot directly hedge the risk of fluctuations in physical home prices [32].

Real estate index perpetual futures could break this deadlock. Because they require no complex traditional brokerage account and support very fine-grained trade sizes, home-price perpetual futures could attract large numbers of ordinary residents seeking to hedge the risk of home purchases, as well as global capital seeking diversified investment. Once the participant base crosses a critical point, liquidity would reinforce itself, ultimately forming a continuous pricing curve that reflects expectations of future home prices. The common feature of these non-traditional assets is that the liquidity of their traditional derivatives markets is weak or even nonexistent. Perpetual futures need not compete with entrenched incumbents; instead, by lowering the barrier to entry, they create an entirely new liquidity pool "from scratch."

27.6.3 Prediction markets

If the logic of the funding rate anchoring mechanism is pushed to its limit, the underlying asset of perpetual futures need no longer be confined to the price of a financial asset but can extend to any quantifiable variable or discrete event. Prediction markets are the direct application of this generalized logic. In a prediction market, the value of a contract depends on whether a particular event — an election result, an economic data release, or a geopolitical conflict, for example — occurs.

Decentralized prediction markets, exemplified by Polymarket, have grown rapidly. During the 2024 U.S. presidential election, Polymarket's trading volume far surpassed that of the traditional regulated prediction platform Kalshi, and it maintained strong momentum thereafter. Recent data show that Polymarket's single-day notional volume once exceeded $478 million (March 2026) [33]. Academic research on prediction markets indicates that they are highly efficient in price discovery and that in some settings their accuracy can match or even exceed that of traditional opinion polls [34].

From the standpoint of mechanism design, an event contract in a prediction market is essentially a binary perpetual futures contract. Traders continuously price "whether an

event will occur," and the price fluctuates between zero and one, reflecting the market's consensus on the probability of the event. So long as a reliable oracle can adjudicate the event's outcome without dispute, any uncertainty in the real world can be turned into a tradable financial instrument. This trend of financializing temperature changes, macroeconomic indicators, and even the course of geopolitics has provoked a profound controversy over "the financialization of everything." Supporters hold that it greatly extends the boundaries of risk sharing, drawing more latent information into the price system, while critics worry that it may lead to excessive speculation, degrading serious social issues into a global gambling game. This tension constitutes the core challenge of permissionless finance at the level of social ethics.

27.6.4 Technical feasibility and institutional obstacles

In sum, as a general-purpose pricing infrastructure, the trajectory by which perpetual futures extend their coverage from crypto assets to everything displays a clear gradient of technical feasibility and an increasing set of institutional obstacles. Table 27-2 systematically assesses the prospects for turning six categories of underlying asset into perpetual futures across four dimensions: oracle reliability, the strength of traditional-market substitutes, the core incremental value of perpetual futures, and near-term feasibility. This assessment framework will help the reader understand why the speed at which perpetual futures penetrate different asset classes varies so markedly.

Underlying asset class	Oracle reliability	Traditional-market substitute	Core incremental value of perpetual futures	Near-term feasibility assessment
Crypto-native assets	Very high (on-chain native data)	None (perpetual futures already dominate)	Mechanism fully validated and implemented	Fully realized
Major foreign exchange pairs	High (deep liquidity, stable data sources)	Interbank spot market and CME foreign exchange futures	Around-the-clock (24/7) continuous pricing and inclusive global access	Relatively high
Equity indices (such as the S&P 500)	Moderate (limited by the data vacuum during non-trading hours)	ETFs and CME equity index futures	Filling the Asian-session pricing vacuum and providing permissionless global access	Moderate
Commodities (gold/crude oil)	Moderate (dependent on traditional exchange quotes)	Mature commodity futures such as those of the CME and LME	Eliminating roll costs and lowering the barrier to entry	Moderate
Non-traditional assets (carbon credits/home prices)	Relatively low (low data-collection frequency, difficult to standardize)	Market liquidity weak or nonexistent	Creating an entirely new, unified global pricing market for illiquid assets	Relatively low
Prediction markets (events of every kind)	Very low (heavily dependent on manual adjudication and complex fact-checking)	Traditional betting, or no substitute	Realizing the highest-potential risk sharing, while facing the greatest oracle challenge	Very low

Table 27-2. Feasibility assessment of turning different underlying assets into perpetual futures (Data source: constructed by the author on the basis of the three preceding thought experiments)

As shown in Table 27-2, from crypto-native assets to prediction markets, the feasibility of turning assets into perpetual futures displays a clear declining gradient. This gradient is determined mainly by two variables. The first is oracle reliability: as the underlying asset extends from highly standardized financial instruments toward non-standardized physical entities and real-world events, oracle reliability declines exponentially. An oracle must transmit off-chain information to an on-chain contract accurately, with low latency, and tamper-resistantly. For crude oil or an equity index, the oracle need only relay quotes from a traditional exchange; but for a home-price index or a complex political event, the design of the oracle faces enormous game-theoretic challenges. Moreover, when perpetual futures attempt to price carbon credits or macroeconomic indicators, they inevitably touch the regulatory boundaries of sovereign states. Technology can build a permissionless trading layer, but it cannot eliminate the physical world's need for delivery, nor can it bypass the deeply rooted trust structures and institutional constraints of human society. Together, these ultimate constraints draw the real-world

boundary of the "Everything Perpetual" thought experiment.

27.7 The dynamics of pricing-power migration

The migration of pricing power requires several preconditions: liquidity reaching critical mass, institutional recognition, and, for non-crypto-native assets, oracle reliability (the preconditions and timeline of each stage are developed one by one in Section 27.7.5). The speed of migration depends on the overall performance of perpetual futures across several dimensions: efficiency, cost, access, resilience, and fairness.

Given these preconditions, the migration of pricing power is not a sudden event in the financial system but an evolutionary process that advances gradually along liquidity, informational efficiency, and institutional acceptance. If the perpetual futures mechanism does have the potential to take over global asset pricing, this process will not be completed overnight but will follow a clear four-stage dynamic model. Each stage marks a structural reorganization of the relationship between on-chain pricing infrastructure and the traditional financial system, and crossing each stage requires a particular level of technical maturity and specific institutional preconditions as support.

27.7.1 Stage one: crypto-native assets

The first stage of pricing-power migration is not a theoretical extrapolation but an empirical fact that has already occurred. In this stage, perpetual futures successfully established their status as the core pricing venue for a particular asset class. For crypto-native assets such as Bitcoin and Ethereum, the perpetual futures market has already surpassed both the spot market and the traditional delivery futures market to become the dominant venue for price discovery.

According to data on the crypto derivatives market in 2025, total volume in this space reached about $85.7 trillion, with average daily volume exceeding $260 billion, and perpetual futures occupied the dominant position [4]. In the quantitative analysis of price discovery, as cited in Section 27.5.1, crypto derivatives markets already command about half of the information share in Bitcoin price discovery [20][21][22]. Given that perpetual futures surpass quarterly futures in both volume and continuity, their share in price discovery may be higher still; but there is at present no direct point estimate of the information share of perpetual futures specifically, so this judgment is a qualitative inference based on volume and continuity. The microfoundation of this phenomenon is that the built-in leverage, seamless shorting mechanism, and around-the-clock continuous trading of perpetual futures make informed traders more inclined to express their informational advantage in such venues.

The completion of the first stage proves the effectiveness of the funding rate anchoring mechanism. It shows that, absent the constraint of physical delivery, pure synthetic exposure can still bear enormous sums and sustain an efficient price-discovery function. Yet the success of this stage owes much to the characteristics of crypto assets themselves: they are digitally native, have no hard binding to physical-world delivery, and, in their early development, faced little competition from strong traditional-finance substitutes.

27.7.2 Stage two: shadow pricing

When the underlying assets of perpetual futures extend from crypto-native assets to traditional financial assets — foreign exchange, equity indices, or commodities — pricing-power migration enters its second stage. In this stage, on-chain perpetual futures begin to provide price signals for traditional assets, but these prices have not yet won the institutional recognition of the traditional financial system. They play the role of a "shadow price" in the system, analogous to the shadow-pricing role that offshore currency markets play relative to the onshore official exchange rate.

The core value of shadow pricing lies in filling the structural gaps of traditional markets, especially gaps in time coverage. Consider the Asian-session pricing vacuum of SPY, the core ETF product on the S&P 500 index (its causes are discussed in Section 27.4) [35]: if a major macroeconomic event or geopolitical shock occurs during this period, the traditional market can offer no venue for immediate price discovery, and the around-the-clock on-chain perpetual futures become the only active pricing source.

Although in this stage the trading volume of on-chain perpetual futures may account for only a very small proportion of total traditional-market volume — 0.1% to 1%, say — its monopoly on information gives it a disproportionate influence over pricing. When the traditional market reopens after a closure, market makers and algorithmic trading systems refer to the perpetual futures' price movements during the closure to set the opening quote. This information-transmission mechanism allows the shadow price to materially influence the price formation of the traditional market, even before it is officially recognized as a benchmark price.

27.7.3 Stage three: institutional recognition

The third stage of pricing-power migration marks the initial narrowing of the trust gap between the on-chain pricing system and the traditional financial system. In this stage, the liquidity depth and oracle reliability of the perpetual futures market reach critical mass, prompting regulators, asset managers, and traditional market makers to begin formally citing or relying on on-chain price data, thereby granting it institutional recognition.

A precedent for this recognition has already appeared in the 2024 approval of the Bitcoin ETF. The fund was the first institutional bridge between traditional finance and crypto finance, and its pricing mechanism relies indirectly on the liquidity and information flow of the perpetual futures market (the microstructure of this triangular-arbitrage price transmission, intermediated by the Chicago Mercantile Exchange futures market, is detailed in Section 27.9.2).

For non-crypto assets, reaching the stage of institutional recognition requires overcoming more complex obstacles. First, traditional market makers must participate in on-chain market-making across the boundary at scale, to ensure that prices in the two markets are tightly coupled. Second, oracle infrastructure must demonstrate its absolute reliability under extreme market conditions, particularly how it provides a manipulation-resistant reference price while the traditional market is closed. When these conditions are met, the information share of perpetual futures will rise signifi-

cantly, possibly reaching the 20% to 35% range, making them a major pricing venue on a par with traditional exchanges.

27.7.4 Stage four: infrastructure integration

The ultimate form of the four-stage model is the deep integration of infrastructure. In this stage, the binary opposition between "traditional finance" and "on-chain finance" is broken down, and the two merge into different execution layers of a single unified global pricing system. Perpetual futures are no longer a challenger to, or a complement of, the traditional market but become a core component of the underlying infrastructure.

Under this integrated architecture, traditional exchanges might directly operate a clearing layer based on distributed ledger technology (DLT), or introduce the perpetual futures mechanism into their core product lines. A trader could switch seamlessly on a single interface among traditional spot, regulated futures, and permissionless perpetual futures, with all risk exposures net-settled within a single unified global liquidity pool. Such a convergence would not only resolve the settlement-delay risk that has long existed in the traditional foreign exchange market but also greatly widen the access boundary for global capital [36].

Realizing the infrastructure-integration stage would mean a fundamental reconstruction of the underlying logic of financial markets. It would require the regulatory framework to shift from territorial oversight based on institutional entities to global coordination based on code function and protocol logic. In this stage, the vision of perpetual futures as a general-purpose pricing layer would be fully realized, and any asset could be turned, through the funding rate mechanism, into synthetic exposure that is globally accessible, tradable around the clock, and instantly settled.

Figure 27-5 visualizes the four-stage model with the qualitative stages of evolution (from early to distant) on the horizontal axis: stage one, "crypto-native assets," is essentially complete (the information share for BTC and ETH has reached about 50%); stage two, "shadow pricing," is now taking place; and stage three, "institutional recognition," and stage four, "infrastructure integration," are anticipated extrapolations, with the key preconditions for crossing each stage marked at the junctions. The core lesson of this evolutionary path is that the speed of pricing-power migration is determined not by technological progress alone but by the slower of technical maturity and institutional acceptance.

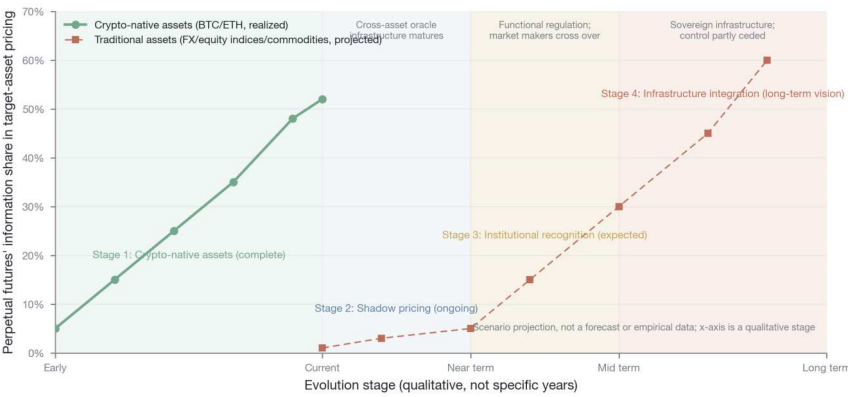

Figure 27-5. The four-stage model of pricing-power migration: stages of evolution and key preconditions (scenario extrapolation, not a forecast and not empirical: built by the author on the four-stage model, with the horizontal axis showing qualitative stages of evolution from early to distant rather than specific years; the stage-one figure "BTC/ETH information share ≈ 50%" draws on Alexander & Heck 2020 [20], which uses the Hasbrouck 1995 information-share method [21], and the figure that "perpetuals account for about 60% of BTC's total market volume" draws on the CoinGlass crypto derivatives report [4]; De Blasis & Webb 2022 [22] is corroborating evidence of derivatives dominance and spillover effects, does not itself provide an information-share estimate, and is not on its own a source for the 50% information share; stages two through four are framework-based scenario projections)

27.7.5 Preconditions and timeline

Each stage of pricing-power migration is subject to particular technical and institutional constraints, and these constraints determine the speed and boundaries of the evolution. The first stage (crypto-native assets) is complete, having taken nearly a decade (2016–2025). The second stage (shadow pricing of traditional assets) is now taking place: several decentralized exchanges have launched perpetual futures on foreign exchange, equity indices, and commodities, completing the proof of concept and the early accumulation of liquidity.

The leap from the second stage to the third (institutional recognition) is the most difficult transition in the entire dynamic model, because it goes beyond engineering and enters the reconstruction of social trust and institutional design. The preconditions for this leap include building a decentralized oracle network capable of withstanding state-level attacks, forming a functional regulatory framework interoperable with traditional finance, and establishing deep trust in smart contract code among institutional investors. Based on the historical pace at which financial infrastructure evolves, realizing this stage may take 5 to 10 years.

As for the fourth stage (infrastructure integration), its timeline is more distant and fraught with uncertainty, and it may take 10 to 20 years to unfold. It depends not only on the full maturation of the technical and regulatory conditions described above but also on a fundamental cession of sovereign states' control over financial markets. The rigid demands of sovereign states regarding capital flows, monetary policy transmission, and anti-money-laundering compliance constitute the fundamental constraint on this

ultimate picture. The complete migration of pricing power may therefore forever be an asymptote — infinitely approached but never fully reached — and it is along this asymptote that perpetual futures will continue to reshape the boundaries of global asset pricing.

27.8 The ultimate constraints

A thought experiment must confront its insurmountable boundaries honestly. In examining the potential of perpetual futures as a general-purpose pricing layer, we must distinguish which constraints are technical, which are institutional, and which are fundamental. Technical constraints can be solved through engineering innovation, and institutional constraints may loosen as regulation evolves, but fundamental constraints reflect the deep structure of human society and the objective laws of the physical world; they will not vanish with technological progress. This section defines the ultimate picture of this thought experiment and analyzes in depth the four ultimate constraints that limit its unbounded expansion.

27.8.1 The ultimate picture

In the limiting case where all technical and institutional constraints are perfectly resolved, perpetual futures could constitute a fully comprehensive global pricing layer. In this picture, anyone, anywhere, at any moment can trade and price any asset. All financial exposure is turned into synthetic products that settle instantly, are globally accessible, and operate continuously around the clock. This eliminates not only the geographic and temporal fragmentation of traditional financial markets but also the access barriers between different asset classes.

The value of this ultimate picture lies not in offering a definite forecast but in revealing the theoretical limit of financial-market evolution. It shows how high the efficiency of price discovery could rise if friction costs fell to zero. In this ideal state, the funding rate mechanism anchors synthetic assets to their underlying perfectly, the oracle network transmits information with no latency and absolute reliability, and smart contracts execute all clearing and settlement logic with a zero failure rate. Yet this perfect state is merely a theoretical asymptote. The physical properties, political structures, and human psychology of the real world constitute insurmountable boundaries, so that this ultimate picture can only be approached infinitely and never fully realized.

27.8.2 The settlement needs of the physical world

There is an essential economic difference between synthetic exposure and physical delivery, and this is the first ultimate constraint that prevents perpetual futures from fully replacing traditional markets. Synthetic products can provide perfect price exposure, but they cannot meet the physical needs of the real economy. A refinery needs real crude oil to keep running, a flour mill needs real wheat to make bread, and a multinational enterprise needs real foreign currency to pay overseas suppliers. However deep the liquidity of a crude oil perpetual futures contract, and however efficient its price discovery, it cannot be refined into gasoline.

In traditional futures markets, although the overwhelming majority of contracts are ultimately closed through cash settlement rather than physical delivery, the possibility of delivery is the ultimate guarantee that the futures price anchors to the spot price. This delivery mechanism builds a solid bridge connecting financial derivatives to physical reality [37]. Perpetual futures attempt to substitute the funding rate mechanism for this anchoring function of physical delivery. For crypto-native assets, the substitution is successful, because crypto assets are themselves digital and have no logistical friction of physical delivery. But when we extend perpetual futures to commodities or agricultural products, whether the funding rate can fully substitute for the anchoring force of physical delivery under extreme market stress remains an unverified assumption.

Perpetual futures may therefore come to dominate pricing power over many assets in the future and become the primary venue for price discovery, but the physical need for settlement and delivery means that physical markets and traditional delivery futures markets must coexist with them. The two would form a division of labor: perpetual futures provide the most efficient information processing and price discovery, while traditional markets handle the logistics and settlement of the physical world. This dual structure is the inherent constraint that the physical world imposes on purely digital finance.

27.8.3 The financial power of sovereign states

The second ultimate constraint arises from the political-economy foundations of the modern nation-state system. The power to issue currency, to control foreign exchange, and to regulate financial markets constitutes the core power of a sovereign state. A fully permissionless global financial market that crosses national borders is, in essence, a direct challenge to a state's financial sovereignty. History shows that sovereign states will not lightly surrender these powers, nor will they remain indifferent to a technology that could weaken the transmission of their monetary policy [38].

The stability of money depends not only on technical architecture but also, and more importantly, on credible public support and the enforcement of par value. In successive financial crises, stability was restored not by the public's access to a particular payment technology but by the ability of the central bank's balance sheet to absorb systemic risk [39]. A permissionless financial network, for all the efficiency it displays in day-to-day operation, lacks a lender of last resort capable of creating liquidity without limit when faced with a systemic collapse.

Faced with the expansion of permissionless finance, the response of sovereign states need not be a simple prohibition; it is more likely to be adaptation and discipline. A state might upgrade its own monetary infrastructure by introducing a central bank digital currency (CBDC), or exert control by bringing decentralized protocols into a new regulatory framework. This means that the globalizing vision of perpetual futures will always operate within the space constrained by national sovereignty. Different jurisdictions will inevitably differ in the degree to which they accept these financial instruments and in the regulatory requirements they impose, leading to a degree of fragmentation in global liquidity. The utopia of fully eliminating national borders and regulatory arbitrage is unattainable so long as the system of sovereign states exists.

27.8.4 The oracle problem

At the technical level, the oracle problem is the foremost obstacle to extending perpetual futures to non-crypto assets. The oracle is the key infrastructure connecting isolated blockchain networks to data from the external world [40]. For crypto-native assets, an oracle can obtain the price directly from the on-chain transactions of a decentralized exchange, and the data source is itself trustless. But for traditional assets such as equities, foreign exchange, and commodities, the oracle must rely on off-chain data sources, such as the market feeds of Bloomberg, Reuters, or a traditional exchange.

This gives rise to a fundamental trust paradox: the goal of the entire decentralized finance system is to build a trustless architecture, yet its acquisition of the underlying asset's price requires absolute trust in these centralized off-chain data sources. The degree to which a system is trustless can never exceed the degree to which its oracle is trustworthy. Even if a decentralized oracle network is used to reduce single-point-of-failure risk through multi-node aggregation, that decentralization is merely superficial if all nodes ultimately depend on the same data interface from Nasdaq [41].

Moreover, during the non-trading hours when the traditional market is closed, the oracle faces the predicament of having no real-time price to report. It can then rely only on alternative data sources or historical data, which greatly weakens the pricing quality and anchoring efficiency of perpetual futures during these periods. Although cryptography and mechanism design can mitigate these problems, so long as the external world's data-generation process is not decentralized, the oracle problem will forever be a technical and trust bottleneck that cannot be entirely eliminated.

27.8.5 Human trust structures

The final ultimate constraint is rooted in the very nature of human cognition and social structure. Technology can shift the object of trust and reduce dependence on particular intermediaries, but it can never fully eliminate the need for trust itself. In traditional finance, participants trust banks, exchanges, and the legal and regulatory systems behind them. In a permissionless financial system, this trust is displaced onto the code logic of smart contracts, the security of cryptographic primitives, the honesty of the oracle network, and the governance mechanisms of DAOs [42].

Although this displacement of trust increases the transparency and verifiability of the system, it does not achieve genuine "trustlessness." For the overwhelming majority of market participants, verifying complex smart contract code or assessing the game-theoretic security of an oracle network far exceeds their cognitive capacity. They are in fact trusting the reputation of code-audit firms, the expertise of core developers, or simply the system's past record of stable operation.

The ultimate constraints of the thought experiment are therefore not only physical, political, and technical but also sociological and psychological. A fully trustless global financial market is a theoretical ideal that points the way toward lower friction and higher efficiency, but the inherent complexity of human society and its psychological need for certainty mean that some form of institutional trust will always be an indispensable foundation of the financial system.

27.9 Anchoring in reality

The value of a thought experiment lies not only in exploring the boundaries of theory but also in providing an analytical framework for observing reality. The foregoing extrapolation of perpetual futures as a universal global pricing infrastructure is not pure logical fantasy; its core elements have already begun to appear in the real world. This section anchors the theoretical extrapolation of the thought experiment to the current reality of financial markets, showing which transformations have already occurred, which infrastructure is being built, and which obstacles the path to the future vision must cross.

27.9.1 Early practice of the Everything Perpetual

Extending the underlying logic of perpetual futures from crypto-native assets to a broader range of financial instruments has already been validated on decentralized exchanges. The decentralized exchange Hyperliquid, for example, offers preliminary empirical evidence for the concept of the Everything Perpetual through its all-asset strategy. The platform not only lists perpetual futures on crypto assets but has also introduced exposure to traditional financial assets through its permissionless builder-deployed market framework (HIP-3).

In implementation, the platform has successfully launched perpetual futures products covering foreign exchange, equity indices, and commodities. Using the same margin system in a fully permissionless environment, a trader can obtain synthetic exposure to the stocks of traditional technology companies such as Nvidia and Tesla, as well as to macro commodities such as gold and crude oil. This aggregation of liquidity across asset classes proves the universality of the funding rate anchoring mechanism: it does not, in fact, depend on the specific physical properties of the underlying asset but requires only a reliable price feed from an oracle.

The evolution of market data further confirms that this cross-boundary demand genuinely exists. Measured by share of average daily volume, from the fourth quarter of 2025 to the first quarter of 2026 the share of traditional assets in Hyperliquid's total volume underwent a marked structural leap, climbing from less than 5% to more than 30% (about 31.6% by the end of January 2026, according to Delphi Digital data) [43]. The structural advantage of the around-the-clock trading of perpetual futures is especially evident in the face of sudden geopolitical events. In late February 2026, for instance, during tensions in the Middle East, the traditional commodity markets were closed for the weekend, and capital seeking to hedge risk poured into the decentralized perpetual futures market, driving a surge in the trading volume of synthetic crude oil and gold assets [44]. This episode bears out the expectation about the advantage of continuous pricing set out in the thought experiment above.

27.9.2 The bridging role of the Bitcoin ETF

Even as the permissionless on-chain financial system extends into the domain of traditional assets, the traditional financial system is actively building channels toward crypto-native assets. The approval of the spot Bitcoin ETF in 2024 marked the es-

tablishment of the first key institutional bridge between traditional finance and crypto finance. The significance of this event lies not only in providing traditional capital with a compliant investment channel but also in connecting two very different pricing ecosystems at the level of microstructure.

From the perspective of pricing-power migration, the introduction of the ETF significantly changed the market's information-transmission mechanism. The influx of traditional institutional capital caused the assets under management of the spot ETF to swell rapidly, and more than 2,000 U.S. investment advisory firms began incorporating such assets into their allocation portfolios [45]. Yet the ETF's own pricing mechanism depends heavily on the arbitrage activity of market makers and authorized participants. In executing their arbitrage strategies, these institutional participants inevitably need to hedge risk using the standardized futures contracts of the Chicago Mercantile Exchange and the more deeply liquid offshore perpetual futures market.

This cross-market arbitrage forms a hidden but efficient chain of price transmission. When large-scale inflows or outflows occur in the traditional market during the regular session, this information is reflected first in the ETF's premium or discount, then transmitted through market makers' hedging operations to the futures market of the Chicago Mercantile Exchange, and finally resonates in price with the perpetual futures market. Although this connection remains indirect at the current stage and is constrained by the trading hours of the traditional market, it establishes an ever-deepening interconnection of liquidity between the two worlds, laying the institutional foundation for fuller infrastructural integration in the future.

27.9.3 The evolutionary roadmap

A significant gap separates today's nascent all-asset perpetual futures from the ultimate vision of genuinely taking over pricing power for core global assets. Closing this gap requires not only technical breakthroughs at the engineering level but also a systematic evolution of institutional and trust structures.

At the level of technical infrastructure, oracle reliability remains the core bottleneck constraining the scaling of perpetual futures on non-crypto assets. When the traded underlying shifts from crypto assets with native on-chain prices to traditional assets that depend on external data sources, the oracle network must be able to provide accurate, latency-free, manipulation-resistant price feeds under extreme market volatility. Moreover, to bear the enormous transaction throughput of traditional financial markets, the clearing efficiency and concurrent processing capacity of the underlying blockchain must still improve by orders of magnitude.

At the level of institutions and social consensus, establishing a functional regulatory framework is unavoidable. The bottom-line demands of sovereign states regarding monetary policy transmission and anti-money-laundering compliance mean that a shadow-pricing system entirely detached from regulation can hardly win broad adoption by mainstream financial institutions. The more likely evolutionary path is a gradual convergence: preserving the core advantages of perpetual futures — continuous trading and efficient settlement — while achieving selective compliance verification at the application layer through cryptographic techniques such as zero-knowledge proofs. The

timeline of this process is fraught with uncertainty, but the direction of technological evolution and the market's intrinsic demand for a more efficient pricing mechanism have already pointed the way for this potentially transformative change to financial infrastructure.

27.10 Chapter summary

The universality of the funding rate anchoring mechanism is the logical starting point of this chapter's thought experiment. This mechanism does not depend on the physical or financial properties of the underlying asset and can, in principle, turn any continuously priceable asset into perpetual futures that trade around the clock, are globally accessible, and settle instantly [1]. The "faster, cheaper, more accessible" driving logic of financial history was confirmed repeatedly across three migrations — from spot to futures, from the trading floor to the electronic screen, and from delivery futures to ETFs [46]. Perpetual futures hold a structural advantage on the first two of these dimensions but still face a significant gap on the "more trustworthy" dimension.

The three thought experiments in this chapter reveal a consistent pattern: perpetual futures offer distinctive structural incremental value in each asset class — around-the-clock pricing in foreign exchange, Asian-session coverage for equity indices, and zero roll cost for commodities — but each also faces the hard constraints of oracle reliability, regulatory compliance, and the need for physical delivery. The ultimate picture of the "Everything Perpetual" is bounded by four insurmountable limits: the settlement needs of the physical world, the financial power of sovereign states, the trust paradox of the oracle, and the trust structures inherent in human society [47].

Returning to the counterfactual with which the chapter opened: if the Chicago Board of Trade had launched perpetual futures rather than delivery futures in 1848, the globalization of pricing power might have arrived earlier, but the constraints of physical delivery and sovereign control would not have vanished as a result. What perpetual futures can do is push the efficiency frontier of financial markets as far as possible toward its limit, within these irremovable constraints. The next part of the book, Part 10, "Trustless Engineering," examines how, through decentralized architectural design, one might build an on-chain financial system that preserves the offensive advantages of perpetual futures while repairing their defensive deficiencies.

From the Monolithic Black Box to Layered Architecture

In November 2022, FTX—one of the top three cryptocurrency exchanges by global trading volume—collapsed within days, revealing a gap of more than $8 billion between customer assets and corporate liabilities [1]. The bankruptcy investigation exposed a central engineering fact: the platform had never technically segregated customer assets from corporate assets, and all funds were commingled in a wallet system that lacked cryptographic access controls [2][3]. The affiliated trading firm Alameda Research received a secret exemption from the automated liquidation system, and before the system collapsed, no publicly available method allowed outside observers to detect these violations [4]. This event was not an isolated case; rather, it laid bare a structural flaw in the architectural design of centralized exchanges.

This flaw can be defined as the monolithic black box architecture. In a traditional centralized exchange, the core functions of the trading system—including the matching engine, the clearing and settlement system, asset custody, the market-making system, and the risk-control system—are all integrated and run within a single opaque server cluster controlled by one entity: the exchange itself. The data that users see in the front-end interface and through the API are merely the selective output of this black box. Inside the box, users have no way whatsoever to verify whether assets are being kept safe, whether orders are matched honestly according to price-time priority, or whether liquidation parameters are being secretly altered to trigger improper liquidations.

When we apply the lens of systems engineering to this architecture, the lesson of FTX is no longer merely an isolated case of *one management team's moral failure*; it is a textbook instance of systemic architectural failure. The monolithic black box architecture concentrates all of a system's operating trust assumptions in a single entity, thereby creating an enormous single point of trust failure across the entire financial ecosystem. In distributed-systems theory, the failures of different components are typically independent of one another. In a monolithic trust architecture, however, because all functions share the same root of trust, once that root becomes corrupted or collapses, the propagation of failure is total and instantaneous. The system moves directly from a state of seemingly flawless operation into one of complete collapse, with no intervening buffer or graceful degradation.

This brings us to the central question of this chapter: starting from the first principles of engineering, can we design a fundamentally different architecture for a trading sys-

tem? Such an architecture must preserve the performance advantages of centralized exchanges (low latency and deep liquidity) while decomposing the *monolithic black box* into multiple independent and verifiable modules, minimizing the trust dependency at each one. Its core objective is to build a highly resilient system in which, even if the operating entity of one module suffers a moral hazard or a technical failure, the core functions of the whole system and the safety of user assets remain protected by cryptography and consensus mechanisms.

Solving this problem is not a simple binary choice between a centralized exchange (CEX) and a decentralized exchange (DEX). The analyses in the preceding nine parts have repeatedly exposed a central tension: centralized exchanges deliver the best trading performance but require users to bear extremely high trust risk, whereas early decentralized exchanges eliminated trust risk through fully on-chain execution yet were constrained by the physical limits of blockchains and could not meet the microsecond latency and high throughput that professional trading demands. We therefore need an engineering solution that strikes an optimal balance between *trust minimization* and *performance maximization*. This search is not without precedent. Over several centuries, and through repeated crisis-driven reform, traditional finance gradually built a layered trust architecture that separates matching, clearing, custody, and regulation. The establishment of institutions such as the central counterparty (CCP) and the DTCC was, in essence, a decomposition of the early monolithic financial black box [5]. The cryptocurrency market, however, is attempting to achieve this goal through technical code rather than regulatory agencies. A new generation of infrastructure, exemplified by application-specific blockchains (app-chains) such as Hyperliquid, is demonstrating the feasibility of this migration from monolithic to layered design [6]. Through customized consensus mechanisms and specially optimized state machines, these systems are attempting to find a new and efficient frontier between performance and trust.

This chapter serves as the overall blueprint for building a trustless financial system (Figure 28-1), guiding the reader from the perspective of an analyst to that of a systems architect. It first uses the trust stack to dissect the implicit trust embedded in the life cycle of a single trade; it then traces, along the *trust-performance frontier*, the migration path from the monolithic black box to a layered, transparent architecture; it proceeds to conduct an architectural audit of representative protocols such as Hyperliquid; and it finally distills these into an engineering framework for judging *sufficient decentralization*.

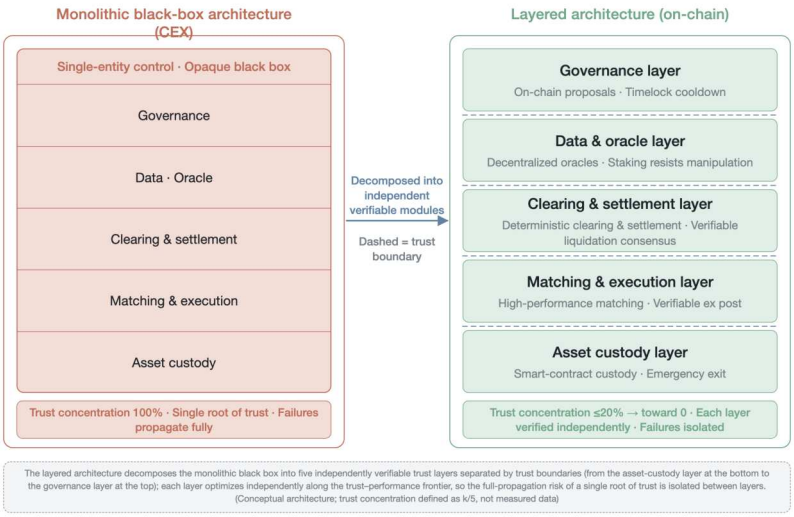

Figure 28-1. A comparison of the monolithic black box architecture and the layered architecture (conceptual schematic: on the left, a centralized exchange fuses five functions—asset custody, matching and execution, clearing and settlement, data oracles, and governance—into an opaque black box controlled by a single entity, with trust concentration reaching 100%, so that once the single root of trust is corrupted, failure propagates completely and instantaneously; on the right, the layered architecture decomposes the same five functions into mutually independent, separately verifiable trust layers, running from the asset-custody layer at the bottom to the governance layer at the top, with each layer optimized independently along the trust-performance frontier and isolated from the others by trust boundaries, lowering trust concentration to 20% or even close to 0)

28.1 A trust anatomy of the CEX monolithic black box

Before discussing how to build a trustless financial system, we must first identify precisely what the current system requires users to trust. When we say that centralized exchanges carry structural risk, that risk is not an abstract notion; it is embedded deep in their architectural design. In using a centralized exchange, a user makes at least five implicit trust assumptions over the life cycle of every trade. Most users are entirely unaware of them—until a crisis erupts and these implicit assumptions are systematically violated.

28.1.1 The five trust assumptions in a trade's life cycle

When a user opens a long position in Bitcoin perpetual futures on a centralized exchange, that user traverses a long and fragile chain of trust. Each step in this chain is an implicit trust assumption. This example is not a hypothetical thought experiment but a routine operation that millions of traders repeat every day. Every click of the trade button, every entry of an order quantity, means that the user is entrusting the safety of their funds and the fairness of their trades to a centralized, opaque system.

The first is trust in the asset-custody layer. The user deposits dollar stablecoins into the exchange, which marks the start of the entire trade life cycle. At that instant, the user must trust that the exchange will safeguard these funds. Such trust means believing

that the exchange will not misappropriate customer assets for high-risk investments, will not lose the private keys through internal mismanagement, and will not invoke various pretexts to refuse a withdrawal when the user requests one. This assumption is the foundation for all subsequent trading, yet it rests entirely on the exchange's reputation and the moral commitments of its management.

The second is trust in the matching and execution layer. When a user places a limit buy order, they must trust that the exchange's matching engine will execute the order honestly according to price priority and time priority. Although users can obtain some order-book data through the API, they cannot verify the completeness or authenticity of that data, and the exchange is fully capable of hiding internal orders or fabricating liquidity in the API output. Users must therefore trust that the exchange will not let its proprietary market-making desk exploit an informational advantage to jump the queue, will not deliberately delay their orders to capture front-running profits, and will not, under extreme market conditions, prevent them from closing positions by severing their connection.

The third is trust in the clearing and settlement layer. Once each trade is executed, account state is taken over by this layer, which performs two kinds of continuously recurring work: clearing (reckoning the books) and settlement (posting the transfers). Clearing translates a *trade event* into a *change in account state*: it recomputes long and short positions, realized and unrealized profit and loss (P&L), and margin utilization, and it nets the multiple trades of a single account. Settlement is the actual transfer of value, including continuous mark-to-market against the mark price, the periodic funding payments unique to perpetual futures, and the booking of P&L at position closure. In both of these processes, the user must trust the exchange to keep the books and move the funds honestly—neither tampering with the account records nor distorting the mark-to-market and the funding rate. The fairness and transparency of the mark price are the shared benchmark of this layer: it drives both the routine mark-to-market settlement and the determination of whether margin is sufficient. Users must therefore be especially confident that the exchange will not manipulate the mark price in order to trigger liquidations that should not occur, will not abuse the auto-deleveraging (ADL) mechanism when a bankruptcy event arises, and that its declared insurance fund genuinely exists and is properly managed. Liquidation and auto-deleveraging are merely this layer's default-handling tools when an account becomes insolvent, not the whole of its function (the strict distinction among clearing, settlement, and liquidation is developed systematically in Section 28.4.3).

The fourth is trust in data authenticity. The prices, depth, trading volumes, and other data that users see on the exchange's front end are their sole basis for making trading decisions. Users must trust that these data are genuine rather than fabricated. This means believing that trading volume has not been artificially inflated by wash trading, that the order book is not flooded with ghost liquidity, and that market depth reflects genuine buying and selling intent rather than numbers invented by the exchange to manufacture an illusion of prosperity.

The last is trust in governance fairness. The exchange holds the unilateral power to change the rules. If the exchange revises its fee formula, adjusts liquidation parameters,

or alters its market-maker agreements, users must trust that these changes serve the overall interest of the market rather than the exchange's private gain. At the same time, users must trust that such rule changes will be disclosed to all market participants promptly and publicly, rather than made in secret.

These five trust assumptions form the foundation on which a centralized exchange operates. The core engineering insight, however, is this: the violation of any one of the five can inflict irrecoverable losses on users. More critically, in most cases users have no way at all to verify whether these trusts are being honored. Before a collapse, no publicly available method can detect that assets have been misappropriated. From the standpoint of behavioral finance, the way users form trust in a centralized platform is often shaped by cognitive biases: the availability heuristic leads users to substitute a platform's past record of normal operation for a rational assessment of its architectural security, while the herding effect leads large numbers of users to abandon independent judgment in response to the social signal that *everyone else is using it*. These cognitive limitations imply that the value of a layered architecture lies not only in providing verifiability for rational users, but also in protecting—through the architecture itself—those users who are cognitively unable to assess trust risk correctly. This unverifiable trust is precisely the root of systemic risk.

28.1.2 The trust stack model

To analyze the trust assumptions in a trading system more systematically, we propose the *trust stack* method of analysis. This method decomposes the trust assumptions of a trading system into five layers, from asset custody at the very bottom to the governance mechanism at the top. This layered model applies not only to centralized exchanges but equally to decentralized exchanges and to various hybrid architectures.

At the very bottom of the trust stack is the asset-custody layer, whose core question is whether assets are safe; the consequences of its trust failure are the most severe—assets are directly misappropriated or lost—and in a centralized exchange it depends entirely on the exchange's internal management and moral restraint. The second layer up is the matching and execution layer, which concerns whether orders are matched honestly; its trust failures manifest as front-running, queue-jumping execution, and price manipulation. Because the matching engine runs on private servers, outsiders cannot verify the fairness of order matching and can only accept the final execution results the exchange provides. The third layer is the clearing and settlement layer, responsible for post-trade clearing and settlement and for using liquidation as default handling when an account is insolvent (the distinction among the three is detailed in Section 28.1.1). When its trust is broken, the consequences include both the covert distortion of the books and settlement and unfair liquidations and abuse of auto-deleveraging; yet the clearing-and-settlement conventions and liquidation parameters are often treated as trade secrets that users cannot review. The fourth layer is the data and oracle layer, responsible for the authenticity of prices and market data; when its trust fails, the market is flooded with fake volume and price manipulation, and the exchange, as the sole data provider, holds a complete informational monopoly. The top layer is the governance layer, which determines how rules are set and changed; its trust failures manifest as covertly chang-

ing the rules for profit. In a centralized exchange, this governance is usually implicit, with the power to interpret and amend the rules held entirely by management.

Table 28-1 summarizes the core question, the consequences of trust failure, and the verification difficulty at each of the five layers. The *verification difficulty* column reveals a consistent pattern: from the bottom layer to the top, verification difficulty is generally high, which means that under the current centralized architecture users lack effective external means of verification at nearly every layer.

Layer	Core question	Consequences of trust failure	Verification difficulty
Layer 5: governance layer	How are rules set and changed?	Covertly changing rules for profit	Very high (usually black-box decisions)
Layer 4: data layer	Are prices and data genuine?	Fake volume / price manipulation	High (requires complex data forensics)
Layer 3: clearing and settlement layer	Are clearing (reckoning) and settlement (posting) executed per the rules?	Distorted books / unfair liquidation / ADL abuse	High (internal algorithms undisclosed)
Layer 2: matching layer	Are orders matched honestly?	Front-running / queue-jumping / order delay	Very high (full order flow unobtainable)
Layer 1: custody layer	Are assets safe?	Assets misappropriated or lost	Very high (no on-chain verifiable reserves)

Table 28-1. The five-layer trust stack model with its consequences of trust failure and verification difficulty (Data source: compiled by the author)

The analytical value of the trust stack is that it lets us ask three key questions about any trading system at each layer. First, who is being trusted—a particular entity, a piece of code, or a validator set? Second, can this trust be verified—does the user have any means of checking whether the trust is being honored? Third, can this trust be replaced—is there a technical mechanism that can eliminate the dependence on this particular entity? Through this structured questioning, we no longer reduce the problem of trust to a binary opposition between centralized and decentralized; instead, we turn it into a precise problem of engineering design.

The core strength of the trust stack model is that it offers a unified template for comparative analysis across different trading systems. The trust stack of a traditional financial centralized exchange, for example, is entirely different from that of a generalized automated market maker (AMM). Likewise, the trust stack of a perpetual futures exchange on an app-chain differs from that of a centralized exchange. This layered perspective lets us move beyond a simple binary account and into the details of system architecture.

The layers of the trust stack fail in different ways. The asset-custody layer is the most fundamental, and its failure is irreparable because the assets cannot be recovered. A failure in the matching and execution layer may amount only to a poorly executed trade and causes no permanent loss of assets. A failure in the clearing and settlement layer may distort the books or lead to unfair liquidations, but as long as the clearing, settlement, and liquidation rules are transparent, users can at least appeal. A failure

in the data layer may lead to poor decisions, yet once the data are published on chain they remain externally verifiable. A failure in the governance layer is the most insidious: rule changes can be hidden temporarily, until a crisis brings them to light.

In addition, the layered design provides a framework for understanding why different exchanges choose different trust-minimization strategies: centralized exchanges and app-chain exchanges often make opposite trust trade-offs at the custody layer and the matching and execution layer (see the trust-stack audit in Section 28.5), and system designers choose the optimal architecture accordingly, adapting to their specific circumstances.

28.1.3 FTX's extreme failure mode

The true value of the trust stack model is that it is not merely a theoretical framework but an analytical tool that helps us understand the real risks that exist in practice. When we revisit an actual historical event, the model's usefulness becomes especially clear.

When FTX collapsed in November 2022, a gap of more than $8 billion opened between customer assets and corporate liabilities, and at the moment of collapse the firm could not honor redemptions on demand [1]. The subsequent bankruptcy investigation and court filings revealed a grave engineering fact: the platform had never technically segregated customer assets from corporate assets [7]. All assets were commingled in a single wallet system, and no code-level access control or multi-signature mechanism existed to prevent management from drawing on customer funds at will [8]. The only safeguard was management's verbal promise and the users' one-sided trust.

This is precisely the extreme instance of the monolithic black box architecture defined at the opening of this chapter: all functional modules are concentrated in an opaque cluster controlled by a single entity, and the account balance a user sees on the front end is merely a number in a database, backed by no cryptographic proof. Whether assets were transferred to an affiliated market maker, whether orders were matched honestly, and whether liquidation parameters were secretly altered to protect internal accounts—users could neither know nor, still less, verify.

The core defect of the monolithic black box architecture lies in its correlation trap. In a well-designed distributed system, the failures of different components are expected by design to be independent of one another. Yet even in a carefully designed distributed system, common-mode failure—the simultaneous failure of multiple components triggered by a shared software dependency, infrastructure provider, or operational process—remains a systemic risk that is difficult to eliminate entirely. In a monolithic architecture, this problem is pushed to its extreme: all functional modules share the same root of trust. This means that once that root becomes corrupted or fails, the system faces not a partial degradation but the simultaneous collapse of all trust layers.

Examining this collapse through the trust stack model, we can see clearly the catastrophic consequences of the monolithic black box. At the custody layer, customer funds were directly misappropriated to cover the trading losses of an affiliated firm. At the matching layer and the clearing and settlement layer, internal accounts were granted

special privileges that allowed them to bypass the ordinary risk controls and liquidation mechanisms. At the governance layer, the setting and enforcement of rules served the interests of the controlling party entirely, rather than fairness to market participants. Not only were all five trust layers concentrated in the same entity, but that entity used its complete control to violate its implicit promises to users at every layer.

It was precisely to address this single-point-of-failure risk that the traditional financial system gradually developed an architecture of functional separation (see Section 28.3). In modern traditional finance, the exchange handles only matching, the clearinghouse handles risk management and settlement, the custodian bank handles asset safekeeping, and the regulator oversees the rules. Each function is performed by an independent entity, which greatly reduces systemic risk. By recombining all of these functions into a single opaque entity, the cryptocurrency centralized exchange represents, in architectural terms, a severe regression. Academic research shows that this excessive concentration of trust forces centralized exchanges to hold capital reserves far larger than those of traditional financial institutions in order to withstand potential run risk—yet even so, it cannot fundamentally eliminate the possibility of insider malfeasance [9].

FTX's collapse was not an isolated event. In the years that followed, the industry found that other centralized exchanges in the cryptocurrency market suffered from similar architectural defects. Commingled assets, the absence of on-chain verifiable proof of reserves, and inadequate technical barriers against insider malfeasance are not the individual misfortunes of one platform but inherent defects of the monolithic black box architecture of centralized exchanges.

28.1.4 Trust concentration and systemic risk

To assess quantitatively the risk level of different trading-system architectures, we introduce trust concentration as an analytical metric. Trust concentration measures what fraction of the trust layers in a trading system are controlled by the same entity. Its basic definition is as follows: for the five layers of the trust stack, if k of them are controlled by the same entity, that entity's trust concentration is $k/5$. When one entity controls all five layers, trust concentration reaches 100%; when the five layers are controlled by independent entities, the maximum trust concentration of any single entity is only 20%. This definition uses equal weighting—that is, it assumes the five layers carry the same risk weight. In practical assessment, one can introduce differentiated weights according to the severity of the consequences of each layer's trust failure; for example, because a custody-layer failure causes irreversible asset loss, its weight should exceed that of a data-layer failure, which merely biases trading decisions. A weighted trust concentration reflects the actual distribution of a system's fragility more precisely. One illustrative weighting scheme is as follows: custody layer 0.35 (asset loss is irreversible), clearing layer 0.25 (directly affects solvency), matching layer 0.20 (affects the fairness of trading), data layer 0.12 (indirectly affects decision quality), and governance layer 0.08 (affects the direction of rule evolution). Under this weighting, if an entity controls all five layers, the weighted trust concentration is still 100%; but the partial de-trusting of different layers produces differentiated reductions in concentration.

In a typical centralized exchange, all five trust layers are controlled by the same operating entity. Its trust concentration therefore reaches 100%. Such extremely high trust concentration implies extremely high systemic risk. Should the controlling entity's internal controls fail, or should its management act in bad faith, the entire system fails rapidly. No external check exists that could sound a warning or intervene before the crisis strikes.

By contrast, the separated architecture of the traditional financial system substantially lowers trust concentration through institutional design. If the five trust layers are the responsibility of an independent exchange, a central counterparty clearinghouse, a custodian bank, a data provider, and a regulator, respectively, then each entity's trust concentration is only 20%. Although users must still trust these centralized institutions, the trust is dispersed. The failure of one entity does not necessarily lead to the collapse of the others, and the entities have an incentive to monitor one another.

An ideal decentralized architecture pursues a trust concentration close to 0%. In such an architecture, no layer depends on the moral commitment of any single entity; each is instead controlled by open-source code, a consensus algorithm, or a decentralized validator set. Assets are held in custody by smart contracts, the matching and clearing logic executes publicly on the blockchain and is verified by the whole network, data are supplied by a decentralized oracle network, and governance is carried out through on-chain voting by token holders.

Trust concentration is not only a security metric; it also bears directly on the fairness and resilience of the market. The higher the concentration, the greater the room for the controlling party to engage in rent-seeking by exploiting its informational privilege and rule-making power, and the worse the market's fairness. At the same time, high concentration means the system carries a severe single-point-of-failure risk and lacks resilience in the face of internal corruption or external attack. Lowering trust concentration—decomposing the monolithic black box into a layered, transparent architecture—is therefore an engineering necessity for building a resilient on-chain financial system.

Measuring trust concentration provides an objective framework for assessing the relative margin of safety of different trading systems. If an emerging trading platform, by placing its custody layer in an on-chain smart contract and delegating its clearing layer to an independent app-chain, achieves a trust concentration markedly lower than that of a competitor that concentrates all functions in a single entity, then that platform holds a structural advantage along the systemic-risk dimension. This improvement in the margin of safety does not translate directly into an improvement in user experience (which also depends on factors such as latency, liquidity depth, and interface design), but it lowers the probability that users suffer catastrophic losses under extreme market conditions.

Trust concentration also explains the relationship between regulatory pressure and architectural choice. An exchange with higher trust concentration, lacking any architectural technical constraint on insider malfeasance, must compensate for its deficient architectural trust through stricter external regulatory scrutiny and more frequent proof of reserves. This is, in essence, a substitution mechanism that offsets an architectural defect with institutional cost.

28.2 The trust-performance frontier

Given that the centralized architecture carries such a severe single-point-of-failure risk, why not simply migrate every stage of trading onto the blockchain? If smart contracts could execute predetermined logic flawlessly and cryptographic proofs could eliminate the dependence on a single entity, building a *fully on-chain*, trustless trading system would seem to be the only ultimate solution. Reality, however, is otherwise: in the engineering practice of decentralized finance, a fundamental physical constraint stands between trust minimization and performance maximization. This trade-off does not stem from a temporary limit of current engineering capability; it is dictated by the inherent constraints of distributed-systems theory. Understanding this frontier between trust and performance is a prerequisite for designing any robust on-chain financial architecture.

28.2.1 The performance cost of a fully on-chain architecture

Executing the matching, clearing, and settlement of every order on a blockchain network means that every trade's change of state must be confirmed by the consensus of the whole network's nodes or its validator set. Although such global verification achieves an extremely high degree of trust minimization, it exacts a significant performance cost, first evident in a sharp increase in system latency. The internal processing latency of a top centralized exchange's matching engine is typically in the microsecond range, but this figure is meaningful only for colocated users; for ordinary users connecting through a remote API, end-to-end latency typically ranges from 10 to 100 milliseconds, encompassing network transmission, authentication, and risk-control checks. Binance, for example, has continuously increased its matching engine's order-processing capacity from the 1.4 million orders per second published in its 2017 white paper [10], and the peak capacity of leading exchanges now reaches the order of millions per second. By contrast, even an app-chain designed specifically for high-performance trading tends to remain at the millisecond or sub-second level: through its customized HyperBFT consensus, Hyperliquid achieves a median end-to-end latency of about 200 milliseconds and a processing capacity of roughly 200,000 orders per second [11], still three orders of magnitude short of a centralized exchange's microsecond response. Since the Merge, the block time of the Ethereum mainnet has been fixed at about 12 seconds (proof of stake), with a throughput of only 15–30 transactions per second [12], wholly unable to meet the speed requirements of high-frequency trading.

Beyond the hard limits on latency and throughput, a fully on-chain architecture also entails significant economic costs. In a centralized exchange, matching against the internal order book is almost costless, and users pay only a very small percentage fee upon final execution. In a fully on-chain model, however, every placement, cancellation, or modification of an order consumes network resources and incurs a corresponding transaction fee. This mechanism not only greatly increases traders' friction costs but also severely constrains liquidity providers. In the discussion of the structural arbitrage residual in Chapter 18, the efficiency gap between centralized and decentralized exchanges is, in essence, the quantifiable manifestation of this *cost of trustlessness*.

More seriously, the complete transparency of a fully on-chain architecture, while it

solves the trust problem, also introduces a new market-making dilemma. In a fully transparent on-chain environment, a market maker's order flow and capital movements are openly visible to all network participants, which makes them highly vulnerable to attacks based on maximal extractable value (MEV) [13]. To hedge this additional risk created by on-chain transparency, market makers are forced to adopt a series of defensive behaviors: widening the bid-ask spread, reducing quoted depth, increasing the frequency of quote flickering, and, in extreme cases, withdrawing liquidity entirely. In the end, this cost of trustlessness is passed on to all ordinary traders through multiple channels. Attempting to force every stage of trading onto the blockchain therefore not only struggles technically to meet the performance requirements of a professional market but also carries economic frictions that are difficult to overcome.

28.2.2 The systemic risk of a fully off-chain architecture

Given that a fully on-chain architecture faces such formidable performance and cost challenges, should we retreat to a fully off-chain, centralized model? The answer is no. The current centralized exchange is the very archetype of the fully off-chain model, and its extremely high performance rests entirely on an extreme concentration of trust: while users enjoy microsecond latency and cost-free cancellation, they are forced to entrust the full power over asset safekeeping, order matching, clearing execution, and rule-making to a single opaque entity.

The core defect of this fully off-chain black box architecture is that users have no technical means of verifying what actually happens inside the box. Even if a centralized exchange voluntarily chooses to improve transparency—by publishing proof of reserves periodically or disclosing some wallet addresses, for instance—such transparency still rests on a voluntary basis. The exchange can change its disclosure rules at any time, or even stop publishing key data on the eve of a crisis. Such non-architectural guarantees often prove worthless under extreme market conditions. The FTX collapse analyzed in Section 28.1.3 amply demonstrates that when one entity holds both control over assets and the power to interpret the rules, no internal risk-control mechanism or management promise can withstand the systemic default induced by the temptation of enormous gain.

Another latent hazard of the fully off-chain architecture is the high correlation of its failures: as analyzed in Section 28.1.3, all functional modules of the monolithic black box share the same root of trust, and once that root fails—through a hacking attack, internal misappropriation, or a regulatory freeze—the collapse is total and instantaneous, with no buffer between flawless operation and a complete standstill. To retreat to the fully off-chain black box merely because a fully on-chain architecture is not performant enough is therefore to trade a short-term expedient for long-term risk.

28.2.3 Characterizing the trust-performance frontier

Through the comparative analysis of fully on-chain and fully off-chain architectures, we can see clearly a fundamental trade-off in system design: trust minimization and performance maximization cannot both be achieved to the fullest along the same dimension. This trade-off can be described as a *trust-performance frontier*. If we place

the degree of trust minimization (verification depth) on the horizontal axis and system performance (the reciprocal of latency, or throughput) on the vertical axis, then, under given technical conditions, all feasible architectural designs form a set whose Pareto frontier is the trust-performance frontier. Any architectural choice can find its footing only on or inside this frontier; it cannot surpass the frontier itself. In most engineering settings, this frontier curve is convex: when the number of validators is used as a proxy for verification depth, the communication overhead of Byzantine fault-tolerant (BFT) consensus tends to grow superlinearly as the validator set expands, so that the performance cost of deepening verification further from a high-trust region increases at the margin. Verification depth and the number of validators are not the same dimension: an app-chain with only about twenty validators still achieves greater trust minimization than a centralized exchange controlled by a single entity. Convexity is therefore a reasonable characterization of the frontier's shape rather than a strict theorem. This convexity is consistent with the layered strategy: provided that the trust requirements of the layers are heterogeneous and separable, rather than pushing the whole system to one extreme of the frontier, it is better to select a different position on the frontier for each layer, thereby obtaining a superior overall combination of trust and performance. This concept shares a common theoretical root with the widely discussed *scalability–decentralization–security* trilemma of the blockchain field; both arise from the computation and communication overhead inherent in global verification within distributed systems. The trust-performance frontier differs from the trilemma in that the former focuses on the two-dimensional trade-off between trust assumptions and execution efficiency in a trading-system architecture, whereas the latter is a more general constraint on blockchain design as a whole.

Locating three representative categories of trading-system architecture on this frontier makes their respective trade-offs along the trust and performance dimensions immediately visible. In Table 28-2, from the traditional centralized exchange to the Ethereum-mainnet DEX, the degree of trust minimization and the level of performance exhibit a nearly perfect negative correlation, whereas the app-chain architecture attempts to open a new feasible region between the two extremes.

Architecture type	Degree of trust minimization	Performance (latency and throughput)	Position on the frontier
Traditional centralized exchange	Very low (relies entirely on a single entity)	Very high (microsecond latency, throughput in the millions)	Upper-left end of the frontier
Ethereum-mainnet decentralized exchange	Very high (whole-network consensus verification)	Very low (latency on the order of ten seconds, low throughput)	Lower-right end of the frontier
High-performance app-chain (such as Hyperliquid)	Relatively high (customized consensus, decentralized verification)	Moderate (sub-second latency, throughput on the order of 200,000)	Middle of the frontier, toward the right

Table 28-2. The positions of three trading-system architectures on the trust-performance frontier

(Data source: compiled by the author)

On this frontier curve, the traditional centralized exchange sits at the upper-left extreme, trading away trust minimization entirely for the highest performance. The decentralized exchange built on a general-purpose layer-1 network such as Ethereum sits at the lower-right extreme, achieving the greatest degree of trustlessness but forced to endure lower performance. The app-chain architectures that have since emerged, such as Hyperliquid, attempt to find a more balanced equilibrium point on the frontier. Through customized consensus mechanisms and specially optimized network architecture, they raise performance to a level sufficient to support professional derivatives trading while maintaining a relatively high degree of trust minimization.

As the underlying technology advances—through more efficient consensus algorithms, more sophisticated zero-knowledge proofs, and the adoption of parallel execution environments—this trust-performance frontier is indeed shifting toward the upper right. This means that, in the future, systems will be able to obtain higher performance while maintaining the same degree of trust minimization. Yet however the technology evolves, the additional computation and communication overhead of trustless verification is an objective reality, and under any known consensus model that overhead will not be eliminated entirely. Lower trust assumptions generally come with some form of performance compromise.

28.2.4 The logic of layered architecture

The trade-off between trust and performance is unavoidable, and neither the fully on-chain nor the fully off-chain approach is an ideal final solution. The way to resolve this tension lies in breaking the fixed assumption that *the system must, as a single whole, choose one position on the frontier*. A complete trading system is not an indivisible monolith but a trust stack composed of multiple functional layers. The layers differ in the severity of the consequences of trust failure and in their sensitivity to performance. The optimal architectural design should therefore evaluate the requirements of each layer independently and choose the best position on the trust-performance frontier for each. This is the underlying logic of layered architecture.

Three representative layers make this differentiated trade-off clear. A trust failure in the asset-custody layer is irreversible, while deposits and withdrawals are low-frequency operations that are insensitive to latency; this layer should therefore pursue trust minimization to the fullest (custody optimizes for safety). The matching and execution layer directly determines the fluidity of trading and the quality of liquidity, with stringent requirements for latency and throughput; as long as matching is verifiable after the fact, it can tolerate a degree of trust assumption in exchange for performance (matching optimizes for performance). The clearing and settlement layer sits between the two: computationally intensive in normal times yet insensitive to the latency of any single transaction, it must, during violent volatility, balance sufficient performance with an extremely high degree of trust minimization to guarantee the fairness of the rules (clearing sits in between). The optimal positions of these three layers, together with the specialized requirements of the data and oracle layer and the governance layer, are established layer by layer as design principles in Section 28.4.

The core idea of layered architecture is to reject the *one-size-fits-all* compromise. By decomposing the vast monolithic black box into independent modules and implementing a customized trust-performance trade-off within each, layered architecture can preserve the performance advantages of a centralized exchange at the critical stages while achieving the security guarantees of a decentralized network at the critical risk points. This engineering method of recombining the layers is the core design framework for building the next generation of robust on-chain financial systems.

28.3 The layered trust architecture of traditional finance

The trust problems facing the perpetual futures market—counterparty risk, asset safety, and the fairness of the rules—are not new problems of the cryptocurrency era. Over centuries of crisis and reform, traditional finance developed a mature trust infrastructure that includes central counterparty clearinghouses, central securities depositories, and regulators. These institutions are, in essence, the traditional-finance version of the trust stack, each corresponding to one or more layers of the stack. Only by understanding the operating logic, strengths, and limitations of these known solutions can we judge in which respects an on-chain architecture is an improvement, in which a regression, and in which merely a different trade-off.

28.3.1 The historical evolution of functional separation

Traditional finance did not begin with a well-developed trust infrastructure. The nineteenth-century exchange was likewise a monolithic black box, in which trade matching, clearing and settlement, and asset safekeeping all took place within the same exchange or broker. Under this architecture, problems such as counterparty default, brokers' misappropriation of customer funds, and price manipulation occurred frequently—strikingly similar to the problems that today's cryptocurrency centralized exchanges face.

The financial history of the past 200 years is a history of crisis-driven reform. Every major crisis pushed some layer of the trust stack toward independence and institutionalization. The Great Crash of 1929 directly gave rise to the U.S. Securities and Exchange Commission (SEC) in 1934, making the governance layer independent. The Wall Street paperwork crisis of 1973—the breakdown of the settlement system for paper stock certificates—prompted the creation of the Depository Trust Company (DTC, later the depository subsidiary of the Depository Trust & Clearing Corporation, DTCC), marking the independence of the custody layer [14]. Black Monday in 1987 drove the strengthening of clearing mechanisms, and the G20 Pittsburgh consensus after the 2008 global financial crisis directly gave rise to the reform of mandatory central counterparty clearing for over-the-counter (OTC) derivatives—embodied in the Dodd-Frank Act and the European Market Infrastructure Regulation (EMIR)—establishing the independent status of the clearing layer [15].

Traditional finance took 200 years to decompose the trading system from a monolithic black box into five independent layers, each managed by a different institution. At the governance layer are independent regulators such as the Commodity Futures Trading

Commission (CFTC) and the SEC; at the data layer, regulated data providers such as Bloomberg and Reuters; at the clearing layer, independent central counterparties such as CME Clearing and LCH; at the matching layer, regulated matching institutions such as the New York Stock Exchange and Nasdaq; and at the custody layer, independent central depositories such as the DTCC and custodian banks. Each layer is operated by a different specialized entity, with institutional checks and balances among them. In the span of a mere decade, cryptocurrency centralized exchanges recombined these five layers into a single entity—an architectural regression whose extreme consequence was precisely the collapse of FTX.

28.3.2 The CCP and clearing-layer trust

The central counterparty is the core mechanism by which traditional finance addresses clearing-layer trust. Its most critical function is novation. Once a buyer and a seller reach a trade, the CCP steps in, and the original trade is replaced by a trade between the buyer and the CCP and another between the CCP and the seller. The CCP becomes the central counterparty to all trades, so the buyer need not trust the seller—only the CCP [16]. In the language of the trust stack, the CCP concentrates clearing-layer trust from *trust your counterparty* into *trust one strictly regulated, specialized clearinghouse*. This differs fundamentally from the crypto market. In crypto perpetual futures there is no central counterparty, and a trader's counterparty is either a market maker or another trader. Counterparty risk is fully exposed, or borne implicitly by the exchange—yet the exchange may be unable to bear it, as the FTX episode plainly showed. Some leading crypto exchanges have established insurance funds and auto-deleveraging mechanisms that functionally assume part of the CCP's risk-mitigation role. The key difference between these mechanisms and an institutionalized CCP, however, is this: the insurance fund is limited in size and lacks any cross-platform mutualization layer, there is no mutual-aid mechanism analogous to the *loss-sharing by non-defaulting clearing members* in a default waterfall, and there is certainly no central bank acting as lender of last resort to backstop liquidity. They are therefore only an incomplete replica of the CCP's functions, not a genuine institutional substitute.

The CCP absorbs default losses layer by layer through the default waterfall (Chapter 1 has already discussed the basic mechanism of the central counterparty and the default waterfall; the point is restated here briefly in the context of clearing-layer trust): in sequence, the defaulter's initial and variation margin, the defaulter's contribution to the default fund, the CCP's own capital (its *skin in the game*), the mutualized sharing of losses from the default funds of non-defaulting clearing members, and finally the recovery and resolution procedures [17].

Compared with the crypto market, the CCP holds significant advantages. First, trust is concentrated but strictly regulated: the user need only trust one specialized institution supervised by a central bank or the CFTC. Second, the default waterfall has depth—not one major CCP defaulted even during the 2008 financial crisis, which proved the mechanism's effectiveness [18]. Yet the CCPs' effective performance in 2008 rested on an important implicit premise: central banks around the world provided a backstop for the entire financial system through emergency liquidity support, and this sovereign-

credit support is an institutional advantage that a decentralized system cannot replicate. Third, because the CCP's own capital ranks ahead of the clearing members in the default waterfall, the CCP has a strong incentive to maintain the quality of its risk controls.

The CCP also has limitations, however, and these limitations are precisely the directions in which an on-chain system might improve. The CCP is itself a *too big to fail* single point: if it runs into trouble, the entire market seizes up—which has been identified as a new form of systemic risk [19]. The London Metal Exchange (LME) nickel contract crisis of March 2022 laid this limitation bare. When the nickel price rose about 250% over three trading days (climbing to roughly 3.5 times its level), the LME (the decision was made at the exchange level, not by its clearinghouse, LME Clear) chose to suspend trading and retroactively cancel executed trades. This discretionary governance decision provoked serious doubts among market participants about the fairness of the exchange and its clearing infrastructure, and it led to multiple lawsuits [20]. The episode shows that a CCP's discretionary power under extreme market conditions can conflict with its positioning as neutral infrastructure. In addition, the CCP has a high barrier to entry: only large financial institutions can become clearing members, and small participants must go through intermediaries, making it a professional club rather than a permissionless system. The CCP's operating hours are also limited, and it does not support around-the-clock trading. Its transparency, moreover, is insufficient: its risk models and stress tests are confidential, so clearing members and end users cannot fully verify the quality of its risk controls—a form of regulated opacity.

28.3.3 The DTCC and custody-layer trust

The DTCC is the core institution that addresses custody-layer trust. Its core functions include central securities depository services and net settlement. All securities traded in the U.S. market are ultimately held in custody by the DTCC and its subsidiaries; buying and selling are merely transfers of title on its books, and physical certificates no longer move. Trust is concentrated from *every broker safely holds my shares* into *the DTCC safely holds everyone's shares* [21]. Through net settlement, of the trillions of dollars in daily trades, the funds or securities that actually need to be transferred amount to only a small fraction of total trade value, which greatly reduces settlement risk and funding requirements. According to reported figures, in 2024 the DTCC processed securities transactions worth about $3.79 quadrillion and provided custody and asset services for roughly $99 trillion in assets [22].

Within the trust stack, the DTCC solves the core problem of asset custody: assets are held in a strictly regulated, specialized institution independent of the exchange and the broker, so that even if a broker fails, customers' securities remain safe. Compared with the crypto market, the DTCC guarantees, through law and institutional design, the separation of customer assets from the broker's own assets, whereas most cryptocurrency centralized exchanges commingle customer assets with their own. As for settlement delay, the DTCC currently operates on T+1 settlement, whereas an on-chain system can achieve near-instant settlement. Yet, while instant settlement eliminates settlement risk, it also sacrifices the capital efficiency of net settlement: traditional T+1 settle-

ment offsets large volumes of opposing trades within the settlement window, so that the funds actually transferred amount to only a small fraction of total trade value. As for transparency, the DTCC is subject to regulatory audit but is not fully transparent to external participants, whereas in an on-chain system all balances are publicly auditable.

The DTCC's success demonstrates the institutional value of separating custody from the trading and market-making functions. Its depository subsidiary, the DTC (in operation since 1973 and folded into the DTCC as its holding company in 1999), has never lost customer assets in its entire operating history [23]. This approach, however, is a form of centralized institutional trust that depends on a combination of law, regulation, and specialized institutions. The crypto market can achieve the same goal through decentralized architectural trust. In principle, the asset segregation of a smart contract is stronger than the DTCC's, because the code executes deterministically according to preset logic, excluding the possibility of selective default by management. Yet the code itself carries the risk of bugs, and once a flaw appears its consequences are equally deterministic, since an attacker can exploit the vulnerability systematically. The DTC custody system, with more than 50 years of operating record and well-developed legal recourse mechanisms, offers a proven alternative safeguard [23].

28.3.4 The CFTC/SEC and governance-layer trust

Regulators play an irreplaceable role in the trust stack. The CFTC regulates the U.S. futures and derivatives markets, setting margin standards, position limits, and market-maker obligations, prosecuting manipulation and fraud, and overseeing the operation of central counterparties. The SEC regulates the securities markets, performing similar functions [24]. Within the trust stack, these agencies address trust at the governance layer and, in part, at other layers, ensuring that the rules are fair, that participants have channels of appeal, and that rule changes follow due process.

Regulation as a trust mechanism has notable advantages. The first is enforcement power: regulators have the legal authority to penalize violators or shut down offending institutions—a hard power that on-chain governance currently lacks. The second is professional judgment: regulators command experts in finance, law, and technology and can make complex discretionary decisions, and in extreme situations human judgment may be superior to the rigid execution of code. Finally, being regulated is itself a trust signal that lowers participants' cost of gathering information.

But regulation also has limitations. Regulatory processes are often measured in months or years, whereas market changes are measured in days or hours, so regulation always lags innovation. A regulator can govern only the markets within its jurisdiction, whereas the crypto market is global. There is also the risk of regulatory capture, in which the regulated can influence the regulator and skew the rules toward industry interests. Regulators can usually detect problems only after the fact and can hardly guarantee in advance that all is well; FTX, for instance, was never flagged by the CFTC before its collapse, because FTX exploited the regulatory fragmentation among multiple jurisdictions and, through a complex corporate structure (incorporated in the Bahamas, operating in Hong Kong, serving users worldwide), effectively evaded the

effective jurisdiction of any single regulator.

Compared with on-chain governance, regulators' rule-making is expert-led and legally binding, whereas on-chain governance relies on token-holder voting and can be manipulated by large holders. Regulators' human enforcement is subject to delay but carries coercive force, whereas on-chain code executes automatically without delay but is rigid. Regulators' rule-change procedures are transparent but slow, whereas on-chain governance may be fast or slow. Regulators offer legal remedies such as courts and arbitration, whereas the verdict of code in an on-chain system is usually final.

28.3.5 An overall assessment of the traditional trust architecture

The traditional trust architecture—the combination of the CCP, the DTCC, and regulators—has successfully solved many core problems. The CCP resolves counterparty default excellently, and the DTCC resolves asset misappropriation excellently; regulators' containment of price manipulation is moderate, and their guarantee of rule fairness is relatively good (the specific mechanisms of each institution are given in Sections 28.3.2–28.3.4).

The traditional trust architecture also has unsolved problems, however, and these are precisely the opportunities for on-chain systems. The traditional architecture serves only regulated local markets and excludes the world's large unbanked population, whereas an on-chain system is permissionless and open to anyone worldwide. Traditional institutions operate on business days and during trading hours, whereas an on-chain system natively supports around-the-clock operation. The traditional architecture's T+1 settlement still carries a full day of settlement risk, whereas on-chain settlement completes within block confirmation. The traditional architecture's risk models and position data are not fully transparent, whereas in an on-chain system all rules, trades, and positions are visible to everyone. In the traditional architecture, new products require a lengthy regulatory approval process, whereas an on-chain system is permissionless and innovation can be deployed instantly. Moreover, the core institutions of the traditional architecture themselves become systemic single points that require a government backstop, whereas the decentralization of an on-chain system in theory eliminates this single-entity risk.

From this, we can distill three paradigms for realizing trust. The first is institutional trust, exemplified by traditional finance, in which the source of trust is law, regulation, and specialized institutions, and the core mechanisms include the default waterfall, independent custody, and enforcement. Its advantages are 200 years of validation, coercive force, and professional judgment; its disadvantages are a high barrier to entry, geographic limits, slowness, and opacity. The second is platform trust, exemplified by the cryptocurrency centralized exchange, in which the source of trust is trust in the exchange or platform, and the core mechanisms are internal systems, brand reputation, and voluntary audits. Its advantages are the highest performance and the best user experience; its disadvantage is complete dependence on a single entity, with an extreme risk of collapse. The third is architectural trust, exemplified by on-chain systems, in which the source of trust is code, cryptography, and consensus mechanisms, and the core mechanisms are smart contracts, on-chain clearing, and on-chain governance. Its

advantages are transparency, global reach, around-the-clock operation, and permissionlessness; its disadvantages are limited performance, rigid rules, and the risk of code vulnerabilities.

The optimal solution may not be to choose one of the three, but to blend all three. At the asset-custody layer, architectural trust is the strongest—the equivalent of a code version of the traditional depository. At the clearing and settlement layer, architectural trust and institutional trust can be combined, taking the depth of the CCP's waterfall together with the transparent verifiability of the chain. At the governance layer, institutional, architectural, and platform trust can be blended. The design principle of layered architecture is precisely to find, at each layer, the optimal blend of these three trust paradigms.

28.3.6 Functional inheritance from the CCP to on-chain clearing

The narrative that on-chain finance is meant to replace traditional finance is mistaken; it pits the two against each other and ignores the institutional wisdom that traditional finance has accumulated over the long run. A better narrative is that on-chain finance is a technical upgrade of traditional finance's trust infrastructure. It uses code to achieve what the central counterparty already achieves through law, on-chain transparency to achieve what the depository already achieves through audit, and DAOs or multisignature schemes to achieve what regulators already achieve through administrative procedure.

This functional inheritance manifests in several respects. The CCP's novation is realized on chain by a smart contract acting as the impersonal counterparty to all trades, which eliminates the CCP's own default risk but loses the human judgment for handling extreme situations. The default waterfall is realized on chain as margin, the insurance fund, liquidity-provider takeover of liquidated positions, and auto-deleveraging, each step publicly auditable and automatically executed, eliminating the delay of human intervention—but its depth may fall short of a traditional CCP's, and there is no government backstop. The on-chain waterfall also typically lacks a layer corresponding to *skin in the game* (in which own capital bears losses ahead of members), and auto-deleveraging trims the positions of the profitable side, which is not equivalent, in either the population affected or the incentives, to the mutualized loss-sharing by nondefaulting clearing members in a traditional waterfall. Daily marking is upgraded on chain to real-time mark-price computation and continuous margin monitoring—from daily to per-second—reducing risk exposure, though the smoothing of the mark price may lag in a fast-moving market. Margin calls become instant liquidation on chain. This eliminates settlement risk but also denies the trader a second chance to top up margin, making the system more rigid. In a high-volatility environment, however, instant liquidation avoids the danger of risk exposure widening during the call period and may in fact be more prudent. This is all the more true under a multichain architecture, where cross-chain fund transfers often take several minutes or more—limited by source-chain confirmation and bridging delay—so that adding margin in practice becomes extremely difficult, which further reinforces instant liquidation as the appropriate default. Confidential stress tests become real-time risk monitoring based on public data,

which anyone can run independently, though there is as yet no standardized framework.

The design goal of an on-chain clearing and settlement system is not to replace the central counterparty but to realize its core functions through technical means while overcoming its limitations. This raises the key design questions: can an on-chain system achieve a default waterfall of equal depth? How can the optimal balance between risk control and user experience be found? How can the problem of incentive alignment be solved in an on-chain system? These questions constitute the core challenges of building a resilient on-chain financial system.

28.4 Design principles of layered architecture

The essence of layered architecture is not simple modular partitioning but a precise engineering strategy of trade-offs: it allows a system to select the optimal architectural position independently at each functional layer, according to that layer's specific requirements for trust minimization and performance maximization [25], thereby abandoning the crude mode of the monolithic black box entirely and building instead a transparent, verifiable, and highly resilient financial ecosystem.

Layered architecture comprises six core design principles: the first five correspond to the five layers of the trust stack, addressing each layer's distinctive trust challenge and establishing the corresponding standard for technical implementation; the sixth concerns the design of the interfaces between layers, ensuring secure coordination among the modules.

28.4.1 De-trusting the asset-custody layer

The asset-custody layer sits at the very bottom of the trust stack and is the foundation of the entire system's security. In the monolithic black box architecture, users' assets are concentrated in a wallet controlled by a single entity, a design that creates the most severe single-point-of-failure risk. Should the controlling entity succumb to moral hazard or suffer a security breach, all users' assets face irreversible loss. The design principle of the asset-custody layer is therefore clear: it must achieve maximal de-trusting and, even at the cost of sacrificing some performance, must guarantee the safety of assets.

In engineering terms, this means stripping away, to the greatest extent possible, a centralized entity's unilateral control over user assets. Modern on-chain financial systems typically use smart contracts as the vehicle for asset custody, employing immutable code logic to strictly constrain the flow of funds and the conditions for withdrawal. Under this architecture, the transfer of assets no longer depends on management's promise but is bound by cryptographic proof and predefined consensus rules. To strengthen security further, multi-party computation (MPC) and hardware security modules (HSMs) are widely applied in key management, ensuring that even if some nodes are compromised, an attacker cannot reassemble the complete signing authority [26].

In addition, the asset-custody layer must be able to operate independently of the other layers. Even if the matching engine crashes or the clearing and settlement system fails, users' assets must be able to remain safely in the custody smart contract, or users must

be allowed to withdraw their funds back to the underlying blockchain network through an emergency exit mechanism. In practice, however, the emergency exit mechanism faces operational risk: when an app-chain stops producing blocks entirely, the exit mechanism must rely on preset timeout-triggered logic, and in a mass-exit scenario the gas fees on the underlying network may spike sharply, making the exit cost uneconomical for small users. This design logic is of a piece with the traditional-finance principle that the custodian bank is independent of the exchange, but in the on-chain environment it is realized through mathematics and code rather than law and regulation. Smart-contract custody, however, carries an inherent legal vulnerability. In August 2022, the U.S. Treasury's Office of Foreign Assets Control (OFAC) added the immutable smart-contract addresses of Tornado Cash to its sanctions list, showing that a smart contract, too, can become the object of sovereign sanction; yet in November 2024, in Van Loon v. Department of the Treasury, the U.S. Court of Appeals for the Fifth Circuit ruled that an immutable smart contract does not constitute sanctionable "property" within the meaning of the International Emergency Economic Powers Act (IEEPA), and the Treasury accordingly delisted it in March 2025 [27]. This reversal shows that the legal boundaries of smart-contract sanctions are still evolving, but while the sanctions were in force, the legal risk faced by users interacting with the sanctioned contract was real. Moreover, the conflict between a judicial freeze order and the immutability of a smart contract has yet to be adequately resolved within the legal framework. Thus, while cryptographic custody effectively eliminates the operator's moral hazard, it does not eliminate legal risk or sovereign risk, and these two kinds of risk lie beyond the capacity of the technical architecture. At this layer, performance metrics such as transaction latency and throughput recede to secondary importance, because depositing and withdrawing assets are low-frequency operations, whereas security is the non-negotiable bottom line.

28.4.2 The verifiability of the matching and execution layer

Unlike the asset-custody layer, whose core demand is security, the matching and execution layer is the most performance-demanding stage of the entire trading system. Microsecond latency and throughput of tens of thousands of orders per second are necessary conditions for ensuring market liquidity and the trading experience. Subjecting the matching of every order to global consensus verification on the underlying blockchain would produce a performance loss that no active market could bear. The design principle of the matching and execution layer is therefore this: while meeting the demand for high performance, constrain the behavior of the matcher through after-the-fact verifiability mechanisms so as to ensure that orders are executed honestly.

In a layered architecture, the matching engine is usually designed as a high-performance independent module that can run on a customized app-chain or exist as an off-chain compute node. To prevent the matcher from exploiting its informational privilege to front-run or manipulate prices, the system must introduce strict fairness-guarantee mechanisms. The order-matching engine must strictly follow the price-time priority principle, and its execution results must be endorsable by cryptographic proof [28].

One engineering direction under active research and early exploration is the use of

batch proofs or zero-knowledge proof techniques. The matching engine processes vast numbers of orders at high speed off chain and then periodically submits state updates and execution proofs to the chain for verification. This approach preserves the efficiency of centralized matching while, through mathematical proof, stripping the matcher of the ability to act maliciously. Users need not verify the correctness of every trade in real time as it occurs, yet they can be confident that any matching that violates the established rules cannot pass the final on-chain verification. In this way, the matching and execution layer finds an effective balance point on the frontier between trust and performance: it tolerates local centralization in the execution process but, through global verifiability, eliminates one-sided trust in the matcher's honesty.

28.4.3 The clearing and settlement layer: from reckoning and posting to default handling

The clearing and settlement layer connects the results of matching and execution with the state of asset custody, and it is the layer of an on-chain system that corresponds most closely to the function of the traditional central counterparty. Yet it is precisely at this layer that the ambiguity of the Chinese terminology most easily obscures a key engineering distinction. In the context of financial infrastructure, clearing, settlement, and liquidation are three concepts that must not be used interchangeably. Clearing is *reckoning the books*—the state transition after a trade is executed but before funds actually move: replacing the counterparty with the system through novation, performing multilateral netting across multiple trades, recomputing positions and realized P&L, and updating margin utilization. Settlement is *posting*—the actual change of hands of value: mark-to-market against the mark price, the periodic funding transfers unique to perpetual futures, the formal booking of realized P&L at position closure and the release of margin, and, layered on top in the on-chain setting, finality confirmation. Liquidation is another matter entirely: it is the forced closure of a position triggered when account equity falls below the maintenance margin, the layer's handling mechanism in the event of default, not the whole of the layer's function. Many design discussions misjudge risk precisely because they blur all three together under the single word *clearing*. Accordingly, this section decomposes the clearing and settlement layer into three subfunctions—clearing, settlement, and liquidation—and establishes the design principle of each.

The overall design principle of this layer is that all rules must be executed consistently and transparently, so that no one—including the system's developers—can covertly alter parameters or interfere with the process. In traditional finance, this function is assumed by the central counterparty, which raises capital efficiency and isolates systemic risk through multilateral net settlement [29]. The goal of the on-chain architecture is not to abolish this function but to replace the dependence on a trusted clearinghouse with deterministic code and consensus verifiability.

Clearing: the deterministic recomputation of account state. The clearing subfunction answers the question of *what a given trade means at the account level*. In a traditional central counterparty, novation means the buyer and seller no longer expose each other to credit risk and instead face only the clearinghouse as their common

counterparty; in an on-chain system, this role is assumed by a smart contract or the state machine of an app-chain, so that after a trade both sides' positions are recorded according to uniform rules, and a default by either side does not propagate directly to its counterparty but is absorbed by the system. Multilateral netting consolidates a single account's multiple trades into a net change in position, and positions, realized P&L, and margin utilization are recomputed accordingly. The core requirement of the clearing sub-function is determinism: every margin determination and every update to the books must be independently recomputable by each validator, yielding the same result. This is precisely the on-chain embodiment of the principle that *the clearing authority must be a single point, while verification must be open to everyone*—the business-layer discretion over clearing is concentrated in a single deterministic engine, while the consensus layer guarantees that every step of that engine's output can be recomputed and checked by any node.

Settlement: the actual delivery of value. Unlike a traditional contract, which settles once at expiry, the settlement of perpetual futures occurs continuously. Mark-to-market settlement continuously revalues positions against the mark price, reflecting unrealized P&L in account equity in real time; funding settlement transfers funds between the long and short sides at fixed intervals, which is the core mechanism that lets perpetual futures anchor to the spot despite having no expiry; and closing settlement formally books realized P&L and releases margin when a position is closed out. In the on-chain environment, settlement adds a further layer of finality: a change of state becomes irreversible only after it is written into a block and confirmed by consensus. The design principle of the settlement sub-function is the transparency and immutability of posting—every funding transfer and every booking of P&L should be auditable on chain, foreclosing the covert transfers common in centralized exchanges.

Liquidation: the line of defense for handling default. When account equity falls below the maintenance margin, the liquidation mechanism steps in and forcibly closes the position to prevent it from going bankrupt. The complexity of liquidation requires this layer to possess a moderate degree of computational performance while maintaining an extremely high standard of trust minimization: if the liquidation rules could be changed at will, or if the liquidation engine could selectively ignore certain high-risk positions, the entire system's solvency would fail rapidly. The triggering conditions and execution flow of liquidation must therefore be hard-coded as public smart-contract or app-chain consensus logic. In implementation, the system needs a distributed liquidation orchestrator that continuously monitors the risk exposure of all accounts and, when the margin ratio falls below the maintenance threshold, triggers liquidations in an orderly fashion according to the urgency of the exposure. Modern liquidation engines generally adopt a partial-liquidation strategy—closing only the smallest fraction of a position needed to restore the account above the maintenance margin, rather than the traditional full liquidation—thereby reducing market impact while lowering the risk of a systemic reaction set off by a liquidation cascade.

To prevent an attacker from manufacturing spurious liquidations by manipulating oracle prices, the liquidation sub-function must establish a robust interface with the data layer and build a manipulation-resistant mark-price system. A mature mark-price construction typically includes the index price (the median of prices across multiple

exchanges), a basis moving-average term (which uses an exponential moving average to characterize the deviation between the contract mid-price and the index price and adds it to the index price additively), price-band protection (which limits the jump magnitude of the mark price when the deviation exceeds a threshold), and an outlier-exclusion mechanism (which automatically excludes any single data source exhibiting an extreme deviation). When liquidation is still insufficient to cover the losses, the insurance fund serves as the next line of defense to absorb bankruptcy losses; its operating state must likewise be fully on chain, and the injection and depletion of its funds should be bound by strict smart-contract constraints, ensuring that under extreme market conditions the system absorbs tail losses in a transparent and predictable manner rather than relying on an opaque internal bailout.

The relationship among the three sub-functions constitutes the internal logic of this layer: clearing comes first, keeping the books consistent before any further matching occurs; settlement then effects the actual transfer of value and confers on-chain finality; and liquidation is the last line of defense, maintaining the system's solvency when a default occurs. This distinction also runs through the chapters that follow—the next chapter's design of a decentralized clearing and settlement architecture rests precisely on treating clearing, settlement, and liquidation as each performing its own role, rather than conflating them.

28.4.4 Manipulation-resistant design of the data and oracle layer

The data and oracle layer is the sole bridge through which an on-chain system interacts with the external real world. Because a blockchain is itself a closed, deterministic state machine, it cannot directly perceive the prices of external assets or the occurrence of real-world events. It must therefore rely on an oracle network to bring this critical data into the system securely. The design principle of the data layer is to eliminate the fragility of a single data source and to ensure that the price information fed into the system is genuine, manipulation-resistant, and highly available.

The core of the oracle problem is how to introduce subjective or external information into a trustless system without undermining the system's overall security [30]. If a derivatives protocol with billions of dollars in locked value depends on a single exchange's API to obtain its mark price, that API becomes the critical point of fragility for the entire system. An attacker need only use a flash loan to create a brief price spike in a single market to trigger large-scale erroneous liquidations and reap excess profit.

To honor this design principle, the layered architecture must adopt a distributed oracle network. Such a network aggregates quotes from multiple independent data providers and multiple exchanges and removes outliers, thereby producing a robust composite price. In addition, oracle nodes must stake assets, using an economic incentive mechanism to ensure that they report data honestly. If a node submits erroneous data that deviates from consensus, its staked assets are slashed. Through this cryptoeconomic design, the data layer converts trust in *authenticity* into a reliance on economic rationality and decentralized consensus, thereby providing a solid data foundation for the clearing and execution above it.

28.4.5 The procedural legitimacy of the governance layer

Any complex financial system must evolve continuously as market conditions change, which inevitably involves parameter adjustments, contract upgrades, or the deployment of new features. The governance layer is responsible for managing these processes of change. In the monolithic black box, governance is implicit, and management can change the rules at will without notifying users. The design principle of the governance layer is therefore this: all rule changes must be public and thoroughly debated, and their execution must be verifiable and predictable.

Decentralized governance mechanisms aim to eliminate the unilateral control of a few insiders over the system. In an ideal layered architecture, governance power is distributed to token holders or to a council of representatives elected by the community. Any major change to the system—adjusting the base fee rate, revising the liquidation penalty ratio, or upgrading the core smart contracts—must be initiated through an on-chain proposal and put to a vote over a prescribed period [31]. On-chain governance participants may face legal-liability risk: the CFTC's enforcement precedent against Ooki DAO shows that DAO token holders who participate in governance voting may be deemed members of that unincorporated association and thereby bear joint legal liability for the association's debts [32].

More important still, the governance layer must introduce a time-lock mechanism. Even after a change proposal passes, it cannot take effect immediately but must wait a fixed cooling-off period in a time-lock contract. This cooling-off period provides an escape window for users who disagree with the change, allowing them to withdraw their assets safely before the rules change. Through this design, the system not only constrains governance power but also grants users the ultimate right to vote with their feet. The governance layer is no longer a center of power that issues commands unilaterally, but an engine of rule evolution based on consensus and transparent procedure.

28.4.6 Modular design of the interfaces between layers

The success of a layered architecture depends not only on the robust design within each layer but also on how the five layers coordinate securely and efficiently. The last design principle therefore concerns the interfaces between layers: the system must maintain a high degree of modularity and composability, so that the layers can evolve independently while the risk of cross-layer attacks is guarded against.

Modularity means that each layer should provide services externally through a standardized interface while hiding its internal implementation details. The clearing and settlement layer, for example, need not know which specific matching algorithm the matching and execution layer uses; it need only receive trade records in a particular format. Likewise, the matching engine need not care whether the asset-custody layer uses multi-party computation or a hardware security module; it depends only on the proof of available balance that the custody layer provides. This decoupled design greatly reduces the system's complexity, letting developers focus on optimizing the performance or security of a specific layer without having to restructure the whole system.

Modularity also introduces a new challenge, however: interface risk. An attacker often will not attack a hardened layer directly but will instead seek vulnerabilities in the passing of information between layers. For example, if the data layer's latency in passing price information to the clearing layer is too high, the liquidation logic may make erroneous judgments based on stale data. Interface design must therefore include strict data validation, timeout handling, and graceful-degradation mechanisms. When a layer fails or is attacked, the system should be able to isolate it through the interface protocol, preventing the risk from spreading to the other layers and thereby safeguarding the ultimate resilience of the entire financial ecosystem.

28.5 A trust-stack audit of current architectures

Applying the trust stack model to the major trading architectures in the current market reveals the trust state of these systems across the five layers of asset custody, matching and execution, clearing and settlement, data and oracles, and governance. A system's trust audit can not only quantify precisely the trust concentration of different architectures but also lay out clearly the engineering path along which the industry is evolving from the monolithic black box toward a layered, transparent architecture. The following examines, in turn, the trust assumptions and verifiability of the typical centralized exchange, the AMM-type decentralized exchange, the app-chain decentralized exchange, and the emerging hybrid architecture at each layer.

28.5.1 The trust stack of a typical CEX

The architecture of a typical centralized exchange is, in essence, a highly integrated monolithic system, and its trust stack exhibits extreme concentration. Under this architecture, over the entire life cycle of completing a trade, the user must deliver complete trust at all five trust layers to a single entity: the exchange operator. The fragility of this trust structure was amply exposed in the several industry crises of 2022, which demonstrated that when trust concentration reaches 100%, the system's single-point-of-failure risk becomes unbearable [33].

At the asset-custody layer, the user must trust the exchange completely to safeguard the deposited funds. Centralized exchanges typically manage customer assets with internally controlled hot and cold wallet systems, which means the operator has the technical ability to move funds at will. Although some exchanges have introduced proof-of-reserves mechanisms in an attempt to improve transparency, such mechanisms have a fundamental limitation. Proof of reserves is usually based on an asset snapshot at a particular point in time combined with a Merkle tree structure; while it can prove that the exchange controls a certain quantity of assets, it often cannot provide proof of liabilities of equal strength [34]. Worse, the transparency of this off-chain system is provided voluntarily by the exchange and can be withdrawn at any time, rather than being enforced by the underlying architecture. The lag of the snapshot also leaves the exchange room to move funds temporarily in order to pass an audit.

At the matching and execution layer, a centralized exchange's internal order book and matching engine are entirely opaque to the outside. The user must trust the exchange

to execute orders fairly, strictly according to price priority and time priority, without exploiting an informational advantage to front-run, and without deliberately delaying retail orders under extreme market conditions to protect the interests of its proprietary market-making desk. Because the matching process lacks verifiable cryptographic evidence, users who suffer unfair treatment often cannot prove it.

The clearing and settlement layer is likewise an opaque black box. Post-trade clearing of the books (the recomputation of positions, P&L, and margin), mark-to-market and funding settlement, and the triggering and execution of liquidations are all carried out inside the exchange. Although the exchange usually discloses its margin-calculation formulas and liquidation-triggering rules, the specific execution of these rules cannot be audited. During violent market swings, the exchange holds the implicit power to modify the mark-price algorithm or adjust liquidation parameters. The original intent of this flexibility may be to prevent cascading liquidations from triggering a systemic collapse, but in substance it grants the exchange the unilateral power to decide the fate of users' assets.

The data layer and the governance layer further intensify the concentration of trust. The exchange is both the sole provider of market data and the sole maker of the system's rules. Users have no way to verify the authenticity of order-book depth, nor any way to guard against fake volume misleading market sentiment. As for governance, fee adjustments, the listing of new contracts, and modifications of market-maker agreements are all decided unilaterally by the exchange's management, without due process or community oversight.

Table 28-3 maps the foregoing analysis onto the five layers of the trust stack, presenting the trust state and verifiability of a centralized exchange at each layer. The *trust state* column reflects the degree of trust the user must deliver to the exchange operator at that layer, while the *verifiability assessment* column measures the technical feasibility of an external observer independently confirming the operating condition of that layer. Reading the two columns together reveals a central contradiction: the centralized exchange demands complete trust from users at every layer yet offers effective external means of verification at almost none.

Layer	Trust state	Object of trust	Verifiability assessment
Asset custody	Complete trust	Exchange operator	Very low; proof of reserves offers only a limited static snapshot
Matching and execution	Complete trust	Exchange operator	None; the internal matching-engine logic is invisible to outsiders
Clearing and settlement	Complete trust	Exchange operator	Low; the rules are public but the specific execution cannot be audited
Data and oracle	Complete trust	Exchange operator	Low; data authenticity relies entirely on the platform's self-discipline
Governance	Complete trust	Exchange management	Very low; rule changes lack transparency and any mechanism for participation

Table 28-3. A trust-stack audit of a typical centralized exchange (Data source: compiled by the author)

Table 28-3 shows clearly that the typical centralized exchange exhibits, without exception, a state of *complete trust* across all five layers, with verifiability ranging from *very low* to *none*. This severe mismatch between trust and verifiability means that users have the fewest means of verification precisely where they most need protection. Taken together, the trust concentration of a typical centralized exchange reaches 100%. This mode of fully merging the trading, custody, clearing, and settlement functions within a single entity would be unthinkable in the traditional financial system [35]. As discussed in Section 28.3, traditional finance has, through institutional evolution, built a framework of mandatory functional separation. In pursuing the highest performance, the monolithic black box architecture of the centralized exchange sacrifices every attribute of trust minimization.

28.5.2 The trust stack of AMM-type DEXs

AMM-type decentralized exchanges mainly serve spot swaps and are not in the same category as the perpetual futures derivatives on which this book focuses; they are included here only within the trust-stack audit, as one link in the evolutionary lineage of four architecture types, and are not elaborated. Their core achievement is a high degree of trust minimization at the asset-custody layer through smart contracts: user assets are locked in an on-chain liquidity-pool contract, deposits and withdrawals strictly follow public code logic, no single entity holds the private-key authority to misappropriate funds, and the custody-default risk of a centralized exchange is thereby fundamentally eliminated.

Yet while the automated market maker solves custody-layer trust, it introduces new challenges at the other layers. The matching and execution layer abandons the central limit order book (CLOB) and instead relies on algorithmic pricing such as the constant-

product formula; this eliminates trust in a centralized matching engine, but the execution process is exposed in the public mempool, making trades highly vulnerable to MEV attacks, in which validators can extract value from users through front-running or sandwich attacks. At the clearing and settlement layer, because the AMM mainly serves the spot, its logic is relatively simple, usually taking the form of instant swaps of tokens within the liquidity pool; once extended to derivatives, however, it must rely on an external oracle to supply the mark price for computing the funding rate and triggering liquidations, thereby shifting the trust risk to the data layer. The data and oracle layer thus becomes the most fragile link in this type of architecture: once the oracle is manipulated or fails, it can lead to large-scale erroneous liquidations, and even multi-source aggregation and economic staking cannot eliminate this risk entirely. The governance layer generally adopts a DAO model, which improves transparency but faces the problems of voting power concentrating among large holders and low decision-making efficiency.

Table 28-4 summarizes the foregoing analysis within the trust-stack framework. AMM-type DEXs display a marked divergence: the custody layer achieves a breakthrough close to zero trust, while the execution and data layers retain residual trust of differing forms. Unlike the uniform *complete trust* of the centralized exchange in Table 28-3, their trust distribution varies as a gradient across the layers.

Layer	Trust state	Object of trust	Verifiability assessment
Asset custody	Highly trustless	On-chain smart contract	High; the contract code is publicly auditable, and asset flows are traceable on chain
Matching and execution	Partially trustless	Algorithmic pricing and block-ordering parties	Moderate; the pricing logic is transparent, but transaction ordering is subject to MEV
Clearing and settlement	Highly trustless (spot) / partially trustless (derivatives)	Smart contracts and external oracles	High (instant spot settlement) / moderate (derivatives depend on oracles)
Data and oracle	Partial trust	Decentralized oracle network	Moderate; multi-source aggregation, but a manipulation window remains
Governance	Partially trustless	DAO and token holders	Moderate; the voting process is transparent on chain but may be dominated by large holders

Table 28-4. A trust-stack audit of AMM-type decentralized exchanges (Data source: compiled by the author)

The key pattern that Table 28-4 reveals is *solid at the base, weak at the top*: the custody layer and the spot clearing layer reach *high* verifiability, but this gradually gives way

to *partial trust* as one moves up the layers. The MEV problem at the matching and execution layer and the manipulation window at the data and oracle layer constitute the two persistent bottlenecks of this type of architecture, and they also point to the directions in which the later app-chain architecture improves.

28.5.3 The trust stack of app-chain DEXs

The app-chain decentralized exchanges exemplified by Hyperliquid and the fourth-generation dYdX represent the current frontier of engineering exploration on the trust-performance frontier. By *app-chain*, this chapter means an independent blockchain network customized for a single application scenario, whose consensus mechanism, state machine, and network parameters are all deeply optimized around a specific use (such as derivatives trading). An app-chain differs from a general-purpose rollup in that a rollup inherits the security of the underlying chain and submits state proofs to it, whereas an app-chain maintains an independent validator set and consensus process. An app-chain differs from a traditional sidechain in that a modern app-chain is usually based on BFT consensus (such as Cosmos SDK's Tendermint or Hyperliquid's HyperBFT) rather than a simple multi-signature scheme or merged mining. dYdX v4's migration from StarkEx (an Ethereum-based rollup solution) to an independent app-chain built on the Cosmos SDK is a landmark case of this architectural paradigm shift, motivated precisely by the desire to obtain full customization of the consensus and execution layers so as to move order-book matching fully on chain. These protocols abandon the traditional path of building applications on a general-purpose smart-contract platform and instead develop an independent blockchain optimized specifically for trading. This architectural choice achieves an unprecedented, finely balanced equilibrium across the layers of the trust stack.

At the asset-custody layer, the app-chain architecture exhibits partial trustlessness. Because the app-chain itself typically does not host native assets, users must transfer funds from a mainnet such as Ethereum onto the app-chain through a cross-chain bridge. The security of the cross-chain bridging contract therefore becomes the core trust assumption of this architecture. Historical data show that cross-chain bridges are the infrastructure most prone to attack in the decentralized finance ecosystem; by cumulative amount stolen, at one point more than 40% of major hacking losses in 2022–2023 occurred at this link [36]. An app-chain usually relies on its validator set to jointly maintain the security of the cross-chain bridge, which means that the safety of users' assets shifts from trusting Ethereum's mainnet consensus to trusting the app-chain's local validator set.

The matching and execution layer is where the app-chain architecture's core innovation lies. By natively integrating a central limit order book at the consensus layer, these systems achieve a highly trustless matching process. All order submissions, cancellations, and matches are executed within a block, and the results are visible to everyone and immutable. Although the physical constraints of distributed consensus keep an app-chain's block time at the level of a few hundred milliseconds—unable to reach a centralized exchange's microsecond latency—this performance compromise buys complete transparency at the execution level, an acceptable trade-off for the great majority

of non-high-frequency traders [37].

The clearing and settlement layer likewise achieves a high degree of trustlessness. Post-trade clearing of the books, mark-to-market, and funding settlement all execute deterministically on chain according to uniform rules, and the margin requirements, liquidation-triggering conditions, and the operating mechanism of the insurance fund are all hard-coded into the app-chain's underlying protocol. Every liquidation event can be audited precisely through on-chain data, sharply compressing the room for implicit governance maneuvering that is pervasive in centralized exchanges (though the specific liquidation parameters can still be adjusted through the governance process; see Section 28.6.3).

At the data layer, for crypto-native assets, an app-chain can directly use the trade prices generated by its on-chain order book, thereby freeing itself to a great extent from dependence on an external oracle. Only when derivatives on traditional financial assets are introduced does it again face the trust degradation that oracles bring.

At the governance layer, however, current app-chain projects generally exhibit partial trust. To ensure the system's capacity for rapid iteration and its ability to respond to sudden events, the core development team often retains control over protocol upgrades and the adjustment of key parameters. Although these projects usually promise to follow a roadmap of progressive decentralization, at the present stage the concentration of governance power remains a link in their trust stack that cannot be ignored.

Table 28-5 maps the trust state of the app-chain architecture onto the five-layer model. Unlike the centralized exchange's across-the-board *complete trust* and the AMM-type DEX's *solid at the base, weak at the top* pattern, the app-chain architecture displays a distinctive distribution—*solid in the middle, under pressure at both ends*: the three middle layers of matching, clearing, and data all reach *highly trustless*, while the custody layer at one end (constrained by cross-chain bridge security) and the governance layer at the other (constrained by concentrated team control) each retain trust assumptions of differing degrees.

Layer	Trust state	Object of trust	Verifiability assessment
Asset custody	Partially trustless	Cross-chain bridge contract and validator set	Moderate; traceable on chain but exposed to the security risk of cross-chain bridging
Matching and execution	Highly trustless (residual validator-MEV risk exists)	On-chain order book and consensus mechanism	High; all matching logic and results are fully public on chain, but validators still have the potential ability to manipulate transaction ordering
Clearing and settlement	Highly trustless	Protocol-level hard-coded rules	High; the liquidation process strictly follows the code and is auditable after the fact
Data and oracle	Partially trustless	On-chain native data-generation mechanism	Moderate; crypto-asset prices are generated by on-chain trades but face the risk of self-referential price manipulation
Governance	Partial trust	Core development team and early validators	Moderate; the decision process has limited transparency and relies on the team's self-discipline

Table 28-5. A trust-stack audit of app-chain decentralized exchanges (Data source: compiled by the author)

Comparing Tables 28-3, 28-4, and 28-5, a clear evolutionary trajectory emerges: from the centralized exchange's across-the-board *complete trust* over all five layers, to the AMM-type DEX's first breakthroughs at the custody and clearing layers, and then to the app-chain architecture's extension of *highly trustless* to the matching and data layers. The trustlessness assessment of the data and oracle layer, however, requires a more cautious correction: the JELLY (JELLYJELLY) incident of March 2025 showed that even when prices are generated entirely by on-chain trades, the price of a low-liquidity token can still be maliciously manipulated, forcing the market-making vault (HLP) to take over the liquidated position and bear an enormous unrealized loss (peaking at about $13.5 million), which exposed the inherent fragility of the self-referential pricing mechanism. The incident was ultimately quelled only by a vote of the validator set to force a delisting and settle at an off-market price (see Section 28.6.4), which simultaneously exposed discretionary intervention at the governance layer [38]. By the trust concentration metric proposed in Section 28.1.4, the app-chain architecture retains a dependence on a single entity at only the governance layer and part of the custody layer (the cross-chain bridge) among the five layers of the trust stack, giving an equal-weighted trust concentration of about 30% to 40%, markedly below the centralized exchange's 100%. Under the weighting scheme proposed in Section 28.1.4, because the app-chain achieves a high degree of trustlessness at the three middle layers of clearing,

matching, and data and retains a dependence only at the custody and governance layers, its weighted trust concentration is about 25% to 30%. The difference between the two measures arises not from the middle layers (which are trustless under both measures, contributing close to zero to the residual concentration) but from the weighting's reallocation of weight to the custody layer (0.35): the app-chain's core residual risk—the cross-chain bridge—happens to sit at this custody layer whose weight is raised, so the weighted measure in fact highlights the cross-chain bridge's status as the decisive residual risk rather than systematically producing a more optimistic figure. Table 28-5 also lays bare, however, the app-chain's two structural weak points: the cross-chain bridge risk at the custody layer and the team's concentrated control at the governance layer, and these two links constitute the main bottlenecks to the further decentralization of the app-chain architecture.

28.5.4 The trust stack of hybrid architectures

Between the centralized exchange's monolithic black box and the app-chain's fully on-chain approach, an emerging model known as the hybrid architecture is gradually taking shape. The core design philosophy of this architecture is selective trustlessness: applying strict de-trusting at the layers most likely to cause catastrophic consequences, while retaining centralized, high-efficiency operation at the layers with the highest performance requirements.

The hybrid architecture first undertakes a thorough reform at the asset-custody layer. Users' funds are no longer deposited into a wallet controlled by the exchange but are instead held in an independent on-chain smart contract or a regulated third-party MPC custody system. This design ensures that the exchange cannot unilaterally misappropriate customer assets and greatly reduces the risk of the operator doing so. Under extreme market conditions, however, on-chain asset withdrawal may face frictions such as delay from network congestion, spiking gas fees, and cross-chain bridge congestion, so that the theoretical *instant exit* cannot always be realized frictionlessly in practice. The combination of multi-party computation and multi-signature technology requires that asset transfers pass through multi-party authorization, substantially raising the security boundary of the custody layer [39].

At the clearing and settlement layer, the hybrid architecture tends to move rule execution on chain. After the exchange completes matching off chain, it submits the results to an on-chain smart contract for the final confirmation of clearing the books, settling funds, and liquidating positions. This design guarantees the transparency and immutability of the rules, and users can audit the system's solvency and the fairness of its liquidation logic at any time.

At the matching and execution layer, however, the hybrid architecture continues to retain an off-chain centralized engine. This is because, for institutional investors and high-frequency market makers, microsecond latency and extremely high throughput are indispensable. By keeping the matching process off chain, the hybrid architecture can offer liquidity depth and a trading experience fully consistent with those of a traditional centralized exchange. Although this retains, to some degree, a trust black box at the execution level, by introducing cryptographic techniques such as zero-knowledge proofs,

some hybrid architectures have begun to attempt to provide after-the-fact verifiability of matching results without sacrificing performance.

The trust state of the data layer and the governance layer in a hybrid architecture usually falls between the two extremes. Data are still generated mainly by a centralized engine, but because settlement occurs on chain, fabricating fake volume becomes more difficult and costly. The governance layer may adopt a mechanism combining a multi-signature council with a time lock, providing users an exit window while preserving responsiveness.

The trust distribution of the hybrid architecture displays an *interleaved* character quite unlike that of the three preceding architectures: rather than pursuing uniform de-trusting across all layers, it directs limited engineering resources precisely at the layers with the most severe consequences (custody and clearing) while retaining centralized, high-efficiency operation at the performance-sensitive layer (matching). This strategic trade-off is clearly reflected in the table below: two starkly different trust states—*highly trustless* and *partial trust*—coexist within the same architecture, forming a sharp layered contrast.

Layer	Trust state	Object of trust	Verifiability assessment
Asset custody	Highly trustless	On-chain smart contract or third-party MPC custody	High; asset segregation is enforced by code or multi-party authorization
Matching and execution	Partial trust	Off-chain centralized matching engine	Low to moderate; some systems introduce ZKPs to provide after-the-fact verifiability
Clearing and settlement	Highly trustless	On-chain smart contract	High; the settlement rules are transparent and immutable on chain
Data and oracle	Partial trust	Generated by a centralized engine, constrained by on-chain settlement	Moderate; the cost of fabricating fake data is raised by on-chain settlement
Governance	Partial trust	Multi-signature council combined with a time lock	Moderate; rule changes are procedurally constrained but still led by a few

Table 28-6. A trust-stack audit of the hybrid architecture (Data source: compiled by the author)

Table 28-6 reveals the core design logic of the hybrid architecture: the verifiability of both the custody layer and the clearing layer reaches the *high* grade, which ensures the safety of user assets and the fairness of rule execution—even if the matching engine is operated entirely by a centralized entity, the final ownership of funds is still adjudicated by on-chain contracts. Although the matching and execution layer retains *partial trust*, techniques such as zero-knowledge proofs are gradually closing this trust gap. Comparing Tables 28-3 through 28-6, the evolutionary path of the four architectures along the

trust stack is plainly visible: from the centralized exchange's across-the-board opacity, to the AMM-type DEX's breakthrough at the base, to the app-chain's extension in the middle, and then to the hybrid architecture's precise trade-offs across the layers. The hybrid architecture represents the industry's pragmatic choice following a deep understanding of the trust-performance frontier. It acknowledges that different types of market participants have starkly different sensitivities to trust. Retail investors may value the full safety of their assets more highly, whereas high-frequency trading firms are willing to bear a degree of verifiable trust risk for the lowest execution latency. Through modular interface design, the hybrid architecture allows components at different layers to be freely combined, pointing to a path of progressive evolution for the on-chain financial infrastructure of the future.

28.6 Hyperliquid's architectural choices

Turning to the frontier of engineering practice, Hyperliquid is one of the protocols most representative of the current state of the trust-performance frontier. As an app-chain designed specifically for high-performance derivatives trading, each of its architectural choices—from building its own layer-1 network and a built-in central limit order book to the design of its liquidity-provider vault and validator set—is a carefully considered trade-off between trust and performance. Dissecting its architecture shows clearly how the layered-design philosophy comes to ground under real engineering constraints, and at which layers the system compromises in pursuit of the highest performance.

28.6.1 The app-chain and the on-chain order book

Hyperliquid's technology stack is built on a specially customized layer-1 blockchain. Its core architecture comprises an app-chain based on the HyperBFT consensus algorithm, a fully on-chain central limit order book, a bridge contract connecting to Ethereum, and a liquidity-provider vault that handles automated market-making along with an on-chain liquidation engine [40] [6]. The first core question raised by this architectural choice is: why build its own layer-1 network rather than build on an Ethereum layer-2 network?

Building on an Ethereum layer-2 network (such as Arbitrum or Optimism) means one can inherit the security of the Ethereum mainnet but must also inherit its performance constraints. The latency of a layer-2 network is usually greater than one second—a level of latency unacceptable to high-frequency traders and market makers—and it comes with non-negligible gas costs [41]. The performance limits of a layer-2 network stem from its architectural design. To inherit Ethereum's security, a layer-2 network must periodically submit state proofs or transaction data to the Ethereum mainnet, and the speed of this process is limited by the mainnet. Beyond that, transactions on a layer-2 network must ultimately be confirmed on the Ethereum mainnet, which adds to overall latency. In choosing to build its own layer-1 network, Hyperliquid in essence treats the app-chain as a dedicated chip customized for the single purpose of perpetual futures trading, rather than emulating a trading environment on a general-purpose processor. Through deep customization from the underlying network stack to the consensus algorithm, Hyperliquid achieves deep optimization for end-to-end latency [42].

This specialized design means that every component of the system can be optimized for trade processing. The storage structure, for example, can be optimized for the query patterns of the order book, the network protocol for the communication patterns of high-frequency trading, and the consensus algorithm for the rapid confirmation of trades.

The HyperBFT consensus algorithm is the core of this optimization. It draws on the design ideas of the HotStuff consensus protocol [43] and its successors LibraBFT and DiemBFT, but with several key improvements targeting the specific needs of a trading system [44]. Compared with the three-phase commit process of the base HotStuff, HyperBFT adopts the DiemBFT/Jolteon-style two-phase (two-chain) commit rule, which removes one round of inter-validator communication relative to the three-phase version and thereby lowers the confirmation latency of a single block. The two-phase commit is itself a contribution of the predecessor protocols (DiemBFT/Jolteon), not an original invention of HyperBFT relative to HotStuff. On the normal happy path, HyperBFT advances consensus through optimistic responsiveness: the rate of block production depends on the actual communication speed of a validator quorum rather than on a preset fixed timeout parameter, which means that when network conditions are good, consensus latency can be far below the protocol's theoretical upper bound. Optimistic responsiveness governs this happy path (which does not depend on a known time bound), whereas the synchrony assumption is used only in scenarios such as a view change (that is, leader replacement) to guarantee liveness: when network latency exceeds expectations, the protocol falls back to a more conservative consensus path. Whatever the state of the network, the protocol's safety (that is, not producing mutually contradictory state confirmations) is never conditioned on the synchrony assumption.

HyperBFT also introduces two optimizations: pipelined block processing and optimistic execution. Pipelining sends the quorum certificate of the previous block together with the proposal for the next block, so that multiple blocks advance in parallel through the proposal and certification phases. Optimistic execution allows a transaction to begin executing before the block is finally confirmed, further shortening the end-to-end latency the user perceives. Optimistic execution, however, introduces a theoretical risk of block rollback: in extreme cases, an optimistically executed transaction may be reversed because consensus was not reached, and users must distinguish two states—*optimistic confirmation* (low latency but not final) and *final confirmation* (verified by consensus and irreversible). The combined effect of these engineering optimizations lets HyperBFT achieve a median consensus latency of about 200 milliseconds while maintaining the safety guarantee of a BFT protocol. This performance figure, however, is measured under optimistic conditions. Under adversarial conditions—such as some validators going offline or a network partition—block-production latency may spike significantly, and consensus may even stall temporarily. While consensus is paused, the liquidation engine cannot execute protective liquidations, and risk exposure accumulates continuously; this constitutes the inherent fragility of high-performance BFT consensus under extreme conditions.

This technical choice inevitably comes at a cost, however. Building its own layer-1 network means the system must rely on its own validator set for security, rather than

being backstopped by the vast computing power of the Ethereum mainnet. Under this architecture, the system's trust anchor shifts: users no longer trust the overall security of the Ethereum ecosystem but must instead trust Hyperliquid's specific validator set [45]. This shift of trust is the starting point for understanding Hyperliquid's architectural trade-offs; it reveals that in pursuing the highest performance, one must make a degree of compromise at the foundational security layer.

28.6.2 An analysis of the trust state at each layer

As the main instance of the *app-chain* archetype audited in Section 28.5.3, Hyperliquid's overall trustlessness at each layer is consistent with the judgments in that section; this section places it within the trust stack model and audits it, focusing on the increments specific to it. At the asset-custody layer (Layer 1), user assets are transferred from the Ethereum network to the Hyperliquid network mainly through a bridge contract. The security of this process depends entirely on the honesty of the validator set and the robustness of the bridge code [46]. At present, a deposit takes effect only after obtaining signatures from validators representing more than two-thirds of the stake weight [47]. As noted in Section 28.5.3, cross-chain bridges are the infrastructure most frequently attacked in decentralized finance—the Ronin bridge, for example, was hacked in 2022 for a loss of more than $600 million—and they therefore constitute one of the weakest links in Hyperliquid's trust stack.

Although the multi-signature mechanism requiring signatures from more than two-thirds of the validators provides some protection, the safety of user assets ultimately depends on the honesty of the validator set and remains inferior to holding assets directly on the Ethereum mainnet—the specific residual risks of the validator set and the cross-chain bridge are detailed in Section 28.6.4.

At the matching and execution layer (Layer 2), Hyperliquid places its central limit order book entirely on chain, with all orders matched within blocks and the results publicly visible [48], so that users can independently verify whether price-time priority is honored. As audited for the app-chain matching layer in Section 28.5.3, this layer is among the most trust-minimized in the entire system; although its latency of about 200 milliseconds is somewhat slower than a centralized exchange's microsecond response, it is entirely acceptable for the great majority of retail users and for some institutional traders [11].

The rules of the clearing and settlement layer (Layer 3) are likewise hard-coded in the on-chain Hypercore execution state machine: post-trade clearing of the books, continuous mark-to-market, funding payments, and unrealized-P&L updates all execute on chain according to deterministic rules and can be recomputed and checked by any node; every liquidation record of the liquidation engine can also be publicly queried; and the takeover of liquidated positions by the insurance fund and the liquidity-provider vault proceeds transparently on chain [49]. As audited in Section 28.5.3, this transparency far exceeds that of a centralized exchange. Here, however, two levels of *hard-coding* must be distinguished: the execution framework of the liquidation logic (such as the formula for computing the liquidation-triggering conditions and the execution flow) is truly immutable logic hard-coded into the protocol, whereas the specific liquidation

parameters (such as the maintenance margin ratio and the maximum leverage) are variables that can be adjusted through the governance process. The rigidity of the former limits the flexibility of the rules: any framework-level modification requires a protocol upgrade, lacking the buffer that human intervention provides in a centralized system for handling extreme market conditions. During the 2008 financial crisis, the central counterparties of the traditional financial system could flexibly adjust their liquidation rules according to market conditions, and this flexibility was sometimes the key to preventing the spread of systemic risk. Although Hyperliquid's hard-coded rules are more transparent, they may lack the flexibility necessary under extreme market conditions.

At the data and oracle layer (Layer 4), the prices of crypto-native assets are generated directly by on-chain trades without an external oracle, achieving—as audited in Section 28.5.3—an extremely high degree of trust minimization. This self-referential pricing, however, carries an inherent fragility for low-liquidity assets: as the JELLY incident described in Section 28.5.3 showed, an attacker can still distort the perpetual mark price by manipulating the on-chain spot price, so this layer is not unconditionally one of *extremely high trust minimization*. At the governance layer (Layer 5), Hyperliquid is currently highly concentrated: the development team controls protocol upgrades, parameter adjustments, and the strategy of the liquidity-provider vault [50], and although it has declared a path of progressive decentralization, the current concentration of governance makes this the layer where the gap from a centralized exchange is smallest (the governance residual is detailed in Section 28.6.4).

28.6.3 The performance-latency trade-off

In a layered architecture, gains in performance often come at the cost of sacrificing some trustlessness. As a Byzantine fault-tolerant consensus protocol, HyperBFT follows the basic safety principle of BFT consensus by design: it prioritizes safety (that is, never producing mutually contradictory state confirmations) and, when the network partitions or inter-validator communication is severely delayed, chooses to pause block production, sacrificing liveness. This means the system would rather halt service briefly than confirm an erroneous trade result. Hyperliquid's performance optimization is achieved not by relaxing its safety guarantee but through engineering means—reducing the number of consensus communication rounds, optimizing the network topology among validators, and adopting pipelined block processing—to maximize throughput and minimize latency without impairing safety. Compared with a fully centralized matching engine, however, the communication overhead of distributed consensus still constitutes an irreducible lower bound on latency. According to official figures, for geographically close clients, Hyperliquid's median end-to-end latency is 0.2 seconds and its 99th percentile is 0.9 seconds [11]. By contrast, a centralized exchange's matching latency is typically in the microsecond range. A quantitative comparison of Hyperliquid's key performance metrics with these two benchmark architectures can pinpoint its position on the trust-performance frontier. In Table 28-7, four metrics characterize the performance differences among the three architectures from different dimensions: end-to-end latency reflects the user experience, throughput capacity reflects the system's carrying capacity, actual operating throughput reflects the match to market demand, and

finality reflects the time window of trade certainty.

Performance metric	Hyperliquid (app-chain)	Top centralized exchange	Typical Ethereum layer-1 DEX
Matching/consensus latency	~200 ms (end-to-end, consensus confirmation)	~5–50 microseconds (inside the matching engine; ~10–100 ms end-to-end for ordinary remote users)	~12 seconds (block confirmation)
Throughput capacity	~200,000 orders/second	Hundreds of thousands to millions/second	Tens to hundreds/second
Actual operating throughput	No independently verified public peak figure yet	Extremely high, depending on market volatility	Limited by block space
Finality	Single-block finality	Instant confirmation by the internal system	Requires waiting for multiple block confirmations

Table 28-7. A comparison of performance metrics between Hyperliquid and other architectures (Data source: compiled by the author based on [10][11][12])

Note: The "throughput capacity" in the table is measured in orders per second, encompassing all operations such as placing, canceling, and modifying orders. The official documentation states that the current mainnet supports about 200,000 orders per second, with the execution layer being the current bottleneck and the consensus and network stack theoretically scalable to millions of orders per second. As of this writing, there is no independently verified public figure for peak on-chain confirmed transactions (TPS), so the "actual operating throughput" row no longer provides a specific value.

For high-frequency market makers, the latency gap from microseconds to 200 milliseconds is decisive. This explains why, under certain extreme market conditions, Hyperliquid's liquidity depth still struggles to fully match that of leading centralized exchanges, because high-frequency market makers cannot execute optimal market-making strategies amid millisecond-scale market swings. The profit model of high-frequency market-making relies on millisecond-scale reactions to market microstructure, and microsecond-latency arbitrage strategies are entirely infeasible on Hyperliquid. Moreover, the 200-millisecond latency also has a substantive impact on non-high-frequency traders: stop-loss orders may face slippage of several price ticks during violent volatility, market makers' delay in responding with cancellations increases the risk of adverse selection, and the execution-time difference of the liquidation engine under extreme conditions may cause the actual liquidation price to deviate significantly from the trigger price. Although these frictions are not fatal, they constitute a systemic cost that all participants must factor into their strategies.

This latency difference also affects the overall quality of market liquidity: on a centralized exchange, high-frequency market makers provide abundant liquidity, allowing traders to fill large orders near the mid-price, whereas on Hyperliquid high-frequency market-making participation is limited, liquidity comes mainly from ordinary market makers and the protocol's built-in algorithmic market-making vault (such as the HLP Vault), and the bid-ask spread may be wider.

In terms of throughput, the Hyperliquid mainnet currently supports a processing capacity of about 200,000 orders per second [11] [51]. Although the consensus algorithm and network stack can in theory scale to the order of one million orders per second, the current bottleneck lies in the execution layer [52]. This means that as the number of users and trading volume grow, the system may run up against a performance ceiling. Compared with an Ethereum layer-1 DEX, however, Hyperliquid's performance is already several orders of magnitude greater.

Yet although Hyperliquid makes the block-construction process more controllable by building its own layer-1 network, the problem of maximal extractable value does not thereby disappear. Validators still have, in theory, the ability to order and manipulate transactions. A validator could, for example, prioritize the inclusion of its own transactions or delay others' transactions for gain. This existence of maximal extractable value is an inherent problem of all blockchain systems, but on Hyperliquid the problem may be more pronounced because the validator set is small.

The Hyperliquid team has recognized this problem and is exploring various mitigations. It is considering, for example, introducing a timestamp-based order-sequencing mechanism to reduce validators' room to manipulate transaction ordering. In addition, increasing the number and geographic distribution of validators can further lower any single validator's ability to manipulate maliciously. Hyperliquid's high performance is therefore not without cost: it is a relative advantage obtained by concentrating trust in a specific validator set and optimizing the execution layer to the extreme.

28.6.4 Hyperliquid's residual trust

In assessing the robustness of any decentralized system, identifying its irreducible residual trust plays an important role. For Hyperliquid, the largest residual trust lies first in its validator set. In its early days, the system ran on just five validators; it then expanded to 16 genesis validators, converted to 21 permissionless nodes in April 2025, and by mid-2026 had grown to about 24 active validators (with the team announcing a further expansion to 27) [53] [54]. Although the team plans to keep enlarging the validator set, at the present stage the number and geographic distribution of validators remain relatively concentrated.

This number needs to be compared with other systems to gain a clearer picture. The Ethereum mainnet crossed the milestone of one million active validators in March 2024, with about 32 million ETH staked, accounting for 26% of total supply [55]. Even a relatively small proof-of-stake chain usually has hundreds to thousands of validators. Hyperliquid's twenty-odd validators are, by comparison, quite concentrated. More critically, the number of validators is only a surface indicator of security; the distribution of stake is the core variable that determines actual independent security. According to reports, the validators under the foundation collectively control about 81% of the staked tokens, which means that even though there are nominally twenty-odd validators, the actual concentration of power is far higher than the count suggests—this proportion exceeds both the one-third threshold needed to halt the chain and the two-thirds threshold needed to control the cross-chain bridge, and the system's number of effective independent validators may be far below its nominal validator count. If the validator

set were attacked or internal collusion occurred, the security of the entire app-chain would be gravely threatened, and user assets would face direct risk. This is the core fragility of the self-built app-chain model: the system's security depends entirely on its own validators rather than on a node network as vast and dispersed as the Ethereum mainnet's.

Second, the cross-chain bridging mechanism from Ethereum to the Hyperliquid layer-1 network constitutes another significant point of centralization risk. The upgrade authority over the bridge contract, its multi-signature configuration, and the emergency-pause power all embody a high concentration of trust. Because all deposits and withdrawals of assets must pass through this bridging channel, it becomes, in substance, the critical conduit for the flow of funds through the entire system. If the bridge contract has a vulnerability or is attacked, users may be unable to withdraw funds, or funds may be stolen outright. The security problems of cross-chain bridges have already caused several major losses in the history of DeFi. The attack surface of a cross-chain bridge is not limited to smart-contract vulnerabilities: supply-chain attacks (such as the penetration of a signer's operating environment or the planting of malicious code in a dependency library) and common-mode failures (such as all validators running the same version of the software stack, so that a single vulnerability can breach all nodes at once) constitute equally serious threat vectors.

Finally, the development team's dominant position in governance is a notable compromise within the decentralized-finance narrative. According to reports, the associated foundation controls the vast majority of the staked tokens, which gives the team near-complete control over key decisions such as protocol upgrades and adjustments to the vault-strategy parameters [56]. Since HIP-3 went live on the mainnet in October 2025, qualified builders who meet the staking threshold have been able to deploy their own perpetual markets permissionlessly, so the listing of new contracts has shifted from complete team control toward partial decentralization. This concentrated governance power means that if the team makes a decision adverse to users, users have almost no way to stop it. Although Hyperliquid has proposed mitigation paths—increasing validator diversity, open-sourcing the bridge contract, and gradually transitioning governance power to the community—these remain, for now, plans on a roadmap rather than realized system features. Moreover, there is a reflexivity risk between the governance token's price and governance power: a rise in the token price increases the cost of a governance attack (raising security) but also increases the potential gain a large holder could obtain through governance manipulation (lowering security), and this positive feedback loop makes governance security hard to predict under extreme market conditions.

The problem with this governance concentration is that it leaves the system vulnerable to errors in the team's decisions. If the team decides to revise the liquidation parameters, adjust the fee structure, or change the incentive mechanism for liquidity providers, users cannot express their dissent through voting or any other democratic mechanism. This runs counter to the traditional ideal of decentralized finance but may be a necessary trade-off for achieving high performance.

28.6.5 The generalizability of the app-chain model

Hyperliquid's success has drawn wide industry attention, and its architectural pattern of an app-chain combined with an on-chain central limit order book seems to point to a viable path for decentralized derivatives trading. Other leading protocols have adopted similar approaches: dYdX v4 builds its app-chain on the Cosmos ecosystem, and Vertex is exploring a similar architecture. This architectural pattern is fully replicable technically. Any team with sufficient engineering capability can build an app-chain, implement an on-chain order book, and connect to Ethereum.

What is truly hard to replicate in the Hyperliquid model, however, is the specific detail of its performance optimization and its cold-start strategy for liquidity. The system's ability to process high-concurrency orders steadily at 200-millisecond latency depends on the team's deep customization and continuous optimization of the consensus algorithm and the underlying network stack [57]. This requires profound knowledge of systems programming and distributed systems. At the same time, the resilience its liquidity-provider vault displayed during a market downturn, together with the nearly $3 trillion in full-year trading volume and the fourfold user growth achieved in 2025, is owed more to the team's outstanding execution and its first-mover advantage in ecosystem-building [58] [59] [60]. These soft strengths and this accumulation of market presence cannot be obtained merely by copying the architecture's code.

A more fundamental problem is that the proliferation of the app-chain model may increase systemic risk. If hundreds of similar app-chain exchanges emerge in the future, each needing to assemble and maintain an independent validator set to secure itself, this will inevitably lead to a fragmentation of security. Each app-chain's economic bandwidth and capacity to defend against attack will be limited. Validator incentives may be insufficient to attract enough high-quality participants, causing the quality of the validator set to decline.

This problem can be understood through the economic concept of *the tragedy of the commons*. Validators are a scarce resource, all the more so high-quality validators with security expertise and infrastructure. If every app-chain must attract its own validator set, validators' compensation must be high enough to draw their participation. But this raises the app-chain's costs, which are ultimately passed on to users. At the same time, because validators are dispersed, the security of each app-chain declines, since its validator set is smaller and more easily attacked.

To alleviate this problem, introducing a shared security layer (such as restaking protocols like EigenLayer) may become a direction of future evolution. Letting multiple app-chains share underlying economic security can lower the cost of securing each independently, but it also introduces more complex cross-chain trust dependencies and potential systemic cascade risk. If the shared security layer itself is attacked, all app-chains that depend on it are affected. More seriously, in restaking the same stake secures multiple app-chains (actively validated services, AVSs) at once, so aggregate security is shared rather than simply summed, and slashing across different app-chains—together with operator failures—becomes correlated. This reintroduces precisely the common-mode failure and correlation risk warned of in Section 28.1.3 [61]. This model shifts trust from a single app-chain's validator set to the validator set of the shared

security layer, but it does not fundamentally solve the problem of security fragmentation.

28.7 The engineering judgment of sufficient decentralization

In the architectural design of on-chain financial systems, a common misconception is to treat *decentralization* as a strict binary state or an ultimate goal to be pursued without limit. Starting from the first principles of engineering, however, the core task facing a systems architect is not to maximize decentralization at any cost but to identify precisely and minimize the unacceptable trust assumptions in the system. This paradigm shift from idealism to realism forms the basis of the engineering judgment of sufficient decentralization [62].

The concept of *sufficient decentralization* acknowledges the objective existence of the trust-performance frontier discussed above. Under given technical constraints, every additional degree of on-chain verification depth inevitably incurs a loss of performance. Good architectural design should therefore provide appropriate trust guarantees for different layers and different user groups, rather than constraining the entire system with a single rigid standard.

28.7.1 Defining 'sufficient'

In the context of financial infrastructure, defining *sufficient decentralization* requires returning to the bottom-line logic of protecting users' interests. A system's meeting the *sufficient* standard does not mean it achieves full peer-to-peer consensus in every technical detail; it means it has established effective safeguards at the critical risk nodes, so that the cost to any single entity of acting maliciously far exceeds the gain it could obtain. This security condition can be formalized as a cost-benefit attack model: the cost of acting maliciously includes the slashing of staked assets, the forgone future income from reputational loss (an opportunity cost), and the risk of legal prosecution; the potential gain depends on the size of the manipulable assets (such as the cross-chain bridge's total value locked, TVL, or the liquidation profit that could be triggered). The system's security condition requires that the ratio of the cost of acting maliciously to the potential gain remain above a safety threshold. When this ratio declines as the protocol's TVL grows, the system must maintain its margin of safety by raising the staking requirement or introducing additional penalty mechanisms.

Specifically, a *sufficiently decentralized* architecture must meet bottom-line requirements along three dimensions. First, at the asset-custody layer, the system must guarantee that no single entity can steal a user's assets. This is the least compromisable link in the entire trust stack. However high the system's performance requirements, control over a user's assets must, and can only, be exercised by the user's own cryptographic signature. Second, at the matching and execution and the clearing and settlement layers, the system must ensure that no entity can covertly manipulate the trading rules for private gain. Although the execution at these layers may be performed by a specific validator set or high-performance nodes, the results must be fully verifiable, and any

deviation from the established rules must be detected promptly and penalized. Finally, at the governance layer, the system's rule changes must be predictable, auditable, and allow users to exit. When the protocol needs to be upgraded or key parameters adjusted, it must follow due process, granting users a full right to be informed and a time window to withdraw their assets before an adverse change takes effect.

Understanding what *sufficient* means also requires clarity about which properties are unnecessary. For example, requiring real-time whole-network consensus verification of every high-frequency order in pursuit of maximal decentralization often sacrifices the system's availability. For most trading scenarios, after-the-fact cryptographic verifiability is already *enough* to guarantee fairness. By the same token, fully decentralized permissionless governance may respond slowly to an urgent security incident, whereas a small expert committee constrained by a time lock and community veto power can often find a better balance between efficiency and security. Moreover, pursuing zero MEV may be impractical under the current public-chain architecture; as long as such value extraction is confined to a sufficiently small and controllable range, it can be regarded as an inherent friction cost of on-chain trading rather than a fundamental defect of the system.

28.7.2 The trust needs of different users

The participants in a financial market are not a homogeneous whole. Retail investors, institutional capital, and high-frequency market makers differ markedly in their core demands and their tolerance for various kinds of risk when participating in on-chain trading. Forcing a single unified architecture to satisfy everyone's needs therefore often yields a compromise that satisfies no one. Excellent architectural design should possess enough flexibility to respond to the specific trust needs of different user groups.

For retail investors, the core concern usually centers on the safety of assets and the fairness of the trading environment. What they least want to see is a repeat of an event like a centralized exchange misappropriating funds, or being subjected to *queue-jumping* arbitrage by an internal market maker inside an opaque matching engine. By contrast, retail investors are relatively insensitive to trading latency, and the difference between a few hundred milliseconds and a few microseconds is all but negligible in their subjective experience. At the same time, retail participants usually lack the time or expertise to engage deeply in a protocol's day-to-day governance. For this group, therefore, the optimal architectural configuration is often full trustlessness at the asset-custody layer, complemented by moderate trustlessness at the matching and clearing layers, while a relatively high degree of expert representation is acceptable at the governance layer. Yet there is a systematic gap between retail investors' revealed preference and their stated preference: in a bull market, retail investors systematically favor the platforms offering the highest leverage and the fastest speed, even when those platforms are conspicuously weak in architectural security. This means that an architectural security advantage may need to be realized through nudge mechanisms such as default-option design (for instance, enabling a self-custodial wallet connection by default), rather than relying on users' active, rational choice.

Institutional investors present a more complex map of trust needs. Beyond the non-

negotiable safety of assets, institutional capital is often subject to strict compliance and regulatory constraints that require the system to be highly auditable. Institutions need to be able to demonstrate clearly to auditors and regulators the flow of their assets and the compliance of their trades. This requires the system to achieve a high degree of trustlessness and full transparency at the asset-custody, matching and execution, and clearing and settlement layers. At the same time, institutional investors usually require the protocol to have a formal and predictable governance framework in order to avoid the policy risk of frequent rule changes. As for performance, although institutional investors do not demand the lowest latency as insistently as high-frequency trading desks do, they still need the system to have the throughput capacity to handle large orders and cope with extreme market swings.

The demands of high-frequency market makers lie at the other extreme. As the primary providers of market liquidity, their strategies' profitability depends heavily on extremely low latency and a certain execution speed. In the latency-sensitive domain of high-frequency trading, any additional latency introduced by a consensus mechanism can render a strategy ineffective or expose it to serious adverse-selection risk. High-frequency market makers are therefore often willing to trade a degree of trust for performance. As long as the underlying asset custody is fully secure on chain, they may even accept the use of a centralized off-chain engine for order matching. This core demand for performance is precisely the driving force behind the market's current favor toward the *off-chain matching plus on-chain settlement* hybrid architecture.

This divergence of user needs foreshadows the future direction of on-chain financial architecture. We are unlikely to see a single unified architecture suited to every scenario; rather, we will arrive at an ecosystem in which multiple architectures coexist. In this ecosystem, different protocols serve specific target user groups precisely by choosing different landing points on the trust-performance frontier.

28.7.3 A gradation of trust

Building on the definition of the *sufficient decentralization* bottom line and the analysis of different user needs, we can construct a more fine-grained framework for grading trust. This framework discards the simple dichotomy of *trust* versus *trustlessness*, dividing the trust assumptions in a system into four progressive levels and matching each level with a corresponding technical implementation path.

At the very bottom, and the most solid link, is the *zero trust* level. At this level, the system's security is guaranteed entirely by code logic and cryptographic primitives, and the user need not trust any external entity, validator set, or governance committee. This level of trust usually applies only to the asset-custody layer. Through self-custodial smart contracts deployed on a decentralized underlying network, users retain complete control over their assets. As long as the underlying consensus mechanism has not been breached, no one can transfer the assets without the user's private-key signature. This is the foundation for building the entire trustless financial system.

One level up is *verifiable trust*. At this level, some of the system's computation or execution may be performed by a specific centralized entity or a few nodes in exchange for higher processing performance. This execution privilege, however, is not unconstrained.

The executor must submit cryptographic proofs (such as zero-knowledge proofs) or publish the full transaction logs to the base chain, so that anyone can verify the correctness of the execution results after the fact. If the executor attempts to deviate from the established rules, a challenge mechanism allows honest nodes to submit a fraud proof, thereby overturning the erroneous state and imposing severe economic penalties on the malicious actor. This model is widely applied at the matching and clearing layers of layer-2 scaling solutions and app-chains, greatly raising the system's throughput while guaranteeing the correctness of results.

The third level is called *exitable trust*. This trust model applies mainly to the system's governance layer. In a complex financial protocol, wholly rigid rules often struggle to cope with a rapidly changing market environment, and a measure of flexibility is necessary. Adjustments to the protocol's parameters or upgrades to its code may be led by a centralized core team or by a DAO representing a small interest group. To prevent this power from being abused, the system must enforce a time-lock mechanism. After any critical rule change is proposed, it must pass through a mandatory waiting period before taking effect. This waiting period provides a window for users who disagree with the change to exit safely, allowing them to withdraw their assets under the old rules. Combined with an emergency-veto mechanism, the broad community can, in extreme cases, block a malicious upgrade proposal.

At the highest level is *replaceable trust*. At certain stages that must rely on external input—such as the oracle layer that obtains off-chain asset prices—the system inevitably needs to trust a data provider. To lower this single-point-of-failure risk, the architectural design should introduce diversified data sources and a seamlessly switchable substitution mechanism. The system should not be bound to a single oracle service but should compute the final result by aggregating data from multiple independent oracles. When a data source is detected to have an anomalous deviation or to have stopped serving, the system can automatically remove it and switch to a backup node. This mechanism, which constrains behavior through redundancy and competition, converts the dependence on a single entity into trust in an entire decentralized service market.

Cross-mapping these four trust levels onto the three-dimensional bottom-line requirements proposed in Section 28.7.1 yields more operational guidance for architectural design. The asset-custody layer, as the first-dimension bottom line ("no single entity can steal a user's assets"), must reach the *zero trust* level, which is the non-negotiable minimum standard. The matching and execution and the clearing and settlement layers correspond to the second-dimension bottom line ("no entity can covertly manipulate the trading rules"), and their minimum requirement is the *verifiable trust* level—execution may be performed by specific nodes, but the results must be endorsable by cryptographic proof. The governance layer corresponds to the third-dimension bottom line ("rule changes are predictable, auditable, and allow exit"), and its minimum requirement is the *exitable trust* level—even if governance power is concentrated in a few hands, users must have a time window to withdraw their assets before a rule change. The data and oracle layer should reach the *replaceable trust* level, using multi-source redundancy to ensure that the system does not depend on any single data provider. This mapping clarifies the minimum admission standard for each layer of the trust stack within the *sufficient decentralization* framework.

28.7.4 The path of progressive decentralization

Having understood the graded architecture of trust, we need to examine the dynamic process by which a system evolves from its initial state toward the ideal architecture. For the vast majority of on-chain financial projects, achieving full decentralization across all layers at the genesis stage is not only very difficult in engineering terms but often impractical. Early product iteration, bug fixing, and market expansion require the core team to have a high degree of agility and control [63]. A more pragmatic and widely adopted path is therefore progressive decentralization.

Progressive decentralization is not a vague slogan but a structured, multi-stage evolutionary strategy. In this roadmap, the core task of the first stage is to establish the basic bottom line of asset safety—that is, to achieve zero trust at the asset-custody layer. This is the minimum admission threshold for anything that calls itself a decentralized finance protocol. The team must ensure that control over the smart contracts cannot be used to misappropriate user funds at will, which usually requires multi-signature schemes, rigorous audits, and immutable custody logic. Only once asset safety is established can the system earn the initial trust of early users.

As the system enters the second stage, the focus shifts to improving the transparency and verifiability of the matching and clearing processes. At this stage, the team may still run a centralized sequencer or matching engine to ensure the user experience, but it must begin to introduce mechanisms that let these components' behavior be externally audited. This may include periodically publishing transaction logs to a data-availability layer, or beginning to develop and integrate zero-knowledge proof techniques. The goal of this stage is to eliminate the internal information black box, so that the fairness of operations no longer depends solely on the team's reputation.

Once the protocol's business model is validated and its technical architecture stabilizes, progressive decentralization enters the third stage: the devolution of governance power. This is a challenging transition period in which the core team must gradually transfer control of the protocol to a broad community of token holders. This usually begins with the adjustment of non-critical parameters, gradually extends to the allocation of treasury funds, and ultimately encompasses the upgrade authority over the core smart contracts. In this process, establishing a healthy representation system, guarding against governance attacks, and maintaining decision-making efficiency are the difficult problems the team must solve.

The final stage addresses the decentralization of external dependencies, particularly infrastructure such as oracles and cross-chain bridges. This requires the system to move from depending on a single trusted party to connecting to diversified decentralized networks—for example, replacing an internally maintained price feed with a decentralized oracle network, or upgrading a multi-signature-controlled cross-chain bridge into a trustless bridging solution based on light clients or zero-knowledge proofs.

Taking today's representative app-chain architectures as an example, many leading projects are at different stages of this progressive path. They have achieved a relatively high degree of trust minimization at the asset-custody and execution layers but still retain significant centralization residue in the allocation of governance power and the security of cross-chain bridging [45]. This state is not the architecture's endgame but

a slice of the process of evolution.

The path of progressive decentralization, however, also harbors structural risks. The greatest hidden danger is that *gradual* may degenerate into a pretext for the team to retain power indefinitely. When the core team grows accustomed to the efficiency and convenience of centralized governance, or when vested-interest groups reap rich returns under the current architecture, they often lack any intrinsic motivation to truly advance the last few steps of decentralization. Empirical observation supports this concern: among major DeFi protocols, the proportion that complete the final stage of their decentralization roadmap (such as fully removing admin keys and transferring upgrade authority to permissionless governance) is extremely low, and most protocols stall once they reach the comfort zone of *sufficient decentralization*. Beyond technical feasibility, therefore, the community's continued oversight, transparent roadmap commitments, and a hard-coded timetable for the transfer of power are all key forces for ensuring that progressive decentralization does not stray from its stated goal.

28.8 Modularity, composability, and the trust market

Let us place the choice of a layered architecture back within the macro framework for assessing market quality: as the analytical model established in Chapter 25 holds, the architectural design of any trading system must ultimately withstand examination along five dimensions—transaction costs, price discovery, resilience, fairness, and accessibility. The following analyzes how a layered architecture systematically reshapes these five dimensions, what new forms of risk it introduces, and how architectural design can, at a deeper level, substitute for traditional regulatory intervention.

28.8.1 How layered architecture reshapes the five dimensions of market quality

When we turn our attention to how a layered architecture performs in actual operation, we find that it does not provide an immediate, Pareto-optimal improvement along every dimension. On the contrary, it displays a clear trade-off: it achieves structural breakthroughs along the defensive dimensions (resilience and fairness) but must pay a certain performance cost along the offensive dimensions (transaction costs and price discovery). This trade-off is, in essence, the concrete projection of the *trust-performance frontier* discussed above onto the assessment of market quality.

Along the transaction-cost dimension, a layered architecture inevitably raises explicit costs in the short term. Empirical comparative studies of centralized and decentralized exchanges show that the fixed costs of on-chain trading (mainly gas fees) significantly burden small trades and produce a persistent arbitrage deviation between centralized and decentralized exchanges [64]. Yet if we lengthen the assessment horizon and factor in implicit costs, the conclusion reverses. In the monolithic black box architecture, users have in fact been paying a steep *trust premium* for the exchange's credit risk all along—a premium that stays hidden in calm markets but manifests, when a crisis erupts, as the complete zeroing-out of assets. The persistent arbitrage deviation between centralized and decentralized exchanges recorded in the empirical study by

Barbon and Ranaldo [64] provides quantitative corroboration of this cost structure, while the significant withdrawal premium that briefly appeared at major centralized exchanges after the FTX collapse reflects the existence of this implicit trust cost from another angle. By de-trusting the asset-custody layer and the clearing and settlement layer, a layered architecture fundamentally eliminates this implicit systemic-risk cost. Moreover, empirical data also show that, because fixed costs can be amortized over larger notional amounts, a decentralized architecture can often offer more competitive all-in transaction costs for large trades [64].

Along the price-discovery dimension, the impact of a layered architecture is relatively neutral but holds long-term upside. The efficiency of price discovery depends heavily on the symmetry of information and the depth of liquidity. Although the monolithic black box architecture can provide extremely high instantaneous liquidity through low-latency matching, its opacity often conceals the true dynamics of order flow. A layered architecture decouples the data layer from the matching layer, making all trade records and order-book states fully transparent and verifiable on chain. This transparency eliminates information asymmetry, enabling all market participants to price on the basis of the same genuine data and thereby promoting, over the long run, a more robust and fair process of price discovery.

Along the resilience dimension, a layered architecture brings a structural improvement. Research on systemic risk notes that the most dangerous vulnerability in a complex financial network stems from *the correlation of failures* [65]. In a centralized exchange, all functional modules share the same root of trust, which makes a local failure highly prone to cascading into a systemic collapse. A layered architecture severs this chain of failure propagation through modular design. Even if the matching engine suffers an outage or the oracle network briefly fails, as long as the underlying asset-custody smart contract remains intact, users' principal faces no risk of loss. This architectural property of downgrading *systemic destruction* to *localized functional degradation* endows a trading system with powerful resilience to survive extreme market turmoil. A layered architecture, however, does not eliminate systemic risk entirely; it changes the path of transmission. In a layered architecture, economic contagion may unfold along a specific cascade path: oracle failure $\rightarrow$ the liquidation engine cannot price correctly $\rightarrow$ large-scale erroneous liquidations or delayed liquidations $\rightarrow$ the insurance fund is rapidly exhausted $\rightarrow$ the auto-deleveraging mechanism forcibly harvests profitable positions $\rightarrow$ market confidence collapses $\rightarrow$ run-like withdrawals. The core value of a layered architecture is to downgrade this *instantaneous total collapse* to *gradual stress transmission*, in which each layer's fault-isolation mechanism provides a window of response time; but the ultimate elimination of systemic risk still depends on the adequacy of each layer's risk buffers.

Along the fairness dimension, a layered architecture systematically clears away the conflicts of interest inherent in a centralized exchange. We have diagnosed in detail above how a centralized exchange exploits its multiple roles as rule-maker, referee, and player to gain informational privilege. A layered architecture forcibly separates these functions: the matching logic is encoded as an immutable smart contract or the consensus of an independent app-chain, the liquidation parameters are determined by transparent on-chain governance, and the market-maker agreements are no longer a secret of

behind-the-scenes maneuvering. This architecture-level dispersion of power deprives unfair behaviors—front-running, order queue-jumping, and selective liquidation—of their technical feasibility.

Along the accessibility dimension, a layered architecture inherits the permissionless character of blockchain technology and achieves genuine global access. The traditional trust architecture depends heavily on geographic jurisdiction and licensing barriers, which objectively exclude a large number of potential market participants. A layered architecture establishes trust through code rather than institutions, allowing any user with an internet connection to access the core financial infrastructure on equal terms. Although the current on-chain interaction interface still poses a certain threshold in user experience, in terms of the distribution of access rights a layered architecture has unquestionably expanded the boundaries of the financial market enormously.

Table 28-8 summarizes the five dimensions above, presenting the structural reshaping of market quality by a layered architecture. The *structural impact* column describes the effects already observable at the current stage, while the *long-term evolutionary trend* column makes forward-looking judgments based on the development path of the underlying technology. Reading the two columns against each other helps distinguish the efficiency costs a layered architecture must bear in the short term from the structural gains it can deliver over the long run.

Market-quality dimension	Structural impact of layered architecture	Long-term evolutionary trend
Transaction costs	Explicit execution costs rise slightly (constrained by on-chain verification overhead), but the implicit systemic trust premium is greatly reduced	As modular blockchain scaling technology matures, all-in transaction costs will keep falling
Price discovery	Instantaneous pricing efficiency is slightly affected by latency, but on-chain data transparency fundamentally improves information symmetry	Trends over the long run toward more genuine, more robust price discovery, reducing the room for manipulation
Resilience	Markedly improved; module isolation eliminates single points of failure, downgrading the risk of total collapse to localized failure	As decentralized sequencers and fraud proofs become widespread, the system's stress resistance will strengthen further
Fairness	Markedly improved; the architecture level eliminates informational privilege and conflicts of interest, and the matching and clearing rules are fully transparent and verifiable	Trends markedly toward higher fairness, with any rule change required to pass through a public governance process
Accessibility	Markedly improved; permissionless global access breaks the geographic and licensing barriers of traditional finance	As technologies such as account abstraction mature, the interaction threshold will fall substantially, achieving financial inclusion

Table 28-8. The structural impact of layered architecture on the five dimensions of market quality

(Data source: compiled by the author)

A core judgment can be distilled from the horizontal comparison in Table 28-8: a layered architecture achieves structural breakthroughs along the three *defensive* dimensions of resilience, fairness, and accessibility, and these improvements stem from a fundamental restructuring of trust assumptions at the architectural level rather than marginal parameter optimization. Along the two *offensive* dimensions of transaction costs and price discovery, a layered architecture must bear the friction costs of on-chain verification in the short term, but as modular scaling technology matures, these costs keep falling. Overall, a layered architecture trades short-term explicit efficiency losses for long-term systemic robustness—a trade-off repeatedly validated in the historical experience of traditional finance's introduction of the CCP and independent custody.

28.8.2 New forms of risk in a layered architecture

Although a layered architecture excels at eliminating the single points of failure of a centralized entity, we must recognize clearly that this paradigm shift does not abolish risk out of thin air; rather, it transfers risk from *trust in entities* to *trust in code and protocol interfaces*. This transfer introduces three entirely new forms of systemic risk, which constitute the core problems that on-chain financial engineering must solve in the future.

Inter-module interface risk is a relatively hidden point of fragility in a layered architecture. In a monolithic architecture, the functional modules run within the same controlled memory space, and data transfer and state updates are synchronous and atomic. In a layered architecture, however, the functions of different layers are executed by independent smart contracts or app-chain networks, and communication among them must rely on asynchronous message-passing protocols. This cross-layer communication introduces the possibility of time lags and state inconsistency, thereby creating a new attack surface. For example, if the price-update interface between the oracle layer (Layer 4) and the clearing layer (Layer 3) has a latency vulnerability, an attacker can exploit this time lag to conduct a flash-loan attack, manipulating the price to trigger liquidations that should not occur. Several DeFi security incidents show that oracle manipulation has become a major cross-layer attack vector. In 2022 alone, DeFi protocols lost more than $400 million to 41 oracle-manipulation attacks [66]. This requires architects, when designing inter-layer interfaces, to introduce multi-signature verification, the time-weighted average price (TWAP), and circuit breakers to isolate the chain reactions caused by a single module's failure.

Second is cross-chain bridging risk, the core challenge that a layered architecture faces in today's multichain ecosystem. When a trading system's asset-custody layer (Layer 1) resides on the Ethereum mainnet while its matching and execution layer (Layer 2) resides on an independent rollup or app-chain, the transfer of assets between the two layers must rely on a cross-chain bridge. A cross-chain bridge is, in essence, a complex consensus converter that must lock assets on one end and mint equivalent mapped tokens on the other. If the bridging protocol's smart contract has a vulnerability, or its validator network is compromised, an attacker can drain the reserve funds inside the bridge directly without breaching the underlying asset-custody contract [67][68].

This risk shows that the security of a layered architecture is determined by its weakest connection point. Future architectural evolution must strive to minimize dependence on third-party bridges and adopt instead trustless cross-chain communication protocols based on zero-knowledge proofs, so as to converge this attack surface fundamentally.

Finally, there is the endogenous risk that system complexity brings. The essence of a layered architecture is to decompose a complex system into multiple subsystems, but this inevitably increases the overall topological complexity of the system. Every newly added module and every new communication link means an increase in potential points of failure. This practice of *introducing complexity for the sake of security* is a perennial paradox in engineering. A highly complex system is often hard to subject to exhaustive formal verification, and its emergent behavior under extreme market conditions becomes harder to predict. In pursuing layered decoupling, therefore, architects must maintain constant restraint over complexity, following the principles of *least privilege* and *minimal design* to ensure that the logic of each independent module is sufficiently clear and its boundaries sufficiently well defined.

Although a layered architecture introduces the new risks above, a simplified comparison of the net risk effect helps assess the direction in which overall security changes. The risk that a layered architecture eliminates—the systemic default of a centralized entity, epitomized by the FTX collapse (a gap of about $8 billion in customer assets at the time of collapse)—far exceeds, in the historical magnitude of losses, the new risks a layered architecture introduces. To date, although the cumulative losses from cross-chain bridge attacks and oracle-manipulation incidents have reached the level of billions of dollars, they are distributed across hundreds of independent events, and the systemic impact of any single event is far smaller than the total collapse of a monolithic black box. This shift in risk profile—from *low-frequency, catastrophic-consequence* to *higher-frequency, manageable-consequence*—is the core value proposition of a layered architecture along the dimension of risk management.

28.8.3 Architecture as governance

When we examine the evolutionary history of traditional finance, we find that every expansion of regulators' power was often meant to patch an inherent defect in the underlying architecture. Because the monolithic black box cannot prove its own innocence, auditors are needed; because intermediaries have an incentive to misappropriate funds, custody licenses are needed; because internal matching may involve self-dealing, compliance checks are needed. A layered architecture, however, offers an entirely new line of thinking: eliminating, through technical means, the very environment that generates the incentive to break the rules, thereby rendering part of external regulation unnecessary. This idea can be summed up as *architecture as governance*. The concept is of a piece with the idea of *code is law* proposed by Lawrence Lessig in his seminal work. Lessig argued that in digital space, software architecture, like the law of the physical world, is one of the four forces that constrain behavior [69]. De Filippi and Wright extended this idea further into the blockchain domain, proposing the concept of *lex cryptographica*—the technical embedding of legal rules through self-executing smart contracts [70]. A layered architecture advances Lessig's theory from abstract norma-

tive discussion to the concrete engineering practice of financial infrastructure: it not only uses code as a means of constraint but, through modular layered design, precisely allocates different types of constraint (cryptographic enforcement, economic incentives, and governance procedures) to different architectural layers.

With respect to asset segregation, the traditional regulatory framework treats the physical segregation of customer funds from proprietary funds as a fundamental bottom line. The FTX collapse, however, demonstrated the notable fragility of institutional segregation that relies on audit reports and executive promises. In a layered architecture, the asset-custody layer is devolved to a permissionless underlying blockchain, and open-source smart contracts enforce strict account logic. This means that, absent authorization by the user's private key, no exchange operator can physically touch these assets. This cryptography-based mandatory segregation is more resistant to attack than any legal provision. Regulators no longer need to expend vast resources verifying an exchange's bank accounts, because the architecture itself already provides sufficient proof of asset safety.

With respect to information disclosure, traditional regulation treats it as a core means of protecting investors, requiring financial institutions to publish voluminous financial statements and trading data periodically. These reports, however, are often subject to lag and easily window-dressed. A layered architecture moves all data of the matching layer and the clearing layer on chain, so that the bookkeeping of every order, the triggering conditions of every liquidation, and the flow of every cent are exposed in real time to the oversight of the whole network's nodes. This natural, irrevocable transparency turns information disclosure from *a regulatory-compliance cost* into *a fundamental property of the system's operation*. Under such an architecture, on-chain transparency gives anyone the technical prerequisite to become an auditor. Transparency, however, is a necessary but not a sufficient condition for effective oversight: interpreting raw on-chain data requires professional analytical ability, and the vast majority of users lack the technical literacy to identify anomalous patterns among massive volumes of trade records. Effective community oversight therefore also requires accompanying incentive mechanisms (such as bug-bounty programs and audit contests) to attract professional security researchers to invest their attention continuously.

Architecture as governance does not mean the complete demise of regulation but a fundamental shift in the regulatory paradigm. As the relevant research notes, modular architecture profoundly affects the effectiveness of regulation [71]. Future regulation should no longer fixate on layering endless rule patches on top of a bad architecture but should turn toward *requiring and verifying good architecture*. The regulator's role will shift from *behavior supervisor* to *architecture certifier*, whose core task is to ensure that a trading system follows the principle of layered decoupling from the outset, to ensure the security of the inter-layer interfaces, and to ensure the degree of decentralization of the governance mechanism. This paradigm shift, however, faces real obstacles: the current regulatory framework takes legal entities, not technical architectures, as the object of regulation; the transition to architectural regulation requires regulators to substantially update their technical-assessment capabilities and to develop new legal instruments suited to decentralized protocols, a process that may take years or longer. This deep integration of technology and regulation will pave the way for a

next-generation financial system that is at once trustless and compliant.

28.8.4 The trust market and composability

The ultimate form of a layered architecture is not merely to decompose the monolithic black box into internal modules but to open these modules to the entire ecosystem, thereby giving rise to a highly competitive *trust market*. In this market, trust is no longer a scarce resource monopolized by some centralized institution but a standardized component that can be priced, traded, and freely combined.

Composability is the core driving force of this vision. Once functions such as asset custody, matching and execution, clearing and settlement, and data oracles are encapsulated as standardized on-chain modules, they become financial primitives that can be freely assembled like standardized components. An emerging decentralized derivatives platform no longer needs to build a complete trust stack from scratch. It can choose to plug directly into the Ethereum mainnet as its asset-custody layer to obtain the highest grade of security, adopt a dedicated app-chain as its matching and execution layer to achieve low-latency trading, and integrate a decentralized oracle network to provide price data. The vision of composability, however, faces significant limitations at the execution level. When different functional modules are distributed across different chains or protocols, cross-module atomic operations (such as simultaneously adjusting the margin of multiple related positions) lose their guarantee of transactional consistency. The complexity of cross-chain margin management (involving the confirmation times of different chains, bridging delay, and state synchronization) makes a unified risk view hard to maintain in real time. Under current technical conditions, therefore, composability is better suited to low-frequency settlement-layer operations (such as cross-chain asset transfers and final clearing) than to high-frequency trading-execution-layer operations.

This free combination of modules will drive the rapid diversification of trading-system architectures. Different project teams can seek different balance points on the trust-performance frontier according to the specific needs of their target users, thereby designing a diversity of customized architectures. More importantly, composability breaks the siloing effect of traditional financial infrastructure. An excellent clearing module can serve multiple different matching engines at once, and a deep liquidity pool can be shared by multiple front-end interfaces. These network effects will greatly lower the barrier to financial innovation and push the on-chain financial system to evolve toward greater specialization and refinement.

In the trust market, the providers of the various modules face full and open competition. The modules that offer higher security, lower latency, or superior governance mechanisms will win adoption by more protocols and higher economic returns. This market-based competition grounded in code and consensus will become the main driving force pushing the on-chain trust infrastructure to evolve continuously. In the end, we will see a global financial-infrastructure network woven from decentralized modules—one with a high degree of survivability and a capacity for self-healing.

28.9 Chapter summary

Starting from the systemic architectural failure of the FTX collapse, this chapter proposed the trust stack method of analysis, decomposing the implicit trust assumptions in a trading system into five layers—asset custody, matching and execution, clearing and settlement, data and oracles, and governance—and, through the trust concentration metric, turning the problem of trust into a quantifiable engineering design variable. On this basis, the characterization of the trust-performance frontier revealed a fundamental engineering constraint: trustless verification and high-performance execution cannot both be optimized within the same architectural layer. Layered architecture is precisely the engineering response to this constraint: by independently choosing the balance point between trust and performance at each layer, the system can reserve sufficient performance headroom for the matching and clearing stages while making no compromise on asset safety.

The institutional evolution of traditional finance has validated the effectiveness of functional separation, and on-chain systems are now realizing a technical upgrade of the same functions through cryptography and consensus mechanisms. The app-chain practice epitomized by Hyperliquid shows that this layered migration is engineering-feasible, but the size of the validator set, the security of cross-chain bridging, and the concentration of governance power still constitute residual trust in the current architecture that cannot be ignored. The judgment framework of *sufficient decentralization* decomposes trust needs into four progressive levels—zero trust, verifiable trust, exitable trust, and replaceable trust—and establishes a clear mapping to the layers of the trust stack, providing a structured methodology for planning the path of progressive decentralization.

The trust stack model and the layered design principles established in this chapter will serve, in the chapters that follow, as a unified analytical tool for assessing the architectures of specific protocols. The next chapter focuses on the risk-management mechanisms of perpetual futures protocols, applying this chapter's layered framework to audit, layer by layer, how key components—liquidation logic, the operation of the insurance fund, and oracle dependence—differ in their implementation and risk profile across architectures.

Designing an Ideal Decentralized Clearing and Settlement Architecture

The first 28 chapters of this book have analyzed, one by one, the individual components of a decentralized clearinghouse and the ways in which each can fail: how novation absorbs bilateral credit risk through an impersonal central counterparty (Chapters 5 and 28); how multilateral netting compresses a large volume of bilateral exposures into net positions (Chapters 1 and 5); how the mark price becomes the measurement basis for unrealized profit and loss and for margin (Chapter 14); how margin and leverage define an account's liquidation boundary (Chapter 11); how the reflexivity of liquidation amplifies individual prudence into systemic fragility (Chapter 11); how the default waterfall absorbs losses layer by layer after a shortfall (Chapters 5, 11, and 28); and how insurance funds and auto-deleveraging (ADL) socialize the tail losses that cannot be eliminated (Chapter 12). Yet clarifying each component in isolation is not the same as knowing how to integrate them, absent a traditional central institution, into a whole that can be trusted.

This integration problem is not abstract. In October 2025, a liquidation cascade triggered the liquidation of approximately $19 billion in leveraged positions within a single day [1]. The mechanics of that cascade were analyzed in full in Chapter 11 and are not restated here; it is cited here to make one fact plain: when the components above are integrated into a single high-leverage, around-the-clock, unattended system, the transmission among those components can itself constitute system-level risk. It is not this chapter's argument but its backdrop.

Chapter 28 closed by establishing the identity of the clearing and settlement layer: the layer in an on-chain system that corresponds most closely to the functions of a traditional central counterparty, whose role is clearing (recomputation of the books) and settlement (commitment of account state), rather than mere default management (Section 28.4.3). That chapter also left three constructive questions to the present one: can an on-chain system achieve a default waterfall as deep as that of a traditional central counterparty? How should risk control be balanced against user experience? And how can incentives be aligned in a system in which no single actor can issue commands (Section 28.3.6)? Traditional finance took more than two centuries, driven by successive crises, to arrive at today's clearinghouse; the tiered structure of its default

waterfall is the product of that evolution [2]. What the first 28 chapters provide this chapter is an inventory of components and a catalog of failures; they have not yet given a scheme for integrating those components into a whole, nor answered the three questions that integration necessarily raises.

These three questions must wait for the integration stage because none can be resolved at the level of a single component. Depth asks not whether any one buffer layer is thick enough, but in what order the layers of capital are arranged and who bears losses first. Degradation asks not how fast or slow any single liquidation is, but whether the system can maintain order when selling pressure, liquidity, and confidence contract at once. Incentive alignment asks not whether some parameter is appropriate, but who bears the ultimate loss when all parameters operate as designed and yet some participants rationally choose not to act. All three point to the coordination among components rather than to the performance of the components themselves, and they can therefore be answered only after those components have been integrated into a whole and their interactions made visible. This is why the chapter first carries out the system integration and only then addresses the three questions.

On this basis, the chapter undertakes two tasks: integration and answering the questions. Integration means assembling, for the first time, the components dispersed throughout the book into a complete decentralized clearinghouse, and showing that the system's true fragility lies not in the components themselves but in the seams between them. Answering the questions means addressing, one by one, along the structure of this system, the three questions Chapter 28 left open. Before that, four premises must be made explicit. First, the fragility of a clearinghouse system lies mainly not in any single component but in the seams between components; each component may be well designed, and what breaks the system is usually the transmission between them. Second, two layers of the ideal decentralized clearinghouse remain absent on-chain today: the skin-in-the-game first-loss layer of the operator's own equity, and the layer of prefunded mutualization among members. These two layers are the source of a traditional default waterfall's depth (Section 28.3.6). Third, there is a class of extreme scenarios that no purely algorithmic system can fully cover: absent a lender of last resort, the total losses may exceed all the buffers the system can currently draw upon, and full loss coverage is no longer an achievable goal [3]. Fourth, there is a further boundary that no design of market incentives can cross: there will always be moments when deterministic code must allow human discretion to intervene. These four points are not pessimistic concessions but the premises of the chapter's entire argument: only by first clarifying where integration is impossible, where losses cannot be fully covered, and where incentives fail can we discuss how to integrate, to the greatest extent possible, the parts that can be integrated.

29.1 The overall architecture of a decentralized clearinghouse

29.1.1 A single deterministic state machine

A clearinghouse system is not a simple superposition of several risk mechanisms but a single, deterministic state machine. Each component dissected separately above is, within this system, merely one stage; its value lies not in operating independently but in being incorporated into an uninterruptible chain of state transitions. Describing the margin-calculation module, netting, marking to market, the insurance fund, and auto-deleveraging separately does not automatically yield a clearinghouse system, just as analyzing each component in isolation does not yield a functioning whole. The components also require a determinate set of connections: the output of the previous stage must be the sole, unambiguous input of the next; wherever a connection is mismatched, the entire system's state diverges. Understanding a decentralized clearinghouse should begin with understanding this chain of state transitions, not with enumerating its components.

To understand the clearinghouse as a state machine is not a convenient metaphor but a definition with substantive consequences. The core promise of a state machine is determinism: given the same initial state and the same sequence of inputs, it necessarily evolves to the same final state, with no degree of freedom that depends on timing, on the executor, or on off-chain negotiation. This is the classic abstraction that distributed systems have used for decades to build fault-tolerant services: a service is expressed as a deterministic state machine so that a set of mutually distrusting nodes, each of which may crash or even submit malicious state, can agree on a single input sequence and thereby present themselves to the outside world as a single, never-failing whole [4]. Byzantine fault-tolerant (BFT) consensus extends this abstraction further, to environments in which nodes may exhibit Byzantine behavior, so that the consistency of the state machine holds even when some nodes deliberately submit false information [5]. A decentralized clearinghouse system is, in essence, this service placed within that abstract framework: its task is to let multiple validators who need not trust one another reach an unambiguous agreement on what each account's state should be at this instant.

Applying this abstraction to a clearinghouse requires distinguishing one level, without which the analytical boundary of the term *state machine* becomes unclear. Determinism is one problem; replicated determinism is another, and between them lies the entire decentralization content of the system. A traditional clearinghouse's computation module can, in principle, also be deterministic: given the same inputs, it too will compute the same books. But its determinism holds only within its own internal copies of the system; external participants can neither obtain that input sequence nor hold that rule set, still less recompute the books to check them. What makes state machine replication truly demanding is not that each node be individually deterministic, but that multiple mutually distrusting nodes, any of which may crash or be compromised, evolve from the same input sequence, under the same rules, to the same state, and that this agreement hold even when some of those nodes fail or submit false information [4]. In

other words, the difficulty of a replicated state machine is not merely that the computed result is correct, but that, absent a trusted arbiter, no participant can raise conflicting valid claims about the state. Byzantine fault-tolerant consensus strengthens this condition further: it requires that even when some nodes deliberately submit forged state, honest nodes can identify and exclude it, so that the replicated state remains unique despite the presence of malicious nodes [5]. A decentralized clearinghouse system is decentralized because of this layer of replication: it requires not merely that a single computed result be accurate, but that no one can privately tamper with that result and that everyone can independently verify it has not been tampered with.

It is in this sense that the difference between a decentralized clearinghouse and a traditional central counterparty is not merely the removal of an intermediary. A traditional central counterparty does not satisfy the determinism promise of a state machine: its risk-control model is confidential, its stress-test parameters are not disclosed, and it retains room for discretion at extreme moments. Chapter 28 used the March 2022 nickel-contract crisis at the London Metal Exchange to illustrate how such discretion conflicts with the definition of neutral infrastructure (Section 28.7). A central counterparty is still trusted not because it can be recomputed but because its authority has another source: ample proprietary capital as an underlying backstop, a complete legal recourse regime as institutional guarantee, and strict regulation under continuous scrutiny [6]. Capital absorbs the consequences of error, law provides recourse against breaches of trust, and regulation imposes external constraint on internal loss of control; together these three constitute a form of ex post insurance about responsibility, not ex ante verification of process. An ordinary user has never checked, and could never check, whether a central counterparty's margin model is internally consistent or whether its stress-test parameters are prudent; what the user trusts is never the computation module itself but this institutional framework surrounding it. The trustworthiness of a traditional clearinghouse rests on the three institutional foundations of capital, law, and regulation, not on anyone's ability to recompute the books; the absence of verifiability is what these three institutional foundations compensate for. The central-counterparty institution is itself a transformation of counterparty risk from dispersed bilateral trust into trust in a single regulated professional institution—a transformation of trust, not its elimination [7].

A decentralized clearinghouse loses these three institutional foundations. It cannot appeal to capital, because it has no central-bank-scale proprietary capital; it cannot appeal to law, because its counterparty is borderless code; it cannot appeal to regulation, because it runs on a network that no one can unilaterally halt. What it can appeal to is chiefly determinism itself: expressing the clearinghouse in full as a state machine so that every step of its evolution is uniquely determined by public rules, and so that any node can, from the same inputs, independently recompute the same outputs. Hyperliquid's design is the most complete implementation of this approach to date: it unifies matching, liquidation, and settlement within an on-chain state machine called Hypercore, with HyperBFT consensus reaching agreement on each state transition, so that the entire clearing pipeline becomes a deterministic object recomputable by every validator on the network [8]. The authority of this system no longer derives from an institutional principal behind it but from the fact that each of its steps is independently

recomputable (Section 28.6.2).

This substitution carries an often-overlooked cost that must be made clear at the outset of integration: determinism has a dual effect. Determinism makes the clearinghouse verifiable, but it also makes it predictable; the trigger conditions of a fully deterministic liquidation module, its execution path, and the boundaries of each of its steps can, in principle, all be computed in advance by an adversary with sufficient computational power, the root of the predictability attacks discussed in Chapter 12 (Section 12.4.1). A traditional clearinghouse purchases immunity from such prediction with discretion and secrecy; a decentralized clearinghouse exchanges verifiability for exposure to such prediction. This is not a design oversight but an intrinsic tension of the paradigm: the more a clearinghouse system relies on determinism, the more easily its execution boundaries can be computed in advance by participants able to parse the rules. This is the root of the incentive boundary and residual discretion discussed later in this chapter (Section 29.4).

The core difference between a decentralized clearinghouse and a traditional central counterparty lies not in whether an intermediary is removed but in the different bases of trust in the two: the latter's authority rests on capital, law, and regulation, the former's on the fact that anyone can recompute the books and arrive at the same answer (Sections 28.4.3 and 28.6.2). Every state transition described in the subsequent subsections—the ledger recomputation of clearing, the account-state commitment of settlement, the layer-by-layer bearing of losses in the default branch—must be understood as incorporated into this single state machine. Representing this chain of state transitions in full yields this chapter's core architecture diagram (Figure 29-1).

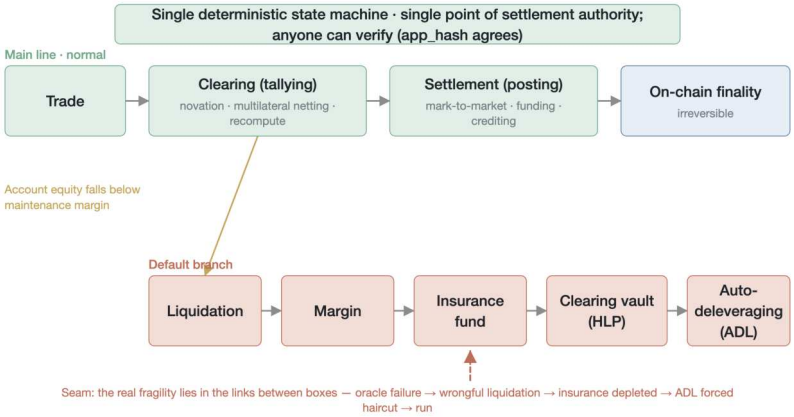

Figure 29-1. The overall state machine of a decentralized clearinghouse: the normal-conditions flow (trade → clearing → settlement → on-chain finality) and the default-management branch (liquidation → margin → insurance fund → liquidation vault → auto-deleveraging), together with the seams between their layers

29.1.2 The clearing stage: novation, multilateral netting, and recomputation

The main line of the state-transition chain processes every trade under normal conditions. After a trade enters the system, it first passes through clearing (recomputation of the books). Clearing, as a stage, consists of three actions each already treated in full earlier; this section does not restate their individual mechanisms but discusses only how they are composed into a single state transition. The first action is novation: the central counterparty interposes itself between buyer and seller, becoming the seller to the buyer and the buyer to the seller, so that a default by either party is no longer transmitted directly to its trading counterparty but is instead absorbed uniformly by the system (Sections 1.1 and 28.4.3). The second action is multilateral netting: multiple trades by the same account in the same contract, and even exposures across multiple counterparties, are consolidated into a single net position change, minimizing the number of entries that must be settled on the ledger (Section 5.2). The third action is recomputation: the system accordingly recomputes the account's position, realized profit and loss, and margin usage, producing a new set of account states. In the vocabulary of traditional clearing, these three steps correspond respectively to updating positions, netting down exposures, and recalibrating margin, and they are the core of a clearinghouse's daily operation [2].

These three actions were treated in separate chapters earlier; what the whole-architecture perspective must supply, and what the earlier discussion never made explicit, is this: within a state machine they are not three independent operations that occur in sequence but a single atomic state transition of the books. By atomic is meant that these three steps are either committed as a whole or rolled back as a whole, with no intermediate state observable from outside in which novation has completed but netting has not, or netting has completed but margin has not been recomputed. For a traditional clearinghouse this is an engineering goal to be approached only through end-of-day batch processing, reconciliation, and manual compensation, because its novation, netting, and margin management belong to different operational stages, even different legal moments, and aligning them into a seamless whole requires layer upon layer of rules, procedures, and end-of-day reconciliation [7]. For an on-chain state machine, by contrast, this atomicity comes from the native constraints of the state machine, because atomicity is inherent to the abstraction itself. Novation, netting, and recomputation can be composed on-chain into a single indivisible transition of the books because they were incorporated from the outset into the same deterministic system, rather than being assigned to three subsystems that must coordinate with one another.

Within this atomic transition there is also an often-overlooked ordering that directly affects how the subsequent default branch is understood: novation must precede netting, and netting must precede recomputation. Novation goes first because only once the central counterparty has become the common counterparty to every trade do exposures originally belonging to different bilateral pairs become eligible to be consolidated; without novation, A's long against B and A's short against C are two claims that cannot offset each other, and only with novation do they both become A's exposure to the system and thus nettable [7]. Netting goes before recomputation because margin

and profit and loss must be computed against the net position, not against the trade flow; if margin were recomputed trade by trade before netting, the result would be a grossly overstated usage, and capital efficiency would fall markedly. This internal ordering—novation before netting, netting before recomputation—is the entire reason clearing can compress tens of thousands of bilateral exposures into a limited number of net states while still measuring each account's risk accurately.

This atomic transition also has a temporal feature: it occurs entirely before any funds actually move. The clearinghouse first computes, on the books, each account's receivable and payable amounts and each account's margin usage accurately; the actual transfer of funds is a matter for the next segment (settlement). This ordering, completing the clearing computation before the settlement commitment, is not an accounting convention but the foundation of risk management: because the clearing computation precedes the settlement commitment, the system can determine, before any funds leave, whether an account is already insolvent and whether it must be routed to the default branch. Understanding clearing as a single atomic transition of the books that occurs before funds move thus draws a clear starting point for the next section's settlement and for the triggering of the default branch.

29.1.3 The settlement stage: marking to market, funding, and finality

After the clearing computation is complete comes settlement (commitment of account state). If clearing translates trading events into accrued states on the books, settlement realizes those accrued states as the accounts' actual states. It, too, consists of several actions treated in full earlier; this section addresses only how they string together into the second segment of the state-transition chain. The system continuously marks open positions to market at the mark price, so that each account's floating profit and loss updates continuously with price (Section 14.4); it charges and pays the periodic funding unique to perpetual futures, continually pulling the contract price toward spot, since perpetual futures have no delivery date and funding is the mechanism that substitutes for expiry-based delivery to maintain the anchor (Section 10.1); at close, it formally books the profit and loss and releases the corresponding margin; and finally, the chain's finality confirms this series of account changes as irrevocable (Section 28.4.3).

What the whole-architecture perspective must supply is the state-machine meaning of the settlement stage: it is the state commitment the clearinghouse makes to the outside world, and the chain's finality is the mechanism that confirms that commitment. Marking to market, funding, and booking are, during the clearing-computation stage, still only numerical evolutions on the books; only when they are settled by the settlement stage and confirmed by consensus into an irreversible stretch of on-chain history do they pass from what the system holds *should be* to what the system holds *already is*. This commitment must be identified separately, and must not be conflated with the clearing computation, because it marks the point at which responsibility transfers: before commitment, an unsettled profit or loss is only an internal computation of the module and may be overwritten or corrected by subsequent inputs; after commitment, it becomes the account's established entitlement, and any change to it can be made only through a new state transition that is likewise verifiable, not revoked without basis.

The settlement stage is therefore the sole boundary at which this system confirms a computed result as an established state. One point is easily misunderstood: finality is never a natural fact but a constructed one. Intuitively, people assume that an asset transfer becomes final the moment it is confirmed, as if irreversibility were an inherent property of the transaction itself; but anyone who has experienced a bank transfer being reversed or a settlement being clawed back because a counterparty went bankrupt knows that *when* finality takes effect is the mechanism most in need of being fixed deliberately. A settlement commitment is irrevocable not because it is physically impossible to reverse but because a set of rules expressly forbids reversal and imposes consequences on anyone who attempts it. In traditional finance this distinction is carried by the legal construction of settlement finality: when a settlement becomes irrevocable is defined jointly by clearinghouse rules, settlement-system rules, and bankruptcy law; the European Union even legislated specifically (the Settlement Finality Directive) to ensure that instructions entering a settlement system are not retroactively unwound because one participant goes bankrupt, thereby preventing systemic risk from spreading through that gap [9]. That this legislation was necessary shows that, absent intervention, this boundary is inherently blurred: the retroactive effect of bankruptcy law would collide head-on with the irrevocability of settlement, and only a dedicated statute carving out an exemption for settlement lets finality hold within that carve-out. On-chain, this same line of *when it becomes irrevocable* is drawn no longer by statute but is carried by the finality of consensus and defined by the consensus protocol itself [5]. Both draw the same boundary: before it, states can still be reordered; after it, no one may renege. The difference lies only in the instrument: traditional finance relies on legal text and court enforcement, on-chain systems on the liveness and safety of the consensus protocol itself.

This comparison reveals a subtlety of on-chain settlement that optimism easily obscures: finality comes in strong and weak forms, and the difference bears directly on the safety of the clearinghouse. Traditional settlement finality is a legal fact, absolute once attained; whereas the finality of many blockchains is probabilistic: a transaction included in a block means only that it very probably will not be rolled back, and the deeper the block, the lower the rollback probability, though not necessarily zero [10]. The divide between these two kinds of finality has its root in distributed-systems theory: for protocols that reach consensus by the longest-chain rule, safety is a decreasing function of the adversary's hashpower or stake share, and the rollback probability decays exponentially with confirmation depth yet never reaches zero; whereas for finality reached by Byzantine fault-tolerant consensus, once a block has been confirmed by a lawful number of validators' signatures, it is, under the protocol's assumptions, absolute and irreversible. The former delivers near-certainty, the latter certainty [10]. For general applications, near-certainty is good enough; waiting a few more blocks pushes the rollback probability down to negligible. But for a clearinghouse system this difference has substantive consequences, and those consequences manifest as an asymmetry. The clearinghouse's loss-bearing has a one-directional execution feature: once a profit or loss is settled by the settlement stage and, on that basis, triggers the next layer of default-branch actions, that layer of action has often already drawn on non-defaulting parties' capital: the insurance fund is tapped, and profitable parties are deleveraged. If at this point a chain

reorganization reverses the profit or loss already booked, the tapped insurance fund and the deleveraged profitable parties are difficult to restore: the prior book state can be rolled back, but the loss-bearing already executed downstream cannot correspondingly be restored. Probabilistic finality therefore leaves a new gap in the loss-bearing of the default branch, arising from a mismatch in which the antecedent is reversible but the consequent is not. This is one reason systems like Hyperliquid choose Byzantine fault-tolerant consensus and pursue deterministic finality that is irreversible once confirmed: a clearinghouse's demand on finality is far more stringent than a general application's, because it cannot afford this asymmetry [8]. Understanding settlement as a state commitment confirmed by finality is therefore not merely an abstract qualitative characterization; it is at the same time a hard constraint on what kind of finality the underlying consensus must provide.

Having clarified the role of finality, one often-confused ordering can be sorted out. Under normal conditions, clearing (recomputation of the books) and settlement (commitment of account state) together constitute all the work this system does: translating a continuous stream of trading events into a continuous stream of account-state changes confirmed by finality. This main line closes on itself: trades come in, states change, finality lands, in a continuous cycle, requiring no default handling. The default branch is a branch rather than part of the main line because it is triggered only when the main line cannot close on itself, that is, when an account's equity falls below maintenance margin under marking to market and the clearing computation, preceding the settlement commitment, determines it to be insolvent. The main line applies to states in which an account is still solvent; the default branch applies to states in which an account is already insolvent. The next section analyzes the latter.

29.1.4 Default management: liquidation and the loss waterfall

Beyond the main line lies a default branch, triggered only when an account's equity falls below maintenance margin. Its place in the state machine is a set of conditional state transitions, wholly dormant under normal conditions and activated only when the clearing stage determines that an account can no longer cover its exposure with its own margin. Its trigger point is liquidation: the system forcibly closes the insolvent position, confining the loss within its margin (Section 11.1.3). Liquidation is itself a default-management submechanism, not a clearing function; placed within the state-machine framework, it is the trigger point from the main line into the branch, and the first node in the entire system that turns a single account's individual loss into a problem that may affect other participants.

But liquidation often cannot confine the loss entirely. Market gaps, insufficient depth, and divergence between the mark price and the execution price can all leave the proceeds of closing out insufficient to cover the position's shortfall, leaving an uncovered shortfall (Chapter 12). The branch therefore continues downward into the default waterfall: after margin comes the insurance fund, after the insurance fund the liquidation vault (such as Hyperliquid's HLP), and after the vault, auto-deleveraging (Section 28.3.6; Chapter 12) [8]. Placed within the state-machine framework, each layer of the default waterfall is a conditional state transition: the exhaustion of the previous layer's buffer is the

condition that activates the next; and each layer, when activated, answers the same question in a different way: who next bears this loss that the defaulter cannot bear for itself. The answer at the margin layer is the defaulter itself; at the insurance-fund layer, the public pool prepaid by all traders; at the vault layer, the capital that voluntarily provides liquidity to the system; and at the auto-deleveraging layer, the profitable parties who are forcibly deleveraged. The waterfall is designed as a descending layered structure so that the bearers are arranged in an order running from those who most ought to bear to those who are most blameless, so that non-defaulting parties are affected as late and as little as possible [2].

Reading the waterfall as a series of conditional state transitions also clarifies an easily overlooked point: this branch shares the same state machine, the same determinism, and the same verifiability as the main line. When liquidation triggers, when the insurance fund is drawn upon, and whom auto-deleveraging selects are all uniquely determined by public rules, with no step left to off-chain negotiation or ex post discretion, in sharp contrast to the discretionary room a traditional central counterparty still retains in default handling, room that must be constrained by dedicated governance procedures [11]. The default branch is therefore not a separate logic outside the main line but the continuation of the same system in the world where it cannot pay in full; for that reason, each of its steps must likewise submit to recomputation by all, a point to which Section 29.1.5 returns.

But this branch also has the strictest limit in the entire system, corresponding directly to the third promise in the opening. Auto-deleveraging is the last layer of the waterfall, and its very existence announces one thing: when the total loss exceeds the capital available at all the preceding layers, the system no longer attempts to make up the shortfall but instead directly cuts the profitable parties' positions proportionally, rebalancing the books at a lower level. Chapter 12 has proved that among determinism, robustness to shocks, and fairness, no purely algorithmic default handling can satisfy all three at once, which constitutes a structural lower bound on bad debt: there is always a class of extreme scenarios in which losses cannot be fully covered and can only be mutualized or truncated (Section 12.2.3) [12]. Placed within the state-machine framework, auto-deleveraging is not a mark of failure but this system's second-best deterministic handling, under given constraints, of the fact that full loss coverage is impossible.

It is on the question of *who bears* that the on-chain waterfall reveals its core difference from the traditional default waterfall, and this difference constitutes the first of Chapter 28's three questions. A traditional central counterparty's default waterfall has five layers: the defaulter's margin, the default fund contributed by the defaulter, the central counterparty's own capital (its skin in the game), the default fund contributed by non-defaulting members (mutualization), and finally recovery and resolution (Sections 5.2.3 and 28.6.2) [2]. Empirically, the resources of these five layers are highly concentrated at the front end: in the default waterfall of credit-derivatives central counterparties, the initial margin posted by defaulters accounts for approximately 77.9% of all prefunded resources, while the central counterparty's own skin-in-the-game capital accounts for only about 2.0%; the latter is small in amount, but its position has structural significance, because it is placed ahead of all non-defaulting members' mutualized funds,

forcing the central counterparty to bear losses first (Section 5.2.3) [13]. The on-chain waterfall has only four layers, and what it skips is those two middle layers, allocating loss-bearing directly from the public pool prepaid by all traders to the profitable parties who are forcibly deleveraged, with neither a layer of skin-in-the-game own equity that bears losses ahead of users nor a layer of prefunded mutualization among members to share them. The depth of a waterfall lies not in how many layers it has but in how many layers of capital willing to bear losses first are placed before losses are allocated to non-defaulting profitable parties; the consequence of these two missing layers is the seam that Section 29.2 will audit specifically. This section establishes only the structure of the branch: it is the extension of the main line when it cannot pay in full, each layer is a conditional state transition, and each transition re-designates the bearer of the loss.

29.1.5 Concentrated adjudicative authority, open verification

Combining the main line and the branch (Figure 29-1) yields the overall architecture diagram of the complete clearinghouse system. The focus of this diagram is not the mechanisms inside each box, which have been analyzed separately in Chapters 5, 11, 12, 14, and 28; the focus is the connection relationships between the boxes and the overall constraint the system as a whole must satisfy. Before discussing this overall constraint, an often-confused pair of concepts must be distinguished: adjudicative authority, and the verification of that adjudicative authority.

Adjudicative authority is the power by which some mechanism determines the final state of each account. In this system, this power is single-point: all clearing computation, settlement commitment, and default handling converge on one deterministic computation module, which issues the sole ruling. Formally, this resembles centralization; the discretion over adjudication is indeed not dispersed but concentrated in one place. But the decentralization of a decentralized clearinghouse never promises to disperse adjudicative authority itself among everyone; handing the power to rule to multiple actors ruling separately yields not a clearinghouse system but a divergence of states that cannot converge. A telling point of comparison: a traditional central counterparty is likewise single-point in adjudication, and the decentralized design does not differ from it here; the entire engineering effort of blockchain consensus is to let multiple dispersed nodes agree on the same determinate state, rather than each maintaining a mutually conflicting ledger [4]. What it truly promises is something else: although adjudicative authority is single-point, the verification of that single point can be performed by anyone.

The technical carrier of this principle is an object often passed over in a sentence yet directly affecting the mechanisms that follow: the state fingerprint. Each time the computation module completes a state transition, its complete state is reduced by a cryptographic hash to a fixed-length fingerprint; the key property of this fingerprint is collision resistance: finding two different states that yield the same fingerprint is computationally infeasible, so identical fingerprints are almost equivalent to bit-for-bit identical states [14]. This property appears ordinary but in fact carries the entire weight of the verification logic. What a collision-resistant hash provides is a commitment in

the cryptographic sense: compressing the positions, margins, and profits and losses of tens of thousands of accounts into a fingerprint of a few dozen bytes, so that once this fingerprint is published, the publisher can no longer claim that the state at the time was substantively otherwise, and any subsequent tampering with the state would be exposed as a fingerprint mismatch. The checkability of this commitment is universal and cheap: a verifier need not trust the publisher, nor replicate all of its computational power, but need only run its own independently computed state through the same hash and compare whether the two fingerprints match—so the problem of comparing enormous states bit for bit is reduced to a single comparison of a few dozen bytes. Without such a commitment object, one that anyone can cheaply recompute yet the publisher cannot repudiate, verification by all would be only a slogan; with it, verification becomes, for the first time, an operation an ordinary node can actually undertake [14]. In an on-chain clearinghouse centered on this state machine, this fingerprint is typically written into each block as an `app_hash`: each validator independently substitutes the same batch of inputs into the same set of rules, computes its own state fingerprint, and then compares through consensus; as long as all nodes compute the same `app_hash`, this proves that they have seen the same path traversed by the same clearinghouse system (Sections 28.4.3 and 28.6.2). This is the concrete implementation of *verifiable by all*: verification is not to trust the module's self-declaration but to independently recompute its account states and then check them with an unforgeable fingerprint. Hyperliquid's HyperBFT consensus is a system that institutionalizes this single-point ruling with recomputation by all: the ruling is uniquely produced by the protocol, while every validator continuously recomputes and agrees on the result [8].

This places the trustworthiness of a decentralized clearinghouse on a foundation utterly different from that of a traditional central counterparty. Decentralization lies not in adjudicative authority itself but in the verification of adjudicative authority. This proposition must be set against common understandings to be understood accurately. One common understanding holds that decentralization should hand every decision to a vote of the many, and that the more power is dispersed among more actors, the more decentralized the system. But a clearinghouse is precisely the setting in which this understanding is hardest to sustain, because the books require a single, convergent ruling; if the state of a particular account at a particular moment were also handed to the many to rule on separately, the result would be not a more decentralized clearinghouse but a system that can never be reconciled and never converge. The key here is that what can and must be dispersed is not the ruling itself but the right to verify the ruling. The ruling must be single-point, or the system will not converge; verification must be by all, or the single point cannot be trusted. The entire engineering effort of blockchain consensus, letting multiple dispersed nodes agree on the same determinate state, was never meant to hand the power of decision to each person, but to let each person independently confirm that the sole decision has not been tampered with or manipulated [4]. The decentralization it promises is always the decentralization of verification, not the decentralization of adjudication. A traditional central counterparty is also single-point in adjudication, but its single point is tolerable because external capital, law, and regulation continuously constrain it and hold it to account when it fails; an ordinary user cannot verify the quality of its risk control and can only trust

that external constraint (what Chapter 28 calls regulated opacity, Section 28.7) [6]. A decentralized clearinghouse adopts the opposite design: it does not require users to trust that the single point will not act maliciously; it requires that every step of that single point be public to all participants and recomputable and falsifiable by anyone at any time. The former guarantees the single point with external authority; the latter constrains the single point with universal verifiability. This principle is the entire reason the chain of state transitions in the preceding sections is called a decentralized clearinghouse rather than merely an automated one: an automated clearinghouse need only be deterministic, whereas a decentralized clearinghouse must also be recomputable by all. For this very reason, this chain of verifiability cannot break at any link: even if only one critical input (for example, the source of the mark price) escapes the range of what can be recomputed, the entire chain's decentralization promise fails, which leads to the seam problem analyzed in the next section.

29.1.6 Inter-layer transmission and systemic fragility

Regarding the connections between the boxes, the true starting point for the rest of this chapter is a proposition more worthy of vigilance than single-point authority and verification by all. Chapter 28 traced a cascading-failure path: an oracle fails, causing the liquidation module to be unable to price correctly, leading in turn to large-scale erroneous liquidations or liquidation delays; erroneous liquidations rapidly exhaust the insurance fund; the exhaustion of the insurance fund triggers the auto-deleveraging mechanism to forcibly cut profitable positions; and the deleveraging destroys the market's last loss-absorbing capacity, inviting a collapse of confidence and run-like liquidity withdrawals (Section 28.8.1). Every link on this mechanistic path is, viewed alone, well designed: the oracle has multi-source aggregation, liquidation has trigger thresholds, the insurance fund has an actuarial model, and auto-deleveraging has ordering rules. Yet once they are connected, the disaster grows from the transmission from one link to the next: the failure of the previous link becomes the trigger condition of the next.

This is not an accident unique to on-chain systems but a commonality of all complex financial networks. Systemic-risk research has repeatedly noted that the most dangerous fragility of a financial system often stems not from the size of any single node but from the connection structure among nodes: risk contagion along these connections amplifies a shock that could have been absorbed locally into a global collapse [15]. This research also reveals a nonlinearity especially pertinent to clearinghouses: the robustness and fragility of a financial network do not vary monotonically with the degree of connection but exhibit a phase-transition-like reversal. When shocks are small, dense connections are beneficial, spreading a loss thinly across many counterparties so that no single node is crushed; but once a shock crosses a certain critical scale, the same dense connections abruptly turn from a robust sharing network into a fragile contagion network, and each connection that just now was used to spread losses becomes, at this moment, a conduit that transmits losses in amplified form [15]. This means that the system's safety margin does not improve smoothly as buffers thicken but has a nonlinear critical point: within the critical point everything appears robust, and beyond it the connections themselves turn into carriers of contagion. Chapter 28 noted that the value of a layered architecture lies in severing this contagion chain, downgrading an

instantaneous total collapse into a gradual pressure transmission, but it also conceded that layering does not eliminate systemic risk—it only changes the path of its transmission (Section 28.8.1). This section pushes that insight to its logical conclusion: since risk transmits along the seams, and transmission amplifies phase-transition-like at the critical point, the safety margin of a clearinghouse system is not the simple sum of its layer buffers but is limited singly by its weakest seam, because collapse always opens a gap at the first critical point to be crossed.

This leads to the core proposition that runs throughout this chapter: the strength of a clearinghouse system depends not on its strongest component but on its most fragile seam. The item-by-item analysis of the first 28 chapters directed attention chiefly to the components: each chapter analyzed one mechanism down to the level of formulas, proving how complex each is and how each fails. But what the whole-architecture perspective reveals is a fact that chapter-by-chapter narration does not readily present—that a system-level collapse almost never begins inside some component but always begins at the seam between two components, a seam for which no one is specifically responsible. The seam between the oracle and liquidation, between liquidation and the insurance fund, between the insurance fund and auto-deleveraging, between auto-deleveraging and market liquidity: the cascading path described above is, in essence, the trajectory of these successive seams being breached in turn. Seams are especially dangerous for a structural reason: each component has a clear owner (market makers are responsible for liquidity, the risk-control team for margin parameters, the oracle team for price-feed quality), but the transmission between two components often falls at the edge of everyone's field of view, becoming a link for which no one is specifically responsible. This ownerlessness is not negligence but a structural byproduct of the division of labor: because each team is assigned to optimize its own component and is assessed on its local metrics, the transmission between components is naturally excluded from clear responsibility boundaries, belonging to no job description, so that no one is specifically responsible for its failure. The strength of the system therefore obeys a near-weakest-link constraint: it is limited singly by the weakest seam, not raised by the strongest component; wherever one seam is breached, the individual complexity of the two components on either side cannot prevent a cascade. The entire point of integrating the clearinghouse into a state machine ultimately falls on identifying and reinforcing these seams, not on adding still more complexity to any component that is already complex enough.

The tasks of the remaining sections of this chapter can therefore be precisely defined along these seams. This chapter will answer, one by one, Chapter 28's three questions, and each question is, in substance, a question about some seam. The depth of the default waterfall is the seam between liquidation and the ultimate bearing of loss: starting from the defaulter's margin, through how many layers of capital willing to bear losses first must the loss pass before it reaches non-defaulting profitable parties? This is the subject of Section 29.2. Orderly degradation under extreme scenarios is the seam between the liquidation shock and the market's loss-absorbing capacity: when liquidation selling pressure strikes and no one plays lender of last resort, how does the system convert an instantaneous total collapse into a controlled, gradual failure? This is the subject of Section 29.3 [3]. Incentive alignment, in turn, is the seam between

deterministic code and the human discretion that can never be replaced by code no matter what: where do pure market incentives fail, and how can the residual discretion be constrained to its narrowest? This is the subject of Section 29.4. Reading the three questions as three seams is the key step by which this chapter turns from local mechanism analysis to whole-architecture analysis, and it is also the first time the catalog of failures discussed piecemeal earlier is gathered into a unified map of fragility.

29.2 The missing layers of the default waterfall

The end of Section 29.1 decomposed Chapter 28's three questions into three seams, of which the first is the most direct and the first to arise: the depth of the default waterfall is the seam between liquidation and the ultimate bearing of loss. Liquidation stops the loss at the defaulter's own margin, and this is the branch's trigger point; but liquidation often cannot confine the loss entirely (market gaps, insufficient depth, and divergence between the mark price and the execution price all leave an uncovered shortfall), so the loss exceeds the range covered by margin, moves down the default waterfall layer by layer, and continues to shift to the next loss-bearing party. Depth is concerned with how many layers this waterfall can draw upon, and from what capital sources, to absorb the loss before allocating it to non-defaulting parties. Chapter 28 condensed this seam into a question—whether an on-chain system can achieve a default waterfall as deep as that of a traditional central counterparty (Section 28.3.6)—and left it to this chapter.

This section's answer is direct, and rather severe: current on-chain systems cannot yet achieve it. This does not mean the chain lacks a waterfall. Section 29.1 already described its four-layer structure—margin, insurance fund, liquidation vault, auto-deleveraging—which is not even fewer in number than the traditional waterfall. The problem is that among these four layers, what is missing is precisely the two key resources that give the traditional waterfall its depth. What is lacking is not imagination in mechanism design but a layer of capital that no clear actor is yet willing to bear: whether the protocol's own equity is willing to sit in the first-loss position. This section proves this judgment through six subsections: first clarifying where depth actually comes from, then examining one by one the various attempts made on-chain to fill these two layers and analyzing why none has yet formed a sustainably operating mechanism, and finally returning to the repeatedly deferred but never avoidable question: what kind of capital is willing to bear the first loss.

29.2.1 The sources of default-waterfall depth

To judge whether the chain can replicate a traditional central counterparty's default waterfall, one must first define what the depth of the traditional waterfall actually means. A common misunderstanding is to understand depth as a large number of layers or a large reserve size. Chapter 28 already gave the complete layer ordering: the defaulter's margin is the first line of defense, the default fund contributed by the defaulter is the second, the central counterparty's own capital is the third (this layer is specifically called skin in the game), the default fund jointly contributed by the remaining non-defaulting members is the fourth, and below that come recovery and resolution procedures (Section 28.6). Among the five layers, what makes this waterfall

qualitatively different from a clearinghouse that relies on margin alone is not that it has as many as five layers but the two layers between the defaulter's resources and the non-defaulting parties' resources: the skin-in-the-game own capital and the members' prefunded mutualized default fund. These two layers are key not because of their size but because of their position.

The significance of the skin-in-the-game layer lies almost entirely in its ordering. Paddrik and Zhang's 2020 statistics on credit-derivatives central counterparties give a starkly contrasting pair of figures: the initial margin posted by defaulting members themselves accounts for approximately 77.9% of all prefunded resources, while the own capital contributed by the central counterparty accounts for only about 2.0% (Section 5.2.3) [13]. It should be noted that these proportions differ by cleared product; the figures cited here are the empirical values for credit-derivatives central counterparties (CCPs), and their absolute magnitudes should not be extrapolated as universal values for all CCPs. The 2.0% proportion is so small as to be almost negligible; by size alone, its actual contribution to loss absorption is minimal. But what traditional central-counterparty rules and regulatory practice retain this layer for is never its thickness but the ordering in which it is placed: it is typically positioned after the defaulter's own resources and before the remaining members' mutualized fund, bearing losses ahead of non-defaulting members' capital [2][13]. The entire purpose of this placement is to bind the clearinghouse's own interests to the risk control it operates.

To show why this ordering matters, imagine removing it. How high a margin a clearinghouse sets for members, what collateral it accepts, and how strict a standard it uses for stress testing—these discretionary choices all directly determine whether the waterfall will be breached, and they are all held by the clearinghouse itself. If the clearinghouse's own capital were not within the waterfall, or were placed after all members' mutualized fund, then the losses occasioned by relaxing its standards by an inch would be borne first by member capital rather than by its own capital, and it would then have a clear incentive: to set margins loosely so as to attract more business, transferring risk as much as possible to members. This is the basic moral hazard in the central-counterparty business model: the party operating risk control can avoid bearing losses for the failure of risk control. The skin-in-the-game layer is the structural corrective to this moral hazard. Once its own equity is forcibly placed ahead of other members' capital, it is, in making every risk-control discretionary choice, no longer a rule-maker that need bear no consequences but an interested party that will bear losses ahead of its clients. It realigns the operator of risk control with the bearer of the consequences of risk-control failure, which is the origin of its name and the reason its value cannot be measured by size. Theoretically, this layer is understood as a calibration of the central counterparty's incentives: when the clearinghouse can fully pass the cost of risk-control failure onto members, it has an incentive to relax standards and expand business; forcing it to place its own capital in the first-loss position is the most direct way to recalibrate this distorted incentive [6][7]. In other words, the 2.0% corresponds not to the principal loss-absorbing capacity but to a credible commitment: that the clearinghouse believes in the risk-control parameters it sets, believes in them enough to bear the risk of those parameter choices with its own capital.

The significance of the member-mutualization layer lies on another dimension, and it

turns on two points: first, prefunded; second, non-defaulting. Prefunded means that this capital is already in place and locked up before the crisis arrives, and does not depend on any party's ad hoc goodwill or resolve in a stress scenario. What a crisis most tests is the ability to raise funds on the spot, because at that moment market liquidity dries up, each actor prioritizes protecting its own liquidity, and participants generally lack the willingness to provide liquidity in extreme stress scenarios; a mutualized fund prepaid and locked up in advance eases this predicament: in a stress scenario it is a definite resource already on the books, not a promise still to be honored amid the crisis. Non-defaulting means that those who bear the loss are the originally non-defaulting members, not some blameless profitable party. These two points together give the central counterparty, when facing the collapse of a single member, a buffer within its authority that need not be raised on the spot and will not be withdrawn on the spot. It converts a single point of default into a bounded collective loss that the entire membership has agreed in advance to share, rather than letting the loss be randomly allocated across the market to some non-defaulting participant [11]. The prior agreement here is especially important: when members join the clearinghouse and contribute to the default fund, they have already accepted the rule that their contributions may be drawn upon when another defaults and its resources are insufficient; so when losses actually occur and the mutualized fund is drawn upon, no one is requisitioned by surprise; every contributor bears, according to the prior contract, a bounded and foreseeable obligation.

A well-designed default waterfall, by means of these two layers (one that makes the operator bear losses first so as to correct its incentives, and one of capital that the benefiting collective prepares in advance and shares by agreement), forms a buffer between the defaulter's margin and the non-defaulting market participants that is thick enough and clearly ordered. At the normative level, the Principles for Financial Market Infrastructures require central counterparties to hold sufficient prefunded resources, to establish default-management procedures, and to disclose key rules; the CPMI-IOSCO recovery guidance and the FSB resolution guidance further institutionalize recovery tools, loss allocation, and resolution continuity [2][16][17]. The specific layer ordering of skin in the game and the member default fund is embodied, in central-counterparty rules and in empirical waterfalls, as an arrangement whereby the clearinghouse, the defaulting member, and non-defaulting members bear losses in a predetermined order [13]. Depth, fundamentally, is this institutionalized, clearly ordered arrangement of resources; what it measures is not the size of capital but how many layers of preplaced capital can, before losses are allocated to non-defaulting parties, absorb losses first, in a set order and unconditionally. With this understanding of depth (ordering, prefundedness, and unconditionality, not the number of layers or their size), turning to look at the chain, the missing places come clearly into view.

29.2.2 The layer gaps in the on-chain waterfall

Placing the depth standard clarified in the previous section back onto the chain, the four-layer structure described in Section 29.1—margin, insurance fund, liquidation vault, auto-deleveraging—forms gaps at the two most critical points of the traditional waterfall, as soon as one asks after the funding source of each layer.

Take the skin-in-the-game layer. What comes closest on-chain to the form of a default fund is a USDC insurance fund like that of dYdX v4 or Perp v2; these funds do exist in advance and are positioned before users bear losses, and from these two points they seem already to have the appearance a buffer layer should have. But as soon as one asks where these funds come from, the difference emerges: their funding source is almost entirely the accumulation of trading fees [18][19]. This is a public pool collected by the protocol and remitted back into the risk buffer: in essence, it uses the fees that market participants themselves pay, accumulated for loss absorption, rather than the protocol putting up its own equity to bear risk. This distinction appears subtle on the surface, yet it is the whole crux of the skin-in-the-game layer. Every unit of capital in the fee public pool ultimately comes from the fees traders pay; it is a redistribution of market participants' funds within the system, and the protocol is merely the aggregator and manager of these funds: its own financial interest is not placed in the loss-bearing order. No one's equity, like the central counterparty's 2.0%, is forcibly placed in the first-loss position and bears losses ahead of everyone else. So on-chain there is a fund but no skin-in-the-game layer. As the previous section said, what skin in the game obtains is a credible commitment: that the operator is willing to bear the economic consequences of its own risk-control parameters; and a public pool supplied by traders' fees, however thick it accumulates, cannot form this commitment, because the financial fate of the protocol operating the system is not bound to the consequences of risk-control failure. This is what Chapter 28's verbatim judgment refers to: the on-chain waterfall typically lacks a layer corresponding to the central counterparty's skin in the game (Section 28.3.6).

Take the member-mutualization layer. The very last end of the on-chain four-layer waterfall is auto-deleveraging, which, after both the insurance fund and the liquidation vault are exhausted, forcibly cuts the profitable parties' positions to make up the shortfall. Formally, auto-deleveraging also shares out losses and seems to play the role of mutualization, but compared against the two conditions above, it is not equivalent to traditional mutualization in either respect. First, it is not prefunded. Auto-deleveraging is a forced allocation that occurs only ex post; before the crisis no capital was set aside for it: it is not a definite resource already on the books but a resource extracted on the spot from profitable parties' positions when the crisis occurs. Prefunded mutualization avoids the ad hoc fundraising constraint, whereas auto-deleveraging extracts this capital on the spot precisely when the crisis occurs, and it does so by forcibly cutting the profitable positions that other participants could have continued to hold. Second, those who bear the loss are not a non-defaulting collective that agreed in advance to share it but those non-defaulting traders who happen to be on the profitable side; they have never signed any contract agreeing to bear another's default losses: their profitable positions are cut merely because, at that moment, they hold profitable positions and can therefore be forcibly deleveraged. Chapter 28 already made this distinction plain: what auto-deleveraging cuts is profitable positions, and it is not equivalent, in either the population that bears losses or the incentives, to the mutualization in a traditional default waterfall, which is prefunded and jointly shared by non-defaulting clearing members (Section 28.3.6). Prefunded mutualization is capital that a set of actors have agreed in advance to share, that is bounded, and that does not withdraw

amid the crisis; auto-deleveraging is a loss allocation imposed ex post on specific non-defaulting parties. The two have only formal similarity; their economic meaning is not the same.

Placing these two gaps together, one can identify the true structure of the on-chain waterfall. It turns from a fee-supplied public pool directly to the ex post forced socialization of losses onto the profitable side, with the two middle layers (own-equity first loss and member prefunded mutualization) both absent. This layer gap is the fundamental reason the on-chain waterfall is shallower than the central counterparty's. It is shallow not in the number of layers; the four layers described in Section 29.1 are all present. It is shallow in this: when the insurance-fund public pool is exhausted, there exists, within the system's available range, no second layer of buffer composed of protocol equity or member prefunding to draw upon, so it can only immediately turn to auto-deleveraging, allocating tail losses to non-defaulting profitable parties more quickly and more directly (Section 29.1). A default waterfall with a skin-in-the-game layer and a member-mutualization layer still has, after public resources are exhausted, two layers of buffer, each independent and each with its own contributors, catching the loss in turn; whereas the on-chain waterfall presents as a structure lacking middle buffer layers, turning to non-defaulting parties to bear losses as soon as the public fund pool is exhausted, with no other buffer layer in between. The depth of a waterfall should be embodied in how many layers of buffer are still set before losses are allocated to non-defaulting parties, and it is at the point where buffers should most be set that the chain has two gaps. The remaining subsections of this section examine one by one the attempts made on-chain to fill these two gaps—whether by transferring the first loss to external capital providers, using a procyclical asset as a substitute for equity, or trying to migrate a mutualization mechanism on-chain, most of which have failed to operate sustainably—and identify why, to this day, no scheme has truly filled the gaps.

29.2.3 Liquidity providers as the counterparty: outsourcing the first loss

Since no actor is yet willing to place its own equity in the first-loss position, the chain has found a path that circumvents this constraint: outsourcing the first-loss position to capital outside the protocol. GMX and Gains are explicit liquidity-pool counterparty models, in which the trader's counterparty is not another trader but a capital pool funded by liquidity providers (LPs); profit and loss settle between the trader and the pool, and the pool is both the market-making liquidity and the first loss that absorbs shortfalls [20][21]. Synthetix's debt pool and Liquity's stability pool and redistribution mechanism are not the same kind of counterparty pool, but in economic meaning they likewise hand tail-bearing to stakers, stability-pool depositors, or other protocol participants, rather than to the protocol's own equity [22][23]. This design lineage does find several first-loss bearers for the chain, and formally it seems to fill the gap: after all, here is a body of preexisting capital that catches losses ahead of users. But the way it fills the gap exposes the meaning of the missing layer all the more clearly: the first loss is outsourced. The protocol itself still does not sit in the first-loss position; it merely places a class of capital providers—who enter voluntarily and can exit at any time—in the first-loss position.

GMX's experience displays the cost of this outsourcing plainly. Its GLP holders have directly borne losses twice, and on neither occasion was there any protocol-layer buffer ahead of them. The first was an oracle manipulation targeting AVAX in September 2022, which PeckShield estimated caused a loss of approximately $565,000 [24]. This figure is an estimate, and the attacker's identity remains unknown to this day: points that must be stated honestly, because this case differs from the clearly attributed manipulation cases discussed in Chapter 12 and must not be conflated with them; GLP holders received no compensation, and the loss was borne by them. The second was a reentrancy vulnerability in a GMX V1 contract in July 2025, which caused a loss of approximately $42 million [25]; only afterward did the protocol arrange compensation of approximately $44 million [26]. GMX has no insurance fund and no fee-supplied public pool, so the loss is simply GLP's loss, with no protocol-layer loss-absorption arrangement ahead of it [20]. The two events together constitute both the existence proof and the cost proof of the liquidity-provider-as-counterparty model: it does give the chain a first-loss layer that absorbs shortfalls, but this first-loss layer is a set of volunteers who can withdraw capital at any time, not an unconditional first loss borne by the protocol's own equity. Comparing the two events reveals another layer of meaning: compensation is ex post, discretionary, and event-dependent. The 2022 event compensated no one, while the 2025 event arranged excess compensation. Whether and how much compensation is paid depends on ex post decision rather than an ex ante contract, which shows that what GLP holders bear is not a first-loss obligation that is rule-bound and bounded but a risk of indeterminate exposure and uncertain compensation.

On the stablecoin side, crvUSD offers an isomorphic second example. It, too, has no dedicated insurance fund: once a shortfall appears on the minting side, it is borne passively by all crvUSD holders in the form of depeg risk; while bad debt in the isolated lending markets is borne by the lenders of each market individually [27]. Two empirical cases lay this bearing mechanism open. In June 2024, the Curve founder's own CRV-collateralized position was liquidated in a chain of liquidations across several lending protocols (including Curve's LlamaLend) as the CRV price fell by about 30%; he publicly acknowledged that this produced approximately $10 million in bad debt (most of which was later covered when a third party took it over at a discount) [28]. In the October 2025 crash, an isolated CRV-long LlamaLend market left approximately $700,000 in bad debt, borne by that market's lenders themselves [29]. Two easily confused things must be distinguished here: crvUSD's LLAMMA continuous soft liquidation and per-market debt ceilings are preventive designs that confine losses to a single market and keep them from spreading; they are not a loss-absorbing fund used to absorb losses after they occur. Prevention and loss absorption are two different things; isolating markets limits the range over which losses can spread, but it does not itself provide any capital to absorb losses; when bad debt truly occurs in an isolated market, it is ultimately still borne by that market's lenders themselves, with no layer of equity ahead of them bearing the loss. What isolation does is limit the range over which losses spread, not provide loss-absorbing capital for the market where the loss occurs.

Placing GMX and crvUSD side by side, the commonality of this class of design becomes clear: they do not lack first-loss bearers; on the contrary, they explicitly designate the

bearers: GLP holders, stablecoin holders, isolated-market lenders. The problem is that these bearers are all outsourced volunteers, not the protocol's own equity. This is exactly the opposite of the skin-in-the-game layer discussed in the previous section: the entire point of the skin-in-the-game layer is to make the operator of risk control bear losses ahead of its clients, thereby correcting its incentives; whereas outsourcing the first loss does the reverse: it moves the loss-bearing position away from the operator and hands it to a class of capital providers who have no say over the risk-control parameters yet must bear their consequences. What the liquidity-provider-as-counterparty model finds for the chain is not the skin-in-the-game layer but its opposite: the protocol transfers the first-loss position to external capital providers and does not itself sit in the first-loss position. This does not fill the gap but temporarily covers it with the funds of another class of capital providers; and since this class of capital providers can withdraw funds at any time, even this temporary cover is not secure.

29.2.4 The procyclical failure of reflexive-token collateral

If the skin-in-the-game layer is missing, and outsourcing the first loss to liquidity providers merely covers that missing layer temporarily, then an idea closer to the protocol's own equity is to have the protocol's token perform that layer's function—that is, to have token holders stake the token as loss absorption, and to slash that stake before users suffer losses. This mechanistic path has already appeared on-chain, and there is a fairly clear existence proof: Aave's Safety Module. The stkAAVE staked into the Safety Module can be slashed when the protocol runs a shortfall, to make up the gap [30]; its successor, Umbrella, further turns this mechanism into an insurance layer that can be configured per market and underwritten in separate tranches [31]. As a primitive, its significance should not be underestimated: it does prove that a first-loss layer can be constructed on-chain that is prefunded, slashable, and bears losses ahead of users. Structurally, this is closer to the intent of skin in the game than a fee public pool, because what is slashed are holders of an asset directly bound to the protocol's interests: they hold and stake the governance token, which is itself a risk-sharing commitment to the protocol's future, and placing their stake in the first-loss position conveys a commitment to bear the economic consequences of the risk-control parameters. As far as existence goes, the chain is not unable to construct an equivalent of the skin-in-the-game layer; stkAAVE and Umbrella are real counterexamples.

But using a token for this layer has an unavoidable tension, and this tension appears precisely when it is most needed: the value of a token is procyclical. What a central counterparty places in the first-loss position is cash, whose face value does not change when a crisis arrives (a dollar is still a dollar) and whose loss-absorbing capacity is independent of market conditions. A protocol token is the opposite: in the very crisis in which the system truly needs it to absorb losses, the token's price often plunges in the same direction as the assets whose losses are being absorbed. The logic here is closed: the system is under stress, bad debt surfaces, the market panics: these are the moments when the token most ought to bear losses; and the token's price is itself the market's discount of the protocol's prospects, so when the protocol suffers a major risk event, the market's judgment of its prospects deteriorates at once, and the token falls sharply at the same moment. Thus loss-absorbing capacity, at the very instant it is

most needed, instead declines: tokens of ostensibly ample value are staked, but by the time they must be realized to make up the shortfall, their own market value has already fallen; worse still, selling these tokens to make up the shortfall further depresses their price, forming a self-reinforcing price decline.

This is not an abstract worry; on-chain cases already show it. Synthetix long used SNX staking and a debt-pool mechanism to back sUSD, one of the most enduring and representative instances of reflexive-token backing [22]; but in April 2025, sUSD once depegged to about $0.68 [32], and by June 2026, SIP-423 had gone further and proposed freezing and retiring legacy sUSD, redeeming outstanding sUSD with newly minted SNX, and decoupling SNX staking from legacy sUSD obligations [33]. This means sUSD should no longer be described as a current success case still stably backed by SNX staking; more accurately, it has exposed the tail fragility of reflexive backing all the way into a governance exit phase. When the value of the backing asset and the stability of the backed asset affect each other, sUSD's stability was supposed to be supported by SNX's value, while SNX's value in turn hinges on whether the system runs well; once sUSD begins to depeg and the market loses confidence in the system, the two slide down together. Perpetual Protocol offers another, weaker piece of corroboration: its v2, through a matching structure based on Uniswap v3, reduced its reliance on the insurance fund itself [19]. Such design shifts show that a protocol token can be incorporated into a tail-tool portfolio but is hard to use as the principal stress-bearing capital in a default waterfall, because selling or issuing a token that is itself under stress to make up a shortfall amid a crisis often adds further selling pressure, weakening rather than strengthening solvency.

Reflexive-token loss absorption amplifies rather than absorbs shocks in the tail precisely because it builds the system's solvency on an asset highly positively correlated with the system. Cash-form own capital can serve as a buffer on the premise that its value is uncorrelated with the system's health; whereas the value of a protocol token is itself the market's discount of the protocol's future, highly positively correlated with the protocol's own fate. Building the first-loss layer on such an asset is tantamount to letting the buffer capital and the risk object being buffered fail together in the same stress scenario. This does not mean token slashing is worthless: stkAAVE and Umbrella prove it can structurally play the role of skin in the game, and under normal conditions and small-to-moderate shocks it does provide a real, slashable buffer, effective against local shortfalls that will not simultaneously crush the token's value. Its limitation is in the tail: in the extreme scenarios that would breach the entire waterfall and that most test depth, procyclicality weakens its absorbing capacity. In other words, the tokenized substitute the chain has found for the skin-in-the-game layer fails most easily where it least ought to fail, and the depth of a default waterfall measures exactly the loss-absorbing capacity in tail scenarios. A buffer effective only under normal conditions, but whose value falls markedly under stress scenarios, cannot yet be counted as the true depth of the waterfall.

29.2.5 Cross-protocol mutualization and the common-mode risk of restaking

While the skin-in-the-game layer is only outsourced or substituted, in limited fashion, by a procyclical asset, the member-mutualization layer's situation on-chain is even harder. Its on-chain candidate is cross-protocol mutual aid or a decentralized guarantee fund: letting multiple protocols share a backstop guarantee, structurally equivalent to the default fund in a traditional waterfall that is prefunded and jointly shared by members. This direction has been tried repeatedly, but the overall result is not encouraging; most attempts have failed to operate sustainably or to reach scale. To answer the first unresolved question, this history cannot be skipped.

The cross-protocol guarantee that has actually left a sustained payout record on-chain is, most typically, Nexus Mutual [34]. It is one of the few in this field that has indeed paid out to policyholders after events, and so it is often taken as an existence proof that on-chain member mutualization is feasible. But this single case itself illustrates the difficulty of the problem: around it, most other mutual-aid-type attempts have failed to operate sustainably. Mutual-aid-type insurers such as InsurAce and Unslashed often expose the pressure on reserves and governance discretion under correlated shocks. The UST depeg is one example: InsurAce's subsequently disclosed UST Depeg claims statistics show 234 covers corresponding to 173 claim filings, of which 155 were approved and 18 rejected, with net payouts of approximately $11.73 million after deductions, against related premium income of approximately $94,000 [35][36]. This set of facts cannot be simply written up as "claim denials" or "tightened payouts"; more accurately, it illustrates the capital pressure a mutual-aid guarantee faces in the face of systemic, co-triggered events: insured events often occur together, a systemic shock triggers claims on a large number of policies at once, and reserves accumulated in advance may be far smaller than the claim requests that arrive simultaneously. Per-market parametric insurance (such as Y2K, Cozy, and Risk Harbor) tries to underwrite with finer contracts triggered by specific risk events, avoiding the discretion problem of the mutual-aid type, but it in turn faces two other structural constraints. The first is basis risk: there is a gap between the payout trigger condition and the loss the policyholder actually suffers, so triggering a payout does not necessarily cover the actual loss, and an actual loss does not necessarily satisfy the trigger condition. The second is fragmentation of liquidity: the finer the slicing by event and by market, the more underwriting capacity is dispersed into isolated small pools, and the harder it is to form meaningful scale. Most of these protocols have already shut down or pivoted. Placing these successive attempts together, the chain's answer to the member-mutualization gap is: there have been repeated attempts, but most have failed to operate sustainably or reach scale, which shows this layer is not easy to construct.

The newly emerged restaking is the latest primitive in this direction and is often invested with high hopes. It directs the same stake toward multiple applications at once, using a single underlying economic security to provide guarantees for multiple protocols; EigenLayer and Symbiotic are its representatives [37][38]. Formally, this looks much like a cross-protocol shared backstop and seems just right to serve as on-chain member mutualization—one body of capital absorbing losses for many protocols at once. But it has two problems that cannot yet be avoided. The first is empirical: EigenLayer's

actively validated service (AVS) slashing went live on mainnet on April 17, 2025, and its design allows AVSs to set custom slashing conditions, Operator Sets, and Unique Stake Allocation [39]; as of publicly available information on June 25, 2026, it has not yet experienced a real, large-scale loss event to test whether it can pay out as designed under stress. A buffer that has never actually been drawn upon remains reliable only at the design level; and the value of each layer of a default waterfall can ultimately be verified only at the moment it is truly breached and truly drawn upon. A guarantee that has not experienced such a moment cannot yet be counted as usable waterfall depth.

The second problem, and the more crucial, is structural: a shared security layer reconcentrates some risk onto the same underlying stake. This point must be made clear, because it directly bears on the boundary of treating restaking as a mutualization primitive. Traditional member mutualization works on an implicit premise—that members' defaults are, to a large extent, mutually independent, so that when one member falls, the rest are healthy and able to share. The structure of restaking weakens this premise. Chapter 28 already issued a clear warning on this: restaking makes the same stake guarantee multiple applications at once, and the aggregate security is shared rather than simply summed, so slashings and operator failures across different applications become mutually correlated, which reintroduces exactly common-mode failure and correlation risk (Section 28.6.5). To be fair, EigenLayer's Unique Stake Allocation tries to confine a given AVS's slashing to the portion of stake the operator has allocated to that AVS, so as to isolate the slashing risk of unrelated tasks [39]; this reduces direct contagion between unrelated AVSs but does not eliminate the higher-level correlations of the underlying collateral asset's price, operator overlap, liquidity-withdrawal pressure, and simultaneous slashing requests. A body of economic security relied upon jointly by multiple protocols, once it shrinks in a systemic shock, correspondingly shrinks the guarantee it provides to all related protocols; if multiple protocols relying on it come under stress simultaneously, slashing or exit demands on the underlying stake arise simultaneously, and their scale may be insufficient to cover the multiple simultaneous requests. It is a new primitive but far from a verified solution: untested in the tail and still carrying the very correlation problem it was meant to ease.

29.2.6 The current absence of an equally deep waterfall on-chain

Taking the preceding five subsections together, Chapter 28's most direct question can, within the range of the main on-chain clearing, perpetual, and lending protocols examined here as of June 25, 2026, only reach one direct conclusion: a default waterfall as deep as that of a traditional central counterparty cannot yet be achieved on-chain (Figure 29-2).

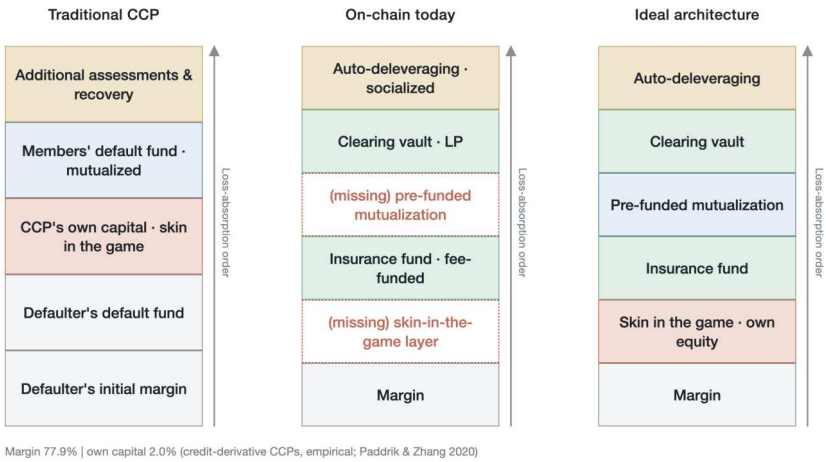

Figure 29-2. A comparison of default-waterfall depth: the traditional central counterparty's five layers, the on-chain status quo's four layers, and the ideal architecture (restoring the skin-in-the-game own-equity layer and the prefunded mutualization layer)

The weight of this conclusion is accurately grasped only after *depth* has been reclarified. Depth is never the number of layers, nor size, but how many layers of preplaced capital can, before losses are allocated to non-defaulting parties, absorb losses first, in a set order and unconditionally. Figure 29-2 places the three side by side: the traditional central counterparty's five-layer waterfall sets, between the defaulter's margin and the non-defaulting parties, the two layers of skin-in-the-game own capital and member prefunded mutualization; the on-chain status quo's four-layer waterfall turns from a fee-supplied insurance fund directly to auto-deleveraging of the profitable side, with those two middle layers absent; and an ideal decentralized clearinghouse needs to restore these two layers. Table 29-1 then compares, item by item, the funding source and ultimate bearer of each layer, so that the position of those two gaps comes clearly into view: in the traditional waterfall, both the protocol-own-equity column and the member-prefunded-mutualization column have clear contributors and bearers, whereas the two corresponding on-chain columns either read as a fee public pool, which is not equity, or point to profitable parties requisitioned ex post. The two exhibits together illustrate the same thing: the on-chain waterfall is not at a disadvantage in the number of layers; what is truly lacking is the two layers of resources that are correctly positioned, clearly ordered, and unconditionally in place.

Waterfall layer	Traditional central counterparty	On-chain status quo
First-loss position · the defaulter itself	Defaulting member's initial margin (approximately 77.9% for credit-derivatives CCPs)	Account margin
Own-equity first loss (skin in the game)	Central counterparty's own capital (approximately 2.0% for credit-derivatives CCPs, placed ahead of member mutualization)	Absent — the insurance fund is fee-supplied, not the protocol's own equity
Prefunded mutualization	Default fund prefunded and jointly shared by non-defaulting members	Absent — auto-deleveraging cuts profitable positions ex post, not prefunded mutualization
Backstop and socialization	Additional assessments and recovery tools	Liquidation vault (liquidity-provider capital) → auto-deleveraging (socialization onto the profitable side)

Table 29-1. Funding sources and ultimate loss-bearers of each layer of the default waterfall: a comparison of the traditional central counterparty and the on-chain status quo (Data source: compiled by the author based on Paddrik & Zhang 2020 [13]; the approximately 77.9% and approximately 2.0% figures are empirical shares of prefunded resources, vary by cleared product, and should not be extrapolated as universal values for all CCPs)

The chain has sought substitutes for these two gaps, and this section has examined them one by one; none has yet formed a sustainably operating mechanism. For the skin-in-the-game layer there are two substitutes: outsourcing the first loss to liquidity providers, and using a slashable token as an equity substitute. The former merely transfers the loss-bearing position to external capital providers rather than the protocol itself, and moreover the party bearing that position is a class of voluntary capital providers who can withdraw capital at any time; the latter, though structurally closest to skin in the game, carries a congenital procyclical defect and fails most easily in the tail scenarios where it most needs to function. For the member-mutualization layer there are also several substitutes: cross-protocol mutual aid, parametric insurance, and restaking. The first two have been tried repeatedly and mostly failed to operate sustainably, while restaking, though a new primitive, runs counter to the intent of dispersion because of common-mode risk and is untested in the tail; and auto-deleveraging at the end of the waterfall, still more, imposes ex post on non-defaulting profitable parties the loss that prefunded mutualization ought to bear. Each substitute touches the correct structural position, but none has yet formed an arrangement of unconditionally committing equity to that layer; they either transfer that position to external capital, or occupy that layer's position with a mechanism that evaporates under stress scenarios, or allocate the loss to actors who ought not to bear it.

The final judgment is therefore clear, and its cause lies not at the technical level. What is lacking is not some complex mechanism, nor engineering feasibility; primitives such as a slashable safety module and a cross-protocol shared guarantee have already appeared, and this section has shown their existence. What is truly lacking is the two most basic and hardest-to-obtain layers of capital: one layer of some actor's own equity willing to bear losses ahead of everyone; and one set of actors willing to prefund jointly, and

share by agreement, before a stress scenario arrives. The substitutes the chain has found for the former have still developed over only a short time and all carry the inherent defect of procyclicality or common mode; the substitutes found for the latter allocate losses ex post to actors who ought not to bear them. Filling these two layers is the precondition for a decentralized clearinghouse to move from *having a default waterfall* to *the default waterfall having sufficient depth*; and the difficulty of filling them was never, from the outset, technical but the basic political-economy question: what kind of capital is willing to bear the first loss. This is the direct answer, on the dimension of depth, to Chapter 28's first unresolved question. It also foreshadows the equally basic and intractable seam the next section will face: when losses ultimately exceed the limit any waterfall can absorb, how should a system without a lender of last resort fail in an orderly way.

29.3 Orderly degradation without a lender of last resort

The second question Chapter 28 left concerns how to balance risk control against user experience (Section 28.3.6). Pursued along this system, this question quickly converges on a harder seam: the seam between the liquidation shock the clearinghouse imposes on defaulting positions and the loss-absorbing capacity the market can provide at that moment (Section 29.1). Liquidation necessarily throws positions onto the market, and the market does not necessarily have sufficient capacity to absorb them; the portion that cannot be absorbed is what orderly degradation must handle. This section answers how a clearinghouse system, when it can neither assume external rescue nor avoid facing its own extreme stress scenario alone, can confine the unavoidable failure at this seam within a controlled range.

29.3.1 The absence of a lender of last resort and the shift in design goals

Traditional finance's extreme moments usually feature a set of external stabilization tools, of which the lender of last resort is only the most conspicuous. A decentralized clearinghouse has no such public credit supporter, a point this book has repeatedly confirmed (Chapter 11, Table 11-2). Its implication is not merely one fewer form of relief; the absence of a lender of last resort means the system cannot outsource its liquidity tail risk to the public sector's ad hoc funding and must face its own extreme stress scenario alone. A central bank can, amid panic, open a liquidity window to an institution facing liquidity-withdrawal pressure but still solvent; a regulator or trading venue can, amid disorder, trigger a halt mechanism; a market maker may, under certain market rules, bear a continuous-quoting obligation. These external supports have no equivalent in an on-chain clearinghouse where no single actor can issue commands.

To show the weight of this absence, one must first list the several tools traditional finance uses to dampen shocks, then confirm one by one which equivalent the chain lacks. The first is the central bank's lender-of-last-resort function, which, through the discount window, injects funds amid panic into institutions that lack liquidity yet remain solvent, cutting off a liquidity crisis before it escalates into a solvency crisis that would other-

wise have turned into liquidity-withdrawal pressure (Chapter 11, Table 11-2); the chain has no actor commanding such a public liquidity-supply mechanism that can create public credit out of nothing, and the balances of the insurance fund and the liquidation vault are both finite and prefunded, and each use depletes them. The second is the exchange's power to trigger circuit breakers and halts; traditional markets can, when prices fall through a preset threshold within a short time, forcibly suspend trading for a few to a dozen or more minutes, providing a time window for margin calls, digesting information, and repricing risk, cutting a stretch out of the positive feedback between panic selling and mechanical liquidation (Chapter 11); on-chain perpetual markets typically run around the clock, and although some protocols have admin pauses, parameter adjustments, or governance emergency channels, these are intra-protocol discretion, not external public authority. The third is market makers' obligation, mandated or institutionally incentivized, to quote continuously; traditional markets, under certain rules, still retain minimal quoting and market-maintenance arrangements; on-chain market making is mostly voluntary capital, which is all the more inclined to pull quotes the more a crisis deepens, so that loss-absorbing capacity evaporates at the very instant it is most needed. The fourth is the margin period of risk buffer; a traditional central counterparty calculates margin over a close-out risk horizon measured in days, leaving a buffer for margin calls, negotiation, and orderly close-out, whereas the chain compresses this time scale to real-time, trade-by-trade, with almost no room to maneuver between discovering insufficiency and executing liquidation (Chapter 11). These tools do not exist at the same intensity in all traditional markets, nor is the chain wholly without internal substitutes; the key difference is that the chain has no external backstop fully equivalent to the institutionalized shock absorbers of public credit, external halt powers, and mandated quoting obligations [3].

Therefore, a clearinghouse system without a lender of last resort must rewrite its design goal from *avoiding failure* to *failing in a controlled way in the worst case*. This adjustment is not an abandonment of risk governance but an acknowledgment of the resource constraint. Chapter 12 has argued that when losses exceed all of the defaulter's own resources and the system lacks sufficient external capital, full loss coverage can no longer be guaranteed by the mechanism itself; Chitra's model of auto-deleveraging likewise gives a formal constraint in the same direction, from the angle that solvency, revenue, and fairness cannot be had together [12]. The question thus shifts from "can no one lose anything" to "who bears the loss, how much, and at what tempo." A system that sets its goal at zero loss is promising a state that cannot be guaranteed by existing internal resources; only a system that sets its goal at controlled failure truly faces its own situation. What "controlled" means can be unpacked into three more concrete engineering goals: predictable (the path and upper bound of losses are written into the rules in advance, rather than adjudicated ad hoc amid the crisis); containable (losses are confined to the range that ought to bear them and do not spill over to unrelated participants); and absorbable (the layer that bears the loss actually has the corresponding resources on hand to absorb it when the event occurs). The conclusion that full loss coverage cannot be unconditionally guaranteed by internal mechanisms does not, in engineering terms, mean the system is doomed to collapse; it means the system must abandon the illusion of leaving no loss and instead shape the unavoidable loss into

a predictable, containable, and absorbable form. Acknowledging this is the starting point of orderly degradation: the system no longer pursues the zero loss that its own resources cannot absorb but instead pursues confining the unavoidable loss within a predictable, containable, and absorbable range.

This is precisely one of the structural deficiencies the Bank for International Settlements pointed out in assessing decentralized finance: on-chain systems generally lack the shock absorbers on which traditional finance relies to dampen shocks: no central-bank liquidity window, no external halt power that a trading venue or regulator can exercise, and no market makers institutionally constrained to quote continuously amid a crisis [3]. A line of research isomorphic to this section's argument likewise notes that, absent such absorbers, the robustness of a decentralized clearing design must be constructed from within the mechanism rather than hoped for from external intervention [40]. The absence of shock absorbers is not the oversight of some protocol but an inherent property of the permissionless architecture; since one cannot seek help outside, the only handling path is to build the capacity to absorb shocks into the clearinghouse's own structure. This sharpens the section's question: to handle that seam between the liquidation shock and the market's loss-absorbing capacity, the chain's most direct and most engineerable internal means are two—confining the shock to as small a range as possible, and turning the shock itself into a design variable that can be actively adjusted. On the shock side, the system cannot conjure thicker market loss-absorbing capacity out of nothing, but it can decide at what scale and at what tempo the shock is thrown onto the market; on the loss-absorbing-capacity side, the system cannot attract external rescue funds, but it can decide which pool is responsible for absorbing, thereby framing the reach of the shock. The former manages the shock as a design variable; the latter delimits the scope of absorption through isolation (one acting on the shape of the shock, the other on the boundary of absorption), and together they constitute the principal internal intervention directions of a clearinghouse system without external aid at this seam. The rest of this section develops these two means in turn, then points out their shared cost.

29.3.2 Risk-pool isolation

The first means is to confine a single market's bad debt within that market's own risk pool, so that it cannot infect elsewhere. Its cautionary counterexample was already dissected in Chapter 12: in the JELLY incident of March 2025, Hyperliquid's liquidity vault HLP was forced to take over a single altcoin's defaulting position, and a risk that should have been confined to a niche market nearly imperiled the entire vault's solvency (Section 12.6) [41]. The problem lay not in the size of the vault but in the commingling of the vault: all markets' risk shared the same loss-bearing pool, so that any one market's tail event could infect participants of all other markets. One pool's capital simultaneously absorbing losses for all markets ostensibly raises loss-absorbing capacity, but in reality it forms a high risk correlation among all markets: once the most fragile market has a tail event, the other markets are affected as well.

The positive design therefore points to a single principle: let each market's risk be borne, as much as possible, by that market's own participants and not spill outward.

This principle already has several mature implementations on-chain, each setting its isolation boundary at a different location, and each mechanism is worth identifying. Aave V3's isolation mode carves out a separate set of constraints for higher-risk collateral: for collateral listed as an isolated asset, the debt borrowed against it is capped by a debt ceiling denominated in a stablecoin, and only governance-approved stablecoins, not arbitrary assets, may be borrowed [42]. These two constraints together lock the bad debt that a high-risk asset may occasion, in advance, within a bounded range measured in the most easily liquidated stablecoin, so that it cannot penetrate the entire lending pool. Euler v2, launched in September 2024, pushed isolation to a fuller position, organizing lending in units of independent vaults, each carrying its own set of risk parameters, so that the risk boundary is defined by the vault boundary and a vault's internal bad debt is held within the vault by that boundary [43]. Compound III organizes the entire protocol into several markets centered on a single base asset, each market having only one borrowable base asset, around which several collateral types are configured; whichever market a lender puts funds into is the only market whose risk it bears, and markets are not interconnected [44]. Morpho Blue goes further, splitting lending into a large number of mutually immutable, mutually isolated markets, each of which, at creation, fixes once and for all its collateral, borrowable asset, liquidation loan-to-value (LTV) ratio, and other parameters, unchangeable thereafter; a lender therefore faces an isolated risk exposure whose boundary and parameters are determined in advance and that no one can adjust after the fact [45]. Hyperliquid itself, in HIP-3, introduced isolated markets in which the deployer bears the risk: whoever launches a new market must post a stake, bringing that market's possible risk, together with its bad debt, into the range borne by the launcher's stake, rather than letting it flow back to the shared vault [46]. There is no basis for saying HIP-3 was directly spawned by JELLY; but as a conceptual point of comparison, the commingling problem JELLY exposed is exactly the kind of problem isolated markets are meant to solve.

The insurance layer is also evolving in the same direction, and this evolutionary thread relates directly to the skin-in-the-game issue discussed in Section 29.2. Aave's Safety Module, already discussed in Section 29.2, whose staked tokens can be slashed in a shortfall event, is a shared first-loss pool—all markets' bad debt can draw on the same stake [30]; its successor design, Umbrella, splits this originally shared, slashable pool into isolated insurance by market, letting stakers choose to provide first-loss guarantees for only one or a few markets, thereby confining the question of *who absorbs this market's bad-debt loss* to those willing to absorb it for that market [31]. From a Safety Module in which one pool is shared and treats all shortfalls alike, to insurance tranched and underwritten per market, the path runs in the same direction, from commingling to isolation; it combines the first-loss guarantee discussed in Section 29.2 with the isolation principle discussed in this section within a single design.

The cost of isolation severing contagion is that it simultaneously causes liquidity fragmentation, and this is the first cost this section must point out. An isolated market cannot call on other markets' depth to absorb its own shock; when it truly has a tail event, the loss-absorbing capacity it can draw upon is limited to the existing resources in its own pool. A commingled pool, though it spreads contagion, also means any one market can borrow the whole pool's depth to absorb a shock; isolation severs this layer

of mutual aid. This cost appears in the same form in each of the primitives above: the debt ceiling Aave V3 sets for an isolated asset, while blocking bad-debt spillover, also limits the absorbing depth such an asset can obtain; the finer Morpho Blue splits markets and the more tightly it locks parameters, the thinner the liquidity a single market can mobilize in a crisis; Umbrella's tranching of shared insurance by market, while making underwriters each responsible for their own, also deprives each market of the possibility of calling on the full thickness of a shared insurance pool. This leads to an unavoidable frontier tension: the finer the pool is split, the more fully contagion is severed, yet the thinner the depth a single market can mobilize in a crisis, and the more easily it is breached by even a modest liquidation; the larger the pool is aggregated, the thicker the loss-absorbing capacity a single market can borrow, yet once one market has a tail event, the risk spreads across the entire network. Depth and contagion are therefore two directions of the same trade-off: isolation trades liquidity fragmentation for contagion blockage (the more strictly the risk boundary is drawn, the fewer the resources available to absorb risk), and there is no optimal solution that simultaneously attains both thicker absorbing depth and contagion blockage.

29.3.3 Active shock management

The second means is to rewrite the price impact that liquidation imposes on the market, from a passively suffered consequence into an actively designed variable. Chapter 11 analyzed the liquidation shock as a passive consequence of cascade dynamics: a price decline triggers liquidations, whose selling in turn depresses the price, and the shock amplifies itself in a feedback loop (Sections 11.3 and 11.5). The idea of active shock management is to move this shock from the end of the causal chain forward to the starting point of design: since liquidation necessarily throws positions onto the market, at what price, at what tempo, and to whom they are thrown are no longer wholly exogenous, uncontrollable variables but parameters that can be designed in advance.

The clearest empirical contrast of this idea comes from two versions of MakerDAO's liquidation system, which happen to sit before and after this means was discovered [47]. Black Thursday, March 12, 2020, was a full exposure of the old system. That day Ethereum fell about 43% in a single day, and on-chain congestion meant that only a very few liquidators could submit bids in the liquidation auctions; the fixed-duration English auction the old system used therefore produced zero-bid outcomes, with approximately $8.32 million in collateral cleared at a price of 0 DAI, and the system was forced to mint more than 20,000 MKR to make up the resulting bad debt [48]. Here two figures must be kept apart: the approximately $8.32 million cleared at zero price is the scale of collateral auctioned off at zero, while the bad debt that ultimately fell within the system's range to bear was approximately $4.5 million to $5.3 million; the two are not the same problem. The root of the failure lay not in the magnitude of the market decline but in the auction mechanism itself compressing the range of loss-absorbing capacity too narrowly. To show this, one must first identify the mechanics of the English auction: an English auction bids upward within a fixed time window, and the highest bidder wins the item; but once the chain is congested and bid transactions cannot make it into blocks, the number of effective buyers able to squeeze into the window drops markedly, the execution boundary closes at the time

limit, and the collateral is then cleared at zero price in a situation where, in effect, no one is effectively bidding [47]. The fixed-duration design limited the entry condition for loss-absorbing capacity to *must submit, amid congestion, a bid that successfully lands on-chain first*, and this entry condition is most restricted when the system most needs buyer participation.

Liquidations 2.0, launched in April 2021, responded one by one to the mechanism failures that day exposed, and its way of responding was to remake every dimension of the auction into an adjustable parameter [47]. It changed the English auction into a Dutch descending-price auction, and the mechanics of a Dutch auction happen to ease the exclusivity that congestion brings: the starting price is set at a multiple above the market price, and the price thereafter decreases over time along a preset curve, so that a liquidator need not bid first amid congestion, contesting scarce block space, but need only wait for the price to fall to a level favorable to it before participating in the transaction to conclude a fill, and the execution boundary of loss-absorbing capacity therefore no longer closes with time in a fixed manner [47]. This descending-price curve is itself a set of adjustable parameters, and this set of parameters happens to correspond to the several dimensions on which the old system failed. The multiple of the starting price relative to the market price determines how high the auction starts, setting an initial price above market for the collateral and then letting the market discover its true absorbing price. The auction duration has a cap; if the price descends through this duration and still no one takes it, the auction is deemed to have reached the cap and must be reset—this duration cap ensures that an auction does not indefinitely keep an unhandled risk position outstanding. The maximum decline the price is allowed to fall along the curve sets a floor, specifying the lowest proportion of the market price to which the price may fall in a single auction; crossing this floor triggers a reset rather than continued low-price disposal, avoiding the collateral being auctioned off at zero in a runaway price decline. This is the execution boundary that directly responds to Black Thursday's zero bids. And the step size of the curve determines whether the price falls smoothly and continuously or jumps down in discrete steps; the finer the step, the closer the price at which loss-absorbing capacity is attracted to the collateral's true liquidation price. Adjusting these several parameters amounts to adjusting the tempo and cost of the whole auction's attraction of loss-absorbers. It also settles fills atomically and in real time, and allows flash loans to participate in bidding: a bidder can, within a single transaction, borrow funds, buy the collateral, and then sell it to repay, with no need to hold cash in advance, so that potential buyers are expanded from the few liquidators holding cash at the time to anyone able, within one transaction, to borrow, buy, and resell, and the range of bidders is therefore greatly widened. It supports partial fills in batches, splitting the collateral in an auction into small portions that can be absorbed in tranches, not requiring a single buyer to absorb all the collateral at once, so that a large liquidation can be jointly digested in tranches by multiple small buyers, and the single-transaction capital required to absorb a large liquidation is broken down, further loosening the demand on a single buyer's financial strength. It is also equipped with a ClipperMom circuit breaker, which can be authorized to trigger a reset or even a suspension of the auction parameters when the oracle price deviates abnormally or the auction exhibits unexpected behavior, serving as a mechanism-level

safeguard. Placing these two versions side by side (Figure 29-4 contrasts the price–time curves of the English and Dutch auctions: the English auction waits for bids within a fixed duration and terminates when the execution boundary expires, while the Dutch auction lets the price descend continuously along a curve, absorbable atomically at any time) reveals the entire point of active shock management: it does not make the liquidation shock disappear entirely but turns the price and tempo of liquidation into mechanism parameters the designer can configure in advance. Every design of the old system that excluded loss-absorbing capacity from the execution range was changed into an adjustable parameter open to more absorbers. Its official design document does not name Black Thursday, but every item of this mechanism corresponds to some failure of that day.

29.3.4 Other degradation mechanisms

The Dutch auction is only one kind of active shock-management tool; the chain has also evolved several degradation primitives that differ in approach yet all refuse to treat the liquidation shock as an exogenous variable. Liquity adopts an absorption mechanism rather than an auction mechanism: it sets up a stability pool, letting stablecoin holders deposit funds into it in advance; when a vault is liquidated, the stability pool immediately burns the corresponding amount of stablecoin in exchange for the liquidated collateral, and the pool's depositors absorb this collateral in proportion to their shares and share in its profit and loss [23]. Because liquidation is triggered only when a position's collateralization ratio falls below a threshold, that is, when the collateral value is still slightly above the debt, the collateral the stability-pool depositors receive is, under normal circumstances, slightly more valuable than the stablecoin they burn, and this difference is their compensation for bearing loss risk; absorption is therefore not uncompensated bearing but a transaction with consideration. This mechanistic path is also equipped with a supplementary mechanism for the case where the stability pool is exhausted: when the stablecoin in the stability pool is insufficient to offset a liquidation, the debt and collateral of that liquidated vault are proportionally redistributed to the remaining still-active vaults, jointly borne by the owners of those vaults [23]. The value of the two mechanisms together is that they are immediate and do not sell to the open

market, thereby wholly avoiding the loss-absorbing-capacity problem an auction must face; the cost is that they socialize the loss onto the stability pool's depositors and even the remaining borrowers, and the absorbing capacity of the stability-pool main path is limited by the stability pool's balance at the time—once the stability pool is exhausted, the system can only fall back on the more dilutive and more contagious backup path of redistribution.

Euler's soft liquidation designs the liquidation discount as a continuous curve that rises as account health declines, so that liquidation is triggered when a position has just crossed the boundary and the discount is still small [43]. To show its mechanistic advantage, take as a contrast Compound III, which uses a fixed-discount liquidation model: whether a liquidator steps in when a position has just crossed the boundary or when it is already deeply insolvent, the discount obtained is the same predetermined fixed value [44]. The problem with a fixed discount is that, when a position has just crossed the boundary and the discount appears too thick relative to the risk, it incites liquidators to engage in front-running and gas-fee bidding to seize this certain profit. Euler's continuous discount curve is a response to this problem, designing the reward to liquidators to grow continuously as health worsens: roughly, the reward is proportional to the degree of health's deviation from a sound level, with the discount higher the closer the position is to insolvency [43]. The effect of this continuous incentive curve is to attract liquidation the moment it becomes marginally favorable: the discount is no longer a fixed value paid out in one lump after a threshold is crossed but rises continuously from a low level, so liquidation becomes earlier, smaller, and more dispersed, the upper bound of profit a single liquidation can seize is lowered, and the front-running and gas-fee bidding among liquidators to seize a large liquidation are correspondingly weakened. crvUSD's LLAMMA rewrites liquidation as a process occurring continuously along a price range: it distributes collateral over a price band and makes markets there, automatically converting collateral grid by grid into stablecoin along the band as the price falls, and back again as the price rises, so that a position is gradually and smoothly soft-liquidated during a decline rather than being hard-liquidated all at once at some threshold [27]. This mechanism in essence distributes the liquidation shock across a continuous market-making process over an entire price range, converting out only a small portion of collateral for each grid of decline, so the price impact is sliced into multiple smaller increments rather than a one-time large sell-off at some threshold; only in the extreme case where the price falls deep out of this soft-liquidation band and stays there for a long time does it fall into hard liquidation. It essentially converts liquidation from a discrete and irreversible event into a continuous transformation process that is reversible when the price recovers. Ajna takes another simplifying path: it removes reliance on an oracle and instead lets lenders each specify, when depositing funds, the collateral valuation they are willing to accept, so the market's liquidation threshold is determined endogenously by lenders' quotes rather than given by an external oracle that may be manipulated or may fail in a crisis [49]. When a borrowing position is undercollateralized by lenders' endogenous pricing, anyone may initiate a liquidation, launching a Dutch auction on that position and letting a descending-price auction find the absorber [49]; it therefore combines Section 29.3.3's Dutch auction with a set of liquidation trigger conditions that do not rely on an oracle into the same

mechanism combination, separating the liquidation-trigger determination from external oracle dependence. What these designs have in common is that they all refuse to accept the premise that the liquidation shock is an exogenous variable that can only be passively suffered; each starts from a different link, yet all convert the shock that Chapter 11 treated as a passive consequence into a parameter the designer can configure. The relationship of this set of examples to perpetual clearinghouses should be stated: they mostly come from lending and overcollateralized-stablecoin systems and cannot directly prove that perpetual clearinghouses already possess equivalent mechanisms; what they prove is that the price, timing, trigger, and absorber of forced disposal can be engineered and reshaped. Migrating them to a perpetual clearinghouse would still require handling compatibility among position transferability, order-book continuity, isolated/cross margin, market-maker inventory, and predefined loss layers. These paths are not mutually exclusive but decompose the same passive shock into several intervenable links (the destination of the selling, the shape of the incentive, the temporal distribution of liquidation, the source of the trigger determination), each of which was once an exogenous, uncontrollable condition and is now rewritten by some primitive into a designable endogenous variable. The chain's active management of the liquidation shock is therefore not the isolated design of some protocol but an engineering line advancing across multiple protocols from multiple angles at once. Together with Section 29.3.3's Dutch auction, they constitute the existing on-chain toolkit for orderly degradation (Figure 29-3 juxtaposes the effect of these two means on the cascade path: risk-pool isolation severs the lateral contagion, and active shock management slows the vertical escalation).

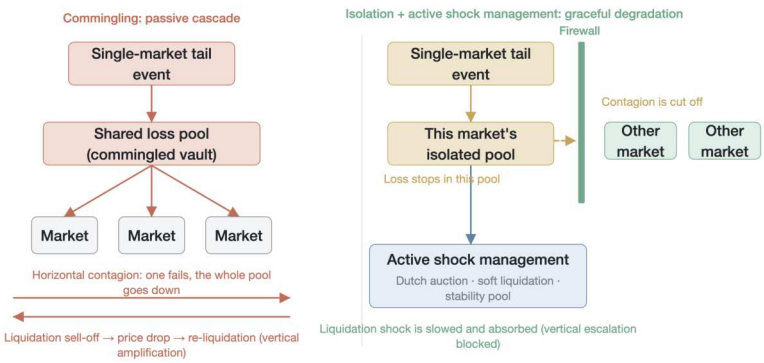

Figure 29-3. Risk-pool isolation and active shock management: from passive cascade to orderly degradation (conceptual illustration)

29.3.5 The three costs of orderly degradation

Every orderly-degradation mechanism has a cost that must be borne. Each means only transfers the loss from one position to another and cannot eliminate the loss itself: this is the architecture-level reappearance of Chapter 12's impossibility theorem (Section 12.2.3). That theorem shows that full loss coverage is no longer attainable; at the architecture level, this means any degradation mechanism can only choose among who

bears, when they bear, and in what form they bear, and cannot make the bearing itself disappear.

The first cost is the dilemma between slowing the auction and deepening bad debt. A Dutch auction slows the tempo to weaken a single shock, but the slower it goes, the greater the risk that the collateral's value continues to fall during the auction, and the deeper the bad debt ultimately left may be. MakerDAO's own design document acknowledges this dilemma almost verbatim, and points in two directions at once: too fast a decline (the price curve falling faster than loss-absorbing capacity enters) means bidders pay a price far below what they would have been willing to pay, producing avoidable permanent bad debt; too slow a decline means the auction price may keep failing to catch up with a still-falling market price, and the collateral keeps depreciating in the slow descent, likewise leaving bad debt; the document even concedes that the choice of price curve remains an active research area, with no single curve optimal in both directions at once [47]. This dilemma cannot be resolved once and for all by tuning parameters: its two ends each point to opposite failures, and it is not a problem with a single optimal solution but a double-bind whose two ends both lead to loss, so the most a designer can do is choose the relatively more bearable of the two losses. A study that quantifies, by simulation, the trade-off between liquidation speed and incentive cost provides a quantitative characterization of this dilemma, confirming that the relationship whereby slower liquidation requires higher incentive cost to attract loss-absorbers is not a qualitative intuition but measurable—each notch of slowing in liquidation requires, to still attract buyer participation at that moment, a higher discount or incentive, and this extra incentive is itself a cost the system bears [50]. The significance of this quantification is that it converts the ostensibly experience-judgeable trade-off of fast versus slow into a cost curve that can be measured yet cannot be eliminated: what faster buys is a smaller risk of market-price decline, and what it pays is a higher immediate incentive cost, and the two can only trade off against each other. Orderly degradation has no uniform standard solution for precisely this reason: the fast-or-slow of the auction sits between two kinds of bad-debt risk, and extremizing the choice in either direction produces loss.

The second cost is that absorption-type mechanisms socialize the loss. What Liquity's stability pool and redistribution trade for immediate absorption is the transfer of the loss from the liquidated party onto the stability pool's depositors [23]; these depositors are not the defaulting party of any position, yet, because they put funds into the stability pool in advance, they share the loss when liquidation occurs. Two different senses of socialization are worth distinguishing here. Under normal circumstances, the collateral depositors receive is slightly more valuable than the stablecoin they burn, and what they take on is less a loss than a transaction with a discounted compensation; only when the market falls deep enough that the collateral, once received, keeps depreciating to less than that stablecoin do depositors truly bear a net loss. The redistribution path goes a step further, allocating a defaulting vault's shortfall to a set of other borrowers who have nothing to do with that default, so the scope of socialization spreads from voluntarily pooled depositors to bystanders who never chose to take on anyone's risk. Socialization is not a defect of this mechanistic path but its mode of operation; it is precisely by spreading the loss thinly onto a set of bearers who are preplaced and largely

voluntary that it trades for immediacy and no selling pressure. That is, absorption-type mechanisms do not eliminate that loss; they merely transfer it from a defaulter forced to bear it onto a set of depositors who agreed in advance to bear it and take collateral at a discount as compensation, or, in the extreme case, onto a set of other borrowers who passively bear the loss; the loss changes bearers, but its total does not diminish.

The third cost is that isolation trades for liquidity fragmentation, a point Section 29.3.2 already made: what isolation trades for by blocking contagion is that each pool can only rely on the depth of its own existing resources to absorb a shock. Placing the three costs side by side reveals that they are, in substance, three facets of the same structural fact: loss can only be redistributed along different dimensions and cannot be eliminated. The fast-or-slow of the auction redistributes the loss along the time dimension: cash it out now at a discount, or drag it into the future and suffer deeper depreciation. Absorption-type mechanisms redistribute the loss along the participant dimension: from the defaulter onto preplaced bearers. Isolation redistributes the loss along the market dimension: deciding whether it is borne by this market alone or spills over to the whole pool. The three together point to the same fact: the core design task of orderly degradation lies not in eliminating these costs but in choosing, under a given market structure, a combination of costs that lets the system survive. They are all projections, on different facets, of Chapter 12's impossibility theorem; since loss cannot vanish into thin air, all engineering effort can only be engineering about how loss is allocated.

29.3.6 The incentive failure of liquidation execution

There is one further cost, more hidden and deeper than the three above, because it leads the discussion into the next section's theme. All these active shock-management mechanisms—auction, soft liquidation, or stability pool—presuppose one premise: that at the moment liquidation needs to occur, there will always be participants willing to execute it. The chain has no liquidators compelled by regulation to perform; liquidation relies on market incentives, and who liquidates depends on whether liquidation is profitable at that moment. To show how fragile this premise is, one must first identify the cost-benefit relationship of on-chain liquidators. A liquidator's decision to execute turns on a cost-benefit difference: the discount or reward obtainable from liquidating this position, minus the gas cost of sending this liquidation transaction on-chain, is worth doing only if the difference is positive. In calm times this difference is large: gas is cheap, discounts are considerable, and liquidators participate actively; whereas it is at the extreme moment when liquidation is most needed that this difference is squeezed from both ends at once. On one end is the gas cost: amid a crisis, on-chain transactions surge, competition for block space intensifies, and to get its transaction on-chain in time a liquidator must keep raising its bid in the priority-fee auction, so gas cost soars and may even exceed the profit of the liquidation itself. On the other end is loss-absorbing capacity: the liquidated collateral must be sellable to realize the discount, and in a crisis market depth precisely evaporates, so a liquidator, even given the chance to dispose of a position, may still show a negative return after selling. With both ends contracting at once, the difference that should have been positive turns negative, so liquidators rationally choose not to participate, and liquidation, at the moment

it is most needed, sees its executors exit.

This cost-benefit relationship has a sharper dynamic, manifesting as a dynamic change on the gas-cost side. The allocation of on-chain block space is itself an auction ordered by priority-fee bids: whoever is willing to pay a higher priority fee for its transaction gets packed first. In calm times this auction is lightly congested, and a liquidator can get on-chain by paying a negligible priority fee; but once a crisis descends and a mass of transactions contests the same batch of scarce block space, priority fees are bid up in competition, and a liquidator, to complete liquidation before the collateral depreciates further, often has to join this bidding up. So the gas cost of a liquidation is not an exogenous constant but a variable that rises endogenously with the degree of congestion: the heavier the congestion, the higher the cost of sending liquidation on-chain, and this occurs at the moment when liquidation most needs to complete quickly. When the priority fee is bid above the height of the liquidation discount, a rational liquidator stops participating—not because it cannot find positions to liquidate but because, on the calculation, it is unprofitable. Congestion and unprofitability here stack into a positive feedback: the deeper the crisis, the more expensive gas and the thinner loss-absorbing capacity, the more unprofitable liquidation, the fewer liquidators willing to execute it, the more unhandled bad positions accumulate, further intensifying the crisis. Liquidators' collective cessation of participation is, in essence, an executor exit that is unorganized yet triggered simultaneously by the same economic calculus.

This is not a theoretical worry but a repeatedly observed fact. In the sharp decline of May 2021, on-chain congestion and soaring gas costs caused some liquidations to fail to execute in time; the liquidation itself was profitable, but the on-chain transaction required to execute it either could not squeeze into a block amid congestion or had its gas cost offset the liquidation profit [51]. In November 2022, a CRV lending position on Aave could not be effectively disposed of by liquidators for a long time amid a targeted market manipulation, ultimately leaving bad debt in that market [52]; liquidators did not fail to exist: rather, when liquidation was unprofitable under such price and liquidity conditions, or when on-chain congestion made it impossible to fill, they rationally chose not to participate. Qin et al. give a systematic empirical characterization of the phenomenon of congestion causing liquidation failures, elevating the fragility whereby liquidation's execution depends on a market condition that may fail precisely in a crisis from an individual case to a measurable general regularity [51]. These two cases sit at the two ends of a spectrum (at one end, gas congestion making a profitable liquidation unexecutable; at the other, market conditions making an executable liquidation unprofitable), and both point to the same structural weakness: the occurrence of liquidation hinges on a condition that is least reliable in a crisis.

This is the structural gap of market incentives substituting for regulatory compulsion. Regulation can command a clearing member to perform, whether or not performance is favorable to it at that moment; whereas a market can attract liquidators only when it is profitable and finds no response when it is not. The divide between mandated performance and incentive-based performance lies here: the former treats executing liquidation as a non-refusable obligation, so a member must perform even at a loss, growing more rigid in a crisis; the latter sets it as an activity one may freely choose whether to join, so a liquidator may exit when it is unprofitable, and the execution

constraint tends to weaken in a crisis, exactly when it most needs to remain rigid. This gap is not the misconfiguration of some incentive parameter but an intrinsic property of the very choice to substitute incentives for compulsion: so long as the occurrence of liquidation depends on whether it pays at that moment, there is always an extreme moment of negative return that makes all carefully designed degradation mechanisms collectively lose their executors. A clearinghouse system that substitutes incentives for commands finds all its capacity for orderly degradation (isolation, auction, or soft liquidation alike) ultimately constrained by the same condition: whether its incentives still hold at the worst moment. And this assumption, whose core is *executors willing to participate at that moment*, is least reliable precisely when it most needs to hold. Orderly degradation thereby reveals its own boundary; this boundary can no longer be resolved by improving degradation mechanisms but must be answered head-on: when the system's stability depends on market incentives, and market incentives reverse in a crisis, what mechanism can this clearinghouse system still rely on? This is precisely the question the next section answers.

29.4 The boundary of market incentives and the constraint of residual discretion

The previous section ended on a gap. At the extreme moment when liquidation is most needed, liquidators may be collectively absent because it is unprofitable, and a clearinghouse system that substitutes incentives for commands finds its capacity for orderly degradation ultimately constrained by whether its incentives still hold at the worst moment. This gap is not an engineering defect that can be resolved by improving code but a boundary problem about what code can and cannot do. It leads to the last seam of this chapter: in a clearinghouse system that runs on deterministic code, there is a seam between the deterministic code and the human discretion that can never be replaced by code no matter what. What this section does is define the exact location of this seam: how far market incentives can reach, from where discretion becomes ineliminable, and how the ineliminable portion of discretion should be constrained to the minimum.

This seam is the hardest of the chapter because it cannot, like the first two, be narrowed by adding a layer of equity buffer or switching to a different auction mechanism. It asks not how to improve the system itself but who fills, and in what way, the remainder once the system's capacity ends. To answer it, one must first understand the first mechanistic premise on which a decentralized clearinghouse operates, then identify the boundary of this mechanistic premise, and finally explain how the scope borne by human discretion beyond that boundary should be compressed and constrained.

29.4.1 Market incentives as a substitute for regulatory compulsion

The first mechanistic premise on which a decentralized clearinghouse operates is the substitution of market incentives for regulatory compulsion. This mechanistic premise is the root-level divide between it and a traditional central counterparty, and to understand it one must start from two utterly different logics of mobilization.

In a traditional central-counterparty system, what makes clearing members fund the default fund and serve as loss-absorbing capacity in a crisis is, in the end, an obligation-based logic. For an institution to obtain clearing membership, it must, according to the rules, contribute its share of the default fund, must satisfy continuous capital and margin requirements, and must take on disposed positions in default-management auctions; these are not choices of whether it is willing but compulsory obligations attached to membership itself, backed by the clearinghouse's membership rules and the regulator's prudential requirements applying pressure jointly (Section 5.3.4) [2]. In comparing the two kinds of default waterfall, this book has already pointed out the strictest facet of this compulsory force: a traditional clearinghouse not only prefunds the default fund but also holds the power to levy statutory additional assessments on members, whereas on-chain protocols' insurance funds generally lack such a compulsory replenishment mechanism (Section 5.4.5, Table 5-2). A central counterparty can therefore, at the moment it most needs resources, conscript directly from a body of rule-bound members; it is this conscriptability that constitutes the reliability source of the mutualized capital in the waterfall's upper layers. That the negative externality of externalizing losses onto the system can be internalized also relies not entirely on participants' goodwill but first on this compulsory institutional arrangement operating as a constraint in the background (Section 12.1.3).

A decentralized clearinghouse has no membership rules that can issue compulsory directives, nor a regulator that can compel performance. What it can rely on is only another logic—mobilization based on self-interest. Liquidity providers voluntarily deposit funds into the liquidation vault because the returns from market making and absorbing liquidations are enough to compensate the risk they bear; liquidators voluntarily execute liquidations because the liquidation discount is profitable to them; arbitrageurs voluntarily close the divergence between the mark price and the spot price because the spread is itself a profit. No link is commanded; the operation of the entire system is built on a complex assumption: that each rational, self-interested participant, in pursuing its own return, happens to take exactly the action the system's stability requires. The clearinghouse commands no one but instead designs a set of payoffs so that dispersed, mutually distrusting participants, who bear no institutional obligation to the system, keep the system running out of self-interest alone. This book's default-waterfall comparison table compresses this divide into the two columns of ultimate loss absorption and liquidation execution: the ultimate backstop in the traditional system is the settlement member bound by statutory obligation, whereas the backstop in the on-chain system is external arbitrageurs and protocol liquidators, relying on the market force of the liquidation discount rather than any directive (Section 5.4.5, Table 5-2).

This substitution has a clear institutional appeal. It requires no trust in any specific actor—no single member constitutes an indispensable pillar of the system's stability, and if any one liquidator exits, another is attracted by the same discount; it also requires no one to obtain permission—becoming a liquidator or liquidity provider needs no qualification review, only an address and a sum of capital. In the language of mechanism design, this system pursues incentive compatibility: designing the rules so that a participant's dominant strategy happens to equal the behavior the system desires, so that the compatibility of incentives itself becomes the enforcement mechanism, with

no need to layer compulsion on top of incentives (Section 12.5.1) [53]. What Chapter 12 pointed out in evaluating Hyperliquid's liquidation vault is the full embodiment of this logic: liquidation profits accrue to liquidity providers, the vault's annualized return becomes directly the market's dynamic pricing of liquidation risk, and risk management thereby turns from the platform's burden into the community's opportunity (Section 12.6.1) [8]. This is also a mirror image of the governance that incomplete-contract theory reveals: since one cannot rely on a complete contract to exhaust and compel all due obligations, one settles for the next best and hands the remaining coordination to appropriately designed property rights and payoffs, letting the parties spontaneously execute, for their own interest, the behavior conforming to the system's goals (Section 12.4.4) [54]. In this sense, a decentralized clearinghouse system is less a law-enforcement system than an incentive structure: it does not stipulate what participants must do; it only ensures that when participants act in their own interest, what they do happens to be what the system needs.

The difference between these two logics is deeper than the literal opposition of compulsion and voluntariness. The obligation-based logic is, in essence, a governance relying on supervision and punishment; it presupposes an authority able to observe whether members perform and to impose sanctions when they default, and the very existence of this authority is an expensive apparatus that must be continuously sustained by capital, law, and institutions. The self-interest-based logic tries to move governance's cost forward to the design stage of the mechanism: once the payoff structure is tuned so that self-interest coincides with the system's goals, there is no longer any need, in real time, for a supervisor watching every participant at every moment, because no one has an incentive to do what the system does not want. This is precisely the ambition of the discipline of mechanism design: to induce, with rules designed ex ante, the behavior that would otherwise require ex post compulsion (Section 12.5.1) [53]. A decentralized clearinghouse pushes this ambition to an extreme that traditional institutions dare not reach: it simply abolishes the supervisory authority and stakes its entire mechanistic premise on the proposition that payoffs alone suffice to substitute for supervision. When the payoffs are sufficient, this is an institutional substitution attractive on a cost-benefit basis, replacing an entire regulatory system requiring trust and continuous maintenance with a payoff rule anyone can recompute. But this institutional substitution harbors an unavoidable point of fragility: the value of a supervisory authority lies in its not depending on whether the supervised still deems performance favorable at this moment; whereas pure payoff incentives stake the system's reliability on whether participants still find it worthwhile at this moment: a condition that varies with market state.

Replacing the obligation-based logic with the self-interest-based logic is a genuine transfer of institutional burden; it removes the entire membership-and-regulation framework on which a central counterparty relies to operate, in exchange for permissionlessness and trustlessness. But this replacement is not without cost. Encapsulated in the removed framework was a compulsory force still effective at the moment of crisis; once it is replaced by voluntary incentives, a hidden problem is inherited along with it: does that coincidence of self-interest and stability hold at all moments?

29.4.2 Procyclicality and predictability attacks

The boundary of market incentives shows itself most clearly precisely at the moment the system most needs them. The first proposition this section advances is: the coincidence of self-interest and stability is a procyclical assumption, holding in calm times and reversing in a crisis.

The fragility of this assumption was seen from one side in the previous section: liquidators rationally exit at the moment liquidation is most needed, because it is unprofitable or the chain is congested (Section 29.3) [51]. But it is not only liquidators who exit. Applying the same logic to the liquidity providers of the liquidation vault yields a stricter conclusion. A liquidity provider keeps funds in the vault to absorb liquidations because, under normal conditions, market-making returns compensate the tail risk it bears; but when volatility suddenly widens, when the mark price begins to jump violently, when successive liquidations are queued waiting to be absorbed, it faces not a business with a fitting risk premium but an exposure that may cause principal loss. A rational liquidity provider withdraws capital at this moment, which is precisely the moment the system most needs loss-absorbing capacity. The incentive has not failed here; it operates fully according to the logic of rational self-interest: it is the correct operation of the incentive that makes the capital meant to serve as a buffer withdraw liquidity at the moment the buffer is most needed. The preceding text already characterized this procyclical resonance of confidence and liquidity: from no one caring to everyone panicking, with almost no smooth transition zone in between (Section 12.3). The first cost of substituting market incentives for regulatory compulsion manifests here: it exchanges a resource that could be conscripted in a crisis for a resource that tends to exit in a crisis. The deeper meaning of the missing shock absorbers the Bank for International Settlements pointed out in assessing decentralized finance lies here: on-chain systems not only lack the central bank's liquidity window but also lack even those private actors that regulation requires to quote and absorb continuously in a crisis, leaving only voluntary capital that can exit as market conditions change (Section 29.3) [3].

The second proposition this section advances is more subtle: the very determinism of a purely algorithmic clearinghouse constitutes an attack surface. A central counterparty's default management is hard to exploit precisely because its critical moments contain discretionary factors; a regulator and market makers can, with unpredictable on-the-spot judgment, add a layer of uncertainty for anyone seeking to profit by exploiting the system's rules. A decentralized clearinghouse adopts the opposite design: all its rules are transparently encoded on-chain, and its reaction to every state is wholly determined and wholly deducible. This determinism is its institutional advantage: anyone can verify in advance how the system will treat them. But the same determinism is also its weakness: anyone can also compute in advance how much it costs to force the system into a particular state, and how much value can be extracted from the system's deterministic reaction in that state (Section 12.4.1). When a system's output for every input can be precisely predicted, it can not only be used but also strategically exploited. An attacker can pre-position ahead of a liquidation or auto-deleveraging that can be algorithmically triggered, letting the system's deterministic action, when pushed into that state, transfer value into the attacker's control. Many of the liquidation cascades and oracle manipulations dissected in Chapters 11 and 14 bear this structure of exploit-

ing predictability: the attacker need not breach any defensive rule; it need only know where and in what manner the defensive rule will trigger, and then exploit the subsequent state transition. The 2022 manipulation of a CRV lending position on Aave is an empirical instance of this structure: the attacker calculated exactly how the system's liquidation rules would react and turned the predictable liquidation logic into an attack parameter (Section 29.3) [52].

This reverse-exploited predictability has a name more general than *attack surface*; Goodhart's law, the Lucas critique, and protective opacity, all introduced next, are different facets of this same phenomenon of determinism being reverse-exploited. When a defensive rule is transparently made public, it turns from a mere rule into the objective function of the attacker's optimization, and the attacker adjusts its strategy precisely against the letter of this rule, making the rule fail exactly where it should most take effect. In analyzing why Hyperliquid's successive ex post patches were always circumvented, Chapter 12 used Goodhart's law and the Lucas critique to make just this point: once a metric is treated as a control target and made public, it ceases to be a reliable metric; defenses formulated on the basis of historical attack patterns fail because of attackers' expectations of those defenses (Section 12.6) [41][55][56]. This explains why a purely algorithmic clearinghouse sits in a loop it can hardly break by itself: its legitimacy requires transparent rules, and the transparency of the rules in turn turns every rule into a target that can be attacked; the more it explains itself clearly, the more fully it exposes its own reaction function. A central counterparty is not as deeply caught in this loop because it retains opacity at the critical points: what regulators and market makers can and cannot do at the moment of crisis is itself a variable the attacker cannot solve in advance. A decentralized clearinghouse, exchanging transparency for verifiability, also gives up this layer of protective opacity: not the oversight of some protocol but the necessary result of the fundamental promise that rules are executed as code and verifiable by all.

These two propositions point to the same deeper judgment: predictability is both the institutional foundation of a decentralized clearinghouse and its fundamental weakness, and this dilemma cannot be escaped by further refining the rules. Writing the rules in finer detail only describes the exploitable states more clearly; raising the incentives higher only briefly delays failure in the face of procyclical capital withdrawal. Market incentives are therefore not a force that can be relied upon unconditionally; they are powerful when marginally favorable but may fail collectively in a systemic crisis, and may even be reverse-exploited because of their own transparency and determinism. Frontier protocols already have direct experience of this: every round of ex post patching against a known attack vector is circumvented by adaptive attackers onto a new attack surface, and this cycle of attack, patch, and new attack is the manifestation of transparently published defensive rules failing in the game (Section 12.6) [41]. Acknowledging this boundary is not to concede the failure of a decentralized clearinghouse but to confirm that its range of capability has a clear boundary. Beyond that boundary lies a class of situations more fundamental than either procyclicality or predictability.

29.4.3 Incomplete contracts and the guarantor of last resort

Beyond the range market incentives can reach lies a most fundamental class of moments: states for which the contract has simply provided no rule. The previous two sections discussed incentives being at some moments not strong enough, or being reverse-exploited; this section discusses another class of problem—that at some moments there is simply no rule to follow.

Economics settled this long ago: contracts are incomplete. Because of bounded rationality and the unpredictability of the future, contracting parties cannot foresee and write down ex ante every future state; there are always situations the rule-drafter never envisioned and therefore never provided for (Section 12.4.4) [54]. Smart contracts push this theorem to the extreme. Called a contract, it is in fact a piece of code deployed on-chain; developers can set parameters only on the basis of their cognizance of the past and their anticipation of a limited set of scenarios, and cannot enumerate every manipulation technique, attack vector, and extreme tail event. When a situation never covered by the code truly descends, the code has no capacity for autonomous judgment: it either executes mechanically by the letter, yielding a result inappropriate or even destructive in that situation, or simply has no corresponding branch to run. The key concept incomplete-contract theory provides for this predicament is residual control rights: the power to decide in situations the contract has not provided for, which must fall to some person or institution (Section 12.4.4) [54][57]. The question is never whether states the contract has not provided for exist, for that is inevitable; the question is who exercises this residual control right when such a state arises.

The bearer a decentralized clearinghouse assigns this residual control right, Chapter 12 calls the guarantor of last resort. It is the role authorized to suspend, change parameters, or even roll back when the system falls into a state the code cannot handle; in a central counterparty this role is played by the clearinghouse operator and the regulator, while in a decentralized system it may fall to a core team holding multisignature authority or to a group of validators (Section 12.4.2). The very existence of this role is a sharp paradox: a system premised on trustlessness and rule-as-code execution must, at the most critical juncture, once again rely on a set of actors' on-the-spot discretion, and once discretion is introduced, the removed trust assumption is reintroduced in implicit form. But precisely because the incompleteness of contracts is structural and ineliminable, this paradox cannot be avoided by further raising mechanism strictness: any system claiming to need no guarantor of last resort at all does not truly not need one but converts that moment with no rule to follow into a systemic failure in the absence of a rule.

This is why the seam of incentives is the hardest of the chapter's four seams. The first two seams, the depth of the waterfall and the tempo of degradation, hard as they are, are after all engineering problems: they can be narrowed by adding a layer of equity buffer or switching to a different auction. This one is not an engineering problem but a problem about power, and it therefore leads a decentralized clearinghouse into its most intractable dilemma. On one hand, if the guarantor of last resort's discretion is too weak, too late, the system will be dismantled in an orderly way by attackers at that moment with no rule to follow, and the insistence on full automation may lead

to systemic failure; on the other hand, if this discretion is too strong, too frequent, it will gradually turn into the very center it was meant to replace, and more dangerously, it will, in the name of protecting the system, carry out selective bailouts. Chapter 12 has explained this layer of danger: when the blow-up of some large account may trigger a chain of liquidations, the guarantor of last resort's participation in trade intervention to protect the insurance fund is, for that large account, a de facto bailout, and for the other participants who acted by the rules, markedly unfair; the too-big-to-fail problem of traditional finance thus reappears on-chain through the emergency-discretion mechanism (Section 12.4.2). A discretion that must be both strong enough to complete crisis handling in extreme stress scenarios and weak enough not to be used for self-dealing or favoritism cannot be obtained by writing the code better; it can only be obtained by designing the shape of this discretion, ex ante, into a particular form. This turns the problem from *whether there should be a guarantor of last resort* into *within what institutional framework of constraint this indispensable and high-risk role should be placed*.

The JELLY incident is an empirical marker of exactly such a moment. When a manipulation of a low-liquidity token pushed the system into a state for which its code had no ready rule to follow, the code could give no answer. In that state, the liquidation vault was forced to catch a position it should not have borne; the oracle faithfully reported the very real market price that had been contaminated by manipulation; and the auto-deleveraging mechanism, which should have absorbed the tail loss, was not triggered, because the liquidation vault had not yet been isolated from the main vault and the denominator of its trigger threshold was computed as the vault's entire enormous assets (Section 12.6). Hyperliquid's ultimate handling was therefore not the execution of any prewritten rule but a discretion unconstrained by preset rules: the validators voted collectively, disregarded the real price the oracle reported, overwrote the market's settlement price to the level before the manipulation, and forcibly closed all related positions on that basis (Section 12.6) [41]. The several mechanisms necessary to hand loss absorption back to the market (asset isolation between the liquidation vault and the main vault, an independent deleveraging trigger threshold, dynamic position caps that adjust with market cap and depth, and the validators' power to delist anomalous assets by on-chain vote) were all filled in only after JELLY (Section 12.6). This ex post filling is itself the most direct acknowledgment that, at the moment of the event, the contract was incomplete: every rule filled in afterward is a retroactive recognition that at the time there was no rule to follow. What it simultaneously exposes is the limit of such ex post rule revision: the later POPCAT incident proved that targeted revision against the previous attack vector cannot prevent an adaptive attacker from finding the next gap (Section 12.6) [41]. This corroborates, from the reverse, the ineliminability of incomplete contracts: the system can make rules for accidents that have already occurred but can never make rules for accidents not yet conceived.

This is the boundary spoken of in the opening, and it can now be stated more precisely: no matter how complex the market incentives are designed, no matter how meticulously the code is written, they cannot cross the boundary of states the contract has not provided for; beyond that threshold, some residual control right must be exercised by a human. Acknowledging this, the ideal architecture no longer faces the question

of *whether discretion can be eliminated* (a foregone absence) but a truly engineerable question: since discretion cannot be eliminated, how can it be constrained to the minimum?

29.4.4 The three constraints on residual discretion

The ideal architecture's handling of this boundary is not to eliminate discretion but to constrain the ineliminable discretion to the minimum. The first proposition this section advances is: acknowledging that discretion cannot be eliminated is by no means the same as providing justification for arbitrary human intervention.

The distance between these two is precisely where the entire value of a decentralized clearinghouse lies. If, on the grounds that discretion cannot be eliminated, broad on-the-spot disposal power were routinely handed back to a center, then this system would regress into the very opaque centralized mechanism it was meant to replace; since the critical moments would still be adjudicated by human actors, the determinism recomputable by any node and the commitment requiring trust in no specific actor would both have only formal significance (Section 29.1). Therefore, acknowledging the ineliminability of discretion must immediately be caught by a constraint in the opposite direction: first, bisect the system's state space. In the large class of states the contract can provide for in advance (normal-condition clearing and settlement, liquidations with clear health, default handling with clear parameters), discretion is not only superfluous but harmful; these states should rely wholly on deterministic code, leaving no room whatsoever for human intervention, because any flexibility here only weakens determinism. Only in the small class of states the contract truly cannot provide for in advance is discretion permitted to intervene. This is the spirit of the two-layer architecture Chapter 12 derived from incomplete contracts: strictly adhere to code day to day, and authorize intervention only in a crisis (Section 12.4.4); and this section, on the basis of this principle, further asks what shape the permitted discretion itself should be given.

The second proposition this section advances is this structure's three constraints: for that portion of residual discretion, the design goal is to make it simultaneously narrow, slow, and visible. First, narrow means that the authorization of discretion is strictly confined within a specific scope and situation; the power the intervenor may exercise is only enough to handle that concrete, contract-unaddressed state, and cannot, under the name of one emergency authorization, do anything outside the authorized scope. An authorization to force settlement of an affected market when the oracle is manipulated is by no means the same as an authorization to rewrite any price at any moment one deems an emergency; the difference between the two is the difference between constrained discretion and unconstrained power. Second, slow means that, except for explicitly defined emergency situations, the exercise of discretion must pass through a timelock constraint that makes it impossible to execute instantaneously and unilaterally: after a decision is made and before it takes effect, a compulsory waiting period is left, giving dissenting participants time to exercise the exit option and withdraw funds, and giving a decision made in haste or under coercion a window to be corrected; and the emergency channel reserved for speed must itself have clear boundaries and an obli-

gation of ex post ratification, and cannot become an unconstrained path that bypasses all constraints (Section 12.4.6). Third, visible means that every exercise of discretion occurs on-chain and can be audited by any node—that is, who did what, when, under what authorization, and on what basis, all leave an undeniable record. Visibility is the natural extension, at the governance level, of the *verification by all* stated in Section 29.1: the discretion over adjudication may be concentrated in a few, but the verification of those few's discretion must be open to all (Section 29.1). The single point of adjudicative authority and the verification by all constrain, under normal conditions, the execution of code; in extreme states they should constrain human discretion.

What each of these three constraints prevents is a different path of discretion running out of control, and none can be omitted. What narrow prevents is the spread of authorization; history repeatedly shows that a power set up to address a particular crisis is all too easily invoked next time to handle situations it should not touch, until that emergency power set up as an exception becomes a routine instrument of rule; slicing the authorization narrow amounts to bounding, ex ante, the upper limit of harm in the worst case, so that even if the intervenor tries to overstep, the range of harm it can cause is limited. What slow prevents is haste and coercion; decisions in a crisis are often made in the few minutes when information is least sufficient and pressure greatest, and a compulsory waiting period gives the market both a right of exit to exercise the exit option and gives the decision itself a chance to be reviewed and overturned, turning an unreviewable unilateral decision into a correctable process. What visible prevents is ex post denial and non-transparent decision-making; if the basis and process of a discretionary act are not fully recorded on-chain, then whether it was to save the system or to shield some private interest can never be distinguished from outside; visibility constrains discretion from being explained however one likes ex post to leaving an immediate trace, so that every intervention must be prepared to accept everyone's review. There is an ordering of priority among the three: narrow constrains the scope of authorization, while slow and visible constrain the procedure of exercising power; an authorization that is sufficiently narrow, even if slow and visible are as yet imperfect, has already had the maximum harm it can cause bounded, whereas an authorization that is too broad, however strict the procedure, merely equips a power that should never have been granted with a set of procedural constraints.

Placing these three constraints on the governance spectrum Chapter 12 sketched, one can identify what exactly the ideal architecture fills. Chapter 12 arranged governance from the wholly opaque G0 to the fully-on-chain-governance-plus-timelock-constraint G3, of which the most mature, G3, with on-chain voting and timelocks, happens to cover the slow and visible spoken of here—it makes discretion slow down and be publicly disclosed (Section 12.4.6). But that spectrum measures transparency, degree of decentralization, and procedural constraint on the exercise of discretion; it answers how slow and how public discretion should be but does not answer how narrow discretion should be. A system reaching G3 may well be procedurally impeccable (every intervention voted on, passed through the timelock, recorded on-chain), yet the scope of authorization broad enough to let the intervenor do almost anything at that moment. Slow and visible constrain the procedure of exercising discretion; narrow constrains the scope of authorization discretion can reach. Narrow is therefore a dimension the

ideal architecture needs to fill beyond G3; it is not the procedural packaging of a broad power but a limitation of the scope of the power itself at the source. A narrow authorization, even with crude procedure, is closer to the ideal than a broad authorization equipped with ever-more-complete voting and timelocks, because the former bounds, at the source, the maximum harm the worst case may cause.

The three constraints of narrow, slow, and visible together give an evaluation standard by which any residual discretion can be measured. What they constrain is not whether a particular intervention is right or wrong but the boundary and exercise conditions of the very power the intervenor holds; a power whose scope is sufficiently limited, whose execution is sufficiently delayed, and whose disclosure is sufficiently full, even if occasionally misused, has its destructiveness bounded by a structural upper limit. This evaluation standard simultaneously redefines what a qualified decentralized clearinghouse means: the mark of qualification is not that it never needs humans but that, when it cannot but need a human, the harm that actor may cause has already been bounded, ex ante, to something sufficiently small.

29.4.5 The JELLY incident and the boundary of the purely algorithmic clearinghouse

Taking the above standard as the analytical baseline and returning to the JELLY incident, its significance divides into two levels. As an event, it is a failure—a failure in which the system was pushed into a state with no rule to follow and had to rely on a group of actors' on-the-spot vote to rescue itself. But as a marker, it indicates where the boundary of the purely algorithmic clearinghouse lies, and this is the last and most important proposition of this section: the boundary lies not in whether discretion is needed but in whether the discretion is constrained narrowly, slowly, and visibly enough.

Measuring JELLY's handling at the time against these three constraints reveals shortfalls in several places. It was not narrow enough: what the validators exercised was a power broad enough to overturn the oracle price and forcibly rewrite the settlement price, not an authorization only enough to handle that specific manipulation state. It was not slow enough: the resolution was reached in an extremely short time with zero opposition (Section 12.6), leaving no time window for dissenters to exit or for a hasty decision to be corrected, and the fast track that should apply only to genuine emergencies was here almost the only track (Section 12.6). Its visibility, too, held only in part: the execution result and on-chain state transition can be tracked, but the decision rationale, the boundary of authorization, the assessment of alternatives, and ex post accountability records were not made public ex ante in an equally full way, and *act first, explain later* replaced *disclose the basis first, then act* (Section 12.6). Add to this that outside auditable information on validator independence and the distribution of governance power was limited, so that a so-called unanimous vote is not by itself sufficient to equate automatically with a sufficiently decentralized governance consensus (Section 12.6) [41], and this discretion fell far short on all three constraints of narrow, slow, and governance visibility. Placing JELLY on the evaluation standard, what it shows is not that the chain should have no discretion but that this discretion was constrained too

loosely.

This is precisely the value of JELLY as a boundary marker: it does not prove that a decentralized clearinghouse is unworkable but marks the conditions under which it works. A misreading would say JELLY proves a purely algorithmic system ultimately needs centralized governance; the reading this section gives is the opposite: JELLY proves that the existence of residual discretion is unavoidable, but the degree to which it is constrained can range from loose to strict, and the quality of a clearinghouse system depends on this degree of constraint. Following this reading, the ideal decentralized clearinghouse should not be imagined as a system that never needs human discretion (a fantasy even incomplete contracts cannot honor); it should be imagined as another institutional arrangement: needing no one most of the time, because the states the contract can provide for are all handed to deterministic code; and in the very few moments when a human is indispensable, that human actor's power is sliced narrow enough, executed with delay enough, and disclosed fully enough that, even given private motives, it can cause only limited harm. The former constitutes the mode of normal operation, the latter the governance arrangement in the boundary state; normal conditions rely on code, boundary states on the constraint of discretion.

Thus the ideal decentralized clearinghouse sits between two attractive but untenable idealized models, negating both. It negates the idealized model of the opaque centralized mechanism, the basis of trust that there is always a sufficiently capable and trustworthy operator to make the right decision for participants at the critical moment, which the earlier parts of this book have repeatedly proved costly through successive failures (Chapter 12). It also negates the idealized model of the purely algorithmic, the full automation that supposes no human need ever intervene so long as the code is written completely enough, which is negated by the law of incomplete contracts: the blank of a contract is not a temporary gap left by insufficiently good current technology but the eternal predicament of any written rule facing an unknown future. The normative goal lies at neither end but in a constrained middle state: hand the states that code can handle to code as much as possible, shrink as much as possible the range of states that code cannot handle and that human actors must take over, and strictly constrain this minimized range with the three constraints of narrow, slow, and visible. This ideal promises neither an omniscient governance actor nor an omnipotent automation system; it requires only that, where reliance on human actors is unavoidable, the harm human discretion may cause be limited to the minimum. It does not pretend the boundary does not exist but places the entire center of gravity of governance on how to govern that boundary.

From this, JELLY also provides a standard for evaluating any real system. Facing a clearinghouse system that calls itself decentralized, the question to raise is no longer the binary one of whether human actors are still needed to intervene, for the answer to that is already fixed as yes; what should be attended to are three questions that can be answered by degree: how many states has it truly handed to code rather than left to discretion? How narrowly is its discretion sliced, how slowly released, how fully disclosed? When it cannot but invoke this residual discretion, where is the worst case bounded ex ante? Standardizing these three questions and using them to evaluate item by item the most frontier systems today, identifying the precise gap between ideal and

reality, is exactly what the next section does.

By this point, the chapter's four seams have each been made clear. The seam of depth is concerned with whose equity bears shortfall losses first; the seam of degradation is concerned with how extreme shocks are isolated and slowed; and the seam of incentives asks how small the scope of that residual power is bounded, and how strong the constraint, when incentives reach their boundary and discretion is unavoidable. Combining this fourth standard—that residual discretion must be narrow, slow, and visible—with the other standards distilled in the preceding three sections, we form a checklist that can be used to measure any real system. The value of a checklist lies not in stating an ideal but in using it to evaluate real systems and identify gaps. This is precisely the task of the final section.

29.5 The ideal-architecture checklist and the Hyperliquid gap audit

Folding the previous section's closing standard on the boundary of discretion into the checklist completes the distillation of the first four sections. Along the four seams, this chapter has each derived a normative principle that an ideal decentralized clearinghouse should satisfy. What remains is to organize these four principles into a reusable evaluation standard and then use it to measure how far the most frontier systems today are from the ideal. This section is therefore both the conclusion of the whole chapter and the transition to the next. It fixes the proposition "what the ideal architecture should look like," unfolded in the preceding text through continuous argument, into a checklist that can be verified item by item, and uses this checklist to conduct an honest and restrained gap audit.

29.5.1 Four normative principles

To distill the first four sections into a checklist, one must first recognize that these four sections are in substance answering four progressively deepening questions, not four mutually isolated ones. They arrange themselves along the same system from external structure to internal incentive: first asking whether this system has been correctly integrated into a whole, then asking whether its depth is sufficient once it begins to absorb losses, then asking whether it can degrade in an orderly way when losses grow too large for the depth to fully absorb, and finally asking where the incentives driving the whole system fail and who takes over after they fail. The four principles are the passing lines of these four questions respectively. The reason for establishing them as principles rather than preferences is exactly this: what each guards is the critical point past which the system, once it fails, degrades along a certain determinate path, so they are necessary conditions, not optional optimizations.

The integrity of the overall architecture is the foundation of all this. The criterion Section 29.1 established is that a decentralized clearinghouse system must be a single, deterministic state machine: clearing, settlement, and the default branch are not three subsystems that can each go their own way but different stages on the same uninterruptible chain of state transitions, where the output of any stage is the determinate

input of the next. The key significance of this principle lies not in determinism itself (a traditional central counterparty's clearing module is likewise deterministic) but in the requirement, unique to decentralization, layered on top of determinism: the discretion over adjudication may be concentrated in a single module, but the verification of every step of this computation module's output must be open to all, so that any node can independently recompute the same books and obtain a bit-for-bit identical result (Sections 28.4.3 and 28.6.2). Once this boundary is breached, the path of degradation is determinate. If adjudication is no longer single-point but split into several separately settling subsystems, the same default may be recorded as inconsistent books on different branches, and default handling degrades from an executable state transition into a set of ex post disputes hard to resolve consistently. If verification is no longer possible for all, external participants can only trust the operator's self-reported results, and the system regresses into an opaque centralized mechanism that happens to be deployed on-chain, losing not performance but the sole credential by which it is called decentralized. The passing line of overall architectural integrity therefore has two halves: one half is the single-point determinism of adjudication, the other the verification-by-all of that determinism; lacking either half, the system no longer has identity. This principle also contains an often-overlooked sub-item, namely whether the system has identified and reinforced its own most fragile seam (Sections 29.1.6 and 28.8.1). Its missing state is likewise determinate: so long as one seam remains unreinforced, what the attacker must do is not to breach the sturdiest module but to head straight for that seam and let the entire system fail as a whole at a link for which no one is clearly responsible.

On this foundation, depth measures how many layers of buffer the default waterfall still sets before losses are allocated to non-defaulting parties. Section 29.2 decomposed the depth of the traditional waterfall into two layers generally absent on-chain. One is a first-loss tranche composed of some party's own equity and positioned ahead of any member or user (skin in the game), whose significance lies not in size but in position; the other is prefunded mutualization in place before the crisis, jointly funded by the parties and dedicated to absorbing the spillover of a single member's default. These two layers are precisely the source of a traditional central counterparty waterfall's depth: the classic hierarchy arranges the defaulter's margin, the central counterparty's own capital, and the members' joint default fund in order ([2]), and empirically the defaulter's own resources make up the overwhelming share, while the own-capital tranche, though small, occupies the key position ahead of member mutualization (Section 5.2.3, [13]). The missing state of each of these two layers exposes why they are necessary conditions rather than decorations. Once the first-loss layer is absent, the designer is no longer bound to the system's safety: the designer can raise leverage and relax listing standards, because the cost of these aggressive parameter choices is borne mainly by users rather than by the designer, so risk appetite shifts systematically in a direction favorable to the designer and unfavorable to users: what the first-loss layer truly constrains is the designer's own risk appetite. Once prefunded mutualization is absent, the system, facing the spillover of a single member's default, has only two equally unfavorable handling paths left: either draw on the profitable positions that ought not to bear loss to make up the shortfall, forcibly spreading an individual default onto the non-defaulting majority; or let the bad debt sit on the books, with the protocol itself

continuously bearing the loss. The former harms fairness, the latter harms solvency, and the significance of prefunded mutualization is precisely to form this common fund in advance, before the crisis, so that the system need not, at that moment, choose between these two unfavorable handling paths. The passing line of this principle is that, before reaching the last resort of forced socialization onto the profitable side, the waterfall must first pass through these two layers, rather than turning directly from a public pool passively accumulated from fees to auto-deleveraging. The conclusion Section 29.2 reached is that, as of the main on-chain systems examined here on June 25, 2026, these two layers have not yet been truly filled; what is lacking is not imagination in mechanism but the political-economy willingness of *what kind of actor's equity is willing to bear the first loss*; whether this willingness can be institutionally induced has spilled beyond the boundary of risk engineering and points to the rule governance of Chapter 30.

Beyond depth, orderly degradation handles the disposal problem after depth is breached. Section 29.3's premise is a fact repeatedly established throughout the book: on-chain systems have no lender of last resort and therefore cannot assume any external liquidity rescue. Layered on the structural constraint that full loss coverage is no longer attainable (Section 12.2.3, [12]), the system's design goal must be rewritten from *avoiding failure* to *failing in a controlled way in the worst case*. The passing line of this principle is composed of two mutually independent yet complementary means: risk-pool isolation, confining a single market's bad debt within that market's pool and severing inter-market contagion; and active shock management, remaking the price impact liquidation imposes on the market from a passively suffered consequence into an actively adjustable design variable (Dutch descending-price auction, continuous soft liquidation, or partial liquidation), replacing the kind of concentrated sell-off, critical-point liquidation that easily invites zero bids. The missing state of each of these two means likewise points to a determinate form of disaster. If isolation is absent, a single edge market's bad debt spreads along the shared capital layer to all markets, amplifying an event that could have been locally absorbed into a system-wide solvency crisis. If active shock management is absent, liquidation regresses into a critical-point one-time sell-off: large collateral is concentrated-sold when buyer liquidity is insufficient, the price is broken further by the liquidation behavior itself, inviting zero bids, and liquidation, far from recovering value, further widens the shortfall and transmits it out through chain liquidations. The qualification of orderly degradation is not that the system never loses but that the system has prepared in advance for the worst case and clearly knows what each preparation must cost.

The boundary of incentives and discretion asks inward after the incentive mechanism that drives the whole system. Section 29.4 pointed out that a decentralized clearinghouse's first mechanistic premise is to substitute the "willing" market incentives for the "must" regulatory compulsion, but this force has a procyclical boundary: it is powerful when marginally favorable but may fail collectively in a systemic crisis, and the full predictability of the system's reactions itself becomes an attack surface. More fundamentally, contracts are incomplete—there are always states the drafter never envisioned and therefore lacking established rules, and in such states, someone must decide. The passing line of this principle is therefore not to eliminate all discretion

(forcing this unattainable goal only regresses the system into an opaque centralized mechanism) but to bisect the state space: hand the overwhelming majority of states the contract can provide for wholly to code, leaving no room for human intervention, and permit discretion only in the minority of states the contract truly cannot provide for, constraining this residual discretion to be simultaneously narrow, slow, and visible: strictly limited in authorization scope, delayed through a timelock in its exercise, and every exercise occurring on-chain and auditable by any node (Section 12.4.6). If any of the three constraints of narrow, slow, and visible is missing, the direction of degradation also differs. Lacking narrow authorization, an intervention that should be confined to an extreme state can seize the occasion to rewrite any parameter, and the emergency power continuously erodes outward into the territory that should have been left to code. Lacking time delay, rules can be rewritten in the instant before users have time to exit, the exit window the timelock was meant to protect disappears, and only a fait accompli remains. Lacking public auditability, discretion turns into a non-public state, and external participants can neither judge whether it has been abused nor hold it to account, so it no longer differs substantively from the unauditable discretion in an opaque centralized mechanism. The dimension of visibility is precisely the natural extension, at the governance level, of the verification-by-all that overall architectural integrity requires.

29.5.2 The Hyperliquid gap audit

Based on the four principles above, one can use them to measure a concrete system. The object of the audit is Hyperliquid, for a fairly clear reason: it is today the on-chain system closest to a complete decentralized clearinghouse with its own on-chain clearing and settlement module, and calibrating with it yields a distance most representative of the frontier level of the entire field. The facts on which the audit relies are all taken from what the preceding text has already treated in full (its consensus and state-machine architecture in Chapter 28, its waterfall layers and the exercise of discretion in the JELLY incident in Chapter 12), so this section does not restate how these mechanisms operate but only places them item by item on the checklist for assessment (Table 29-2).

Checklist item	Ideal standard	Hyperliquid's current status	Assessment
Overall architectural integrity	A single deterministic state machine; single-point adjudication with verification open to all; verification and governance paths do not re-concentrate	HyperBFT consensus and the Hypercore on-chain state machine make state transitions independently recomputable; but validator independence, the bounds of governance discretion, and the disclosure of decision rationales still constitute residual trust assumptions (Sections 28.6.2 and 12.6)	Partially met (state recomputability met)
Waterfall depth	Includes an own-equity first-loss layer (skin in the game) and prefunded mutualization	Margin → insurance fund → HLP vault → auto-deleveraging; the insurance fund is fee-supplied rather than own equity, so there is no skin-in-the-game layer; auto-deleveraging cuts profitable positions rather than providing prefunded mutualization	Partially met
Orderly degradation	Risk-pool isolation and active shock management	JELLY exposed risk-pool commingling; afterward the liquidation vault was isolated from HLP, and dynamic position caps and HIP-3 isolated markets were introduced; auto-deleveraging and partial liquidation exist, but auction-style ex ante shock management is absent	Partially met
The boundary of incentives and discretion	Market incentives; residual discretion that is narrow, slow, and visible	HLP is a permissionless, market-based vault; during JELLY, validators unanimously overrode the oracle price and forced settlement—execution traces are visible, but the decision process and rationale are insufficiently visible, and it was fast (an emergency, no timelock) and broad in scope	Partially met

Table 29-2. The ideal decentralized clearinghouse checklist and the audit of Hyperliquid's compliance (Data source: compiled by the author)

Of the four items, what Hyperliquid comes closest to meeting is the state-

recomputability sub-item of the first, and this is the hardest and most fundamental of the four principles. It is called most fundamental because it is the premise on which the other three stand: the waterfall, degradation, and incentives are all built on the foundation of the ledger being publicly acknowledged by all; if verification is impossible, the latter three, however complexly designed, lose the fulcrum by which external participants can test them, and in a system where no one can independently audit the books, it is meaningless to discuss whether the waterfall is deep enough or degradation orderly. It is called most difficult because it must satisfy two demands pointing in opposite directions at once: adjudication must be sufficiently concentrated to complete that uninterruptible chain of states in milliseconds; and verification must be sufficiently open to let any bystander recompute this high-speed chain bit for bit. Achieving both concentrated execution and open verification in the same system is the hardest tension to reconcile in all of decentralized finance, and it is precisely here that most systems retreat, either sacrificing execution speed for openness or drawing verification into a few actors' authority for speed. Hyperliquid has not retreated on state-machine recomputability: its consensus is produced by HyperBFT, its state maintained by the Hypercore on-chain state machine, the rules of clearing and settlement hard-coded into the protocol and executed identically for all positions, and anyone can pull the on-chain state, independently recompute the books with the same rules, and verify an identical result (Section 28.6.2, [8]). This means it does give, on the point of clearing output being recomputable, the strongest engineering proof. But that state transitions are recomputable does not mean the entire validator organization, governance authorization, and emergency discretion are already trustless; what JELLY exposed is this difference. Therefore the first item cannot be simply judged as met overall but only as met at the state-machine level and partially met at the overall-architecture level. The clearest affirmation in this audit should go to the sub-proposition that "high-speed adjudication and open recomputation can be reconciled by engineering," not to the stronger proposition that "governance and verification power are already fully decentralized."

The other three items are only partially met, and the location of the gap falls, with high consistency, on exactly the absences the earlier sections of this chapter already identified. This consistency shows that these three gaps are not implementation oversights but the appearance, in a real system, of the several structural voids the preceding text predicted from principle. On waterfall depth, it does have four layers (margin, insurance fund, HLP liquidation vault, auto-deleveraging), but measured against Section 29.2's two-layer criterion, both front-placed buffer layers are not in place. Its insurance fund is passively supplied by trading fees, a collected public pool rather than a skin-in-the-game first-loss tranche in which the protocol bears risk with its own equity, which is the concrete landing point of the previous section's *once the first-loss layer is absent, the designer is no longer bound to the system's safety*: a fee pool, however large, does not constitute the designer's commitment to write its own equity ahead of users. Its auto-deleveraging cuts profitable positions, in essence forcibly socializing tail losses onto non-defaulting counterparties rather than a true mutualization funded in place before the crisis (Section 28.3.6): the previous section's *once prefunded mutualization is absent, the former unfavorable handling path chosen between harming fairness and*

harming solvency. In other words, its waterfall skips the two layers the ideal standard requires, turning directly from a public pool to loss socialization. Judging it partially met rather than unmet is because it has indeed built a multi-layer waterfall that can operate in most situations, only with insufficient depth: what is lacking is not the number of layers but the nature of exactly the two most critical layers.

On orderly degradation, its score was driven largely by a single failure. The JELLY incident is exactly the kind of risk-pool commingling Section 29.3 used as a cautionary counterexample: the HLP vault was forced to take over a single altcoin's position and thereby imperiled the whole vault (Section 12.6, [41]). This is the previous section's *once isolation is absent, a single edge market's bad debt spreads along the shared capital layer*, a complete manifestation, with the contagion channel then open by default. After the event, it made a series of reinforcements that all converged toward risk-pool isolation: isolating the liquidation vault from HLP, introducing dynamic position caps, and opening isolated deployer markets through HIP-3 ([46]). But measured against Section 29.3's two means, what it has filled is mainly the isolation means, and it filled it rather passively, as a remedial adjustment after the fact rather than an architecture designed for the worst case in advance, its boundary set according to the type of event that has already occurred and not necessarily equally effective against the next, unforeseen kind of commingling. As for the means of active shock management, it remains incomplete: it has auto-deleveraging, partial liquidation, and a time-weighted mechanism for triggering liquidation, but not a mechanism like the Dutch descending-price auction that actively lowers the price impact by treating it as an adjustable design variable; it has the means to spread losses out but still lacks the mechanism to compress the shock itself before spreading it, and the latter is the core of the lending-side exemplars Section 29.3 showed in MakerDAO [47], Liquity [23], and Euler [43]. Isolation established, active shock management still lacking: hence partially met.

On the boundary of incentives and discretion, the assessment is most complex. Its core capital layer, HLP, is a permissionless, market-based vault into which anyone can deposit funds to serve as counterparty; this side is driven wholly by market incentives, meeting the first half of this principle concerning market incentives. The problem lies on the residual-discretion side. During JELLY it fell into a state with no rule to follow and exercised discretion, the validators voting unanimously to overturn the oracle price and force settlement at the level before the manipulation (the handling is described in Section 29.4.5, [41]). Measuring this discretion against the three constraints of narrow, slow, and visible, the conclusion splits cleanly: the execution traces and final state transition are trackable on-chain, but the decision basis, authorization boundary, assessment of alternatives, and ex post accountability were not disclosed in an equally full way; this is insufficient governance visibility, not unverifiable state execution. It was neither slow nor narrow: this was an emergency intervention made in an extremely short time, with no timelock delay whatsoever, making the previous section's *once time delay is absent, users have no time to exit and only a fait accompli remains* a real-world event; and overturning the oracle pricing and forcibly settling the entire market is far from a strictly limited narrow authorization. State visible, governance insufficiently visible, and both slow and narrow lacking: hence likewise partially met; the slow, narrow, and governance disclosure it lacks all belong to ex ante institutional constraints and could

have been filled with a preset timelock, a limited authorization scope, and a complete on-chain decision record, so the gap in this item belongs especially to the kind that can be converged by engineering.

29.5.3 Unmet items and the frontier of the field

In reading this audit, a common misreading is to read the several *partially met* results as an indictment of Hyperliquid. More accurately, the gaps the audit points out are, none of them, Hyperliquid's own oversight; they are boundaries the entire field has yet to resolve in common. The skin-in-the-game own-equity first-loss layer, true prefunded mutualization, the active shock management not yet mature on the perpetual-clearinghouse side, and discretion not yet constrained narrowly and slowly enough: applying this checklist to measure any other on-chain system yields gaps only more numerous, not fewer. Section 29.2 examined them one by one: as of publicly available information on June 25, 2026, from the fee-supplied-insurance-fund dYdX [18] and the first-loss-outsourced-to-liquidity-providers GMX [20], to the reflexive-token-backed Synthetix now entering the sUSD retirement process [33], and even the crvUSD without a dedicated insurance fund, no perpetual or lending protocol within the range examined here has truly filled those two buffer layers. Section 29.3 also showed that the mature exemplars of active shock management still come mainly from lending-side protocols like MakerDAO [47], Liquity [23], and Euler [43], and remain scarce on the perpetual-clearinghouse side. At the same time, these gaps belong to three different kinds of difficulty (the first loss and mutualization are constrained by political-economy willingness, active shock management by the migration of an engineering paradigm, and constrained discretion by the absence of ex ante institutional design), yet they exist, without exception, before all systems. That Hyperliquid is at the frontier level on state-machine recomputability yet constrained by the same boundary on the other dimensions itself shows that these gaps are structural, not individual: the places where it has not yet met the standard are not where its technology falls short of others' but the common baseline of the entire field.

These several structural gaps are, in substance, the concretization of a single higher-level judgment. Section 29.3 quoted the Bank for International Settlements' assessment of decentralized finance: on-chain systems generally lack the shock absorbers on which traditional finance relies to dampen shocks [3]. This is a highly general diagnosis that does not itself indicate where to improve in a concrete clearinghouse system, and the value of the four-item audit lies in landing this abstract *shock-absorber gap* at the clearinghouse level, translating it into four concrete coordinates that can be tested and improved item by item. Lacking the skin-in-the-game first-loss layer is lacking an endogenous equity absorber that bears losses ahead of users and non-defaulting parties; it differs from a central-bank liquidity window in that it absorbs the designer's own equity loss rather than liquidity temporarily provided by the public sector. Lacking prefunded mutualization is lacking a common fund already formed in advance and reserved for default spillover, for which the chain has yet to form a corresponding mechanism. Lacking constrained active shock management is lacking an absorber that lowers the shock itself and thereby reduces the amount that needs absorbing; its function is akin to market-making arrangements that maintain loss-absorbing capacity amid turbulence and halt

mechanisms in disorder, but it must be rewritten into an intra-protocol, verifiable mechanism. And still-too-fast, still-too-broad discretion is the last absorber, which must be borne by a human actor when all built-in absorbers are breached, not yet engineered and constrained; traditional finance hands this role to a resolution authority with rules to follow, and the chain has yet to form corresponding governance rules for it. The Bank for International Settlements offers a general judgment; this checklist decomposes it into four structural positions that can be filled item by item, and marks for each the absorber it roughly corresponds to in the old world, so the void is no longer a general judgment but four engineering goals with clear specifications.

For this very reason, the true use of this audit is not to judge but to define: it rewrites the question of *how far the frontier system is from the ideal architecture* into a set of engineering goals that can each be separately proposed, separately solved, and separately accepted: which four conditions are still lacking, what structure each condition should have, and by what kind of actor it should be borne. Its clear affirmation of Hyperliquid on the state-recomputability sub-item is the most valuable part of this definition: it proves that the hardest piece of a decentralized clearinghouse, concentrating the discretion over adjudication while opening the state output to recomputation by all, is indeed feasible in engineering and has already been realized by a real running system. Once this foundation is proved buildable, the remaining gaps are no longer questions of *whether possible* but questions to be resolved of *when they are filled, by what kind of actor's equity, and constrained by what governance rules.*

29.5.4 The interdependence of the four principles

One more point must be added, or this checklist is easily misread as four independent items that can each be satisfied separately and are unrelated to one another. They are not. These four principles constitute a progressive dependence within the same system, where the effectiveness of the latter level hinges on whether the former is in place. This means the total quality of the four items is not the simple sum of each item's score but closer to their product along the dependence chain: a shortfall at any link is transmitted and amplified along the dependence relationship.

Depth provides degradation with a buffer space that can be released layer by layer. If the waterfall is itself shallow and both front-placed buffer layers are absent, then the losses that need orderly handling arrive earlier and larger in scale, and the room left for the degradation mechanism to adjust is smaller; the shallower the waterfall, the heavier the execution burden on degradation. Conversely, no matter how complex degradation is, it cannot make up for a deficiency of depth: it can change the way losses are released but not the total amount of loss that needs releasing. So the quality of orderly degradation depends in part on the degree to which depth is filled, which is the deeper reason why, in the previous section, Hyperliquid's waterfall skipping two layers and its degradation mechanism still lacking ex ante shock management simultaneously remain at partially met: the shallow waterfall transfers too heavy an execution burden onto an already incomplete degradation, and the two gaps aggravate each other along the dependence chain.

Degradation in turn depends on incentives to execute. No matter how cleanly risk-

pool isolation is designed or how complexly the Dutch auction's descending-price curve is tuned, these mechanisms need execution actors driven by market incentives to be realized. The liquidator-exit gap at the end of Section 29.3 already showed that once incentives reverse in a crisis and executors exit in sync, even the most orderly degradation design is only an unexecuted design: on-chain congestion pushes up fees, liquidation is unprofitable, and liquidation is delayed or even fails, a point with both empirical cases (such as the CRV position on Aave in November 2022, [52]) and systematic academic characterization ([51]). This layer of dependence also contains a feedback: the shallower the waterfall and the larger the loss pushed to the degradation link, the higher the position risk liquidators must take on and the higher the risk compensation they demand: the same depth gap both aggravates the execution burden of degradation and raises the compensation required for executors to participate.

And incentives themselves are in turn constrained by the boundary of discretion. Market incentives are reliable on the premise that the rules are determinate, predictable to all, and modifiable by no one on the spot. But once discretion is too broad, too fast, too arbitrary, for instance if a position's settlement price can be overturned ex post by an emergency vote, then the very promise that *acting by the rules is profitable*, on which incentives stand, is itself shaken, and rational participants begin to price the risk that *the rules may be changed at any time*, thereby exiting earlier at the moment the system most needs them. Its reflexive feature is especially pronounced: discretion is often exercised in a crisis, at the moment the system most depends on executors' participation in handling, and that one act of overstepping weakens, at the worst point, the determinacy on which executors rely to participate: discretion used for emergency handling instead dissolves the incentives that could have supported emergency handling. Discretion constrained to be narrow, slow, and visible is therefore not only to prevent abuse of power but the foundation of credibility on which market incentives rely to be sustained. Incentives and the boundary of discretion are not two things but two sides of one thing: the more clearly the boundary of discretion is drawn, the more credible the promise of incentives.

Taking this layer of dependence together, what this checklist conveys is not that the four items being individually met suffices but that meeting them must accumulate progressively from the foundation layer up: without the integrity of the overall architecture, it is hard to form a credible default waterfall; without sufficient depth, degradation is hard to keep orderly; without incentives that can keep functioning, no one executes degradation; without constrained discretion, incentives themselves are not credible. The two ends of the dependence relationship are thereby connected into a feedback relationship (the terminal constraint of visible discretion, as the preceding text noted, is itself the extension, at the governance level, of the initial verification-by-all), so this progressive dependence is not a mutually severed linear relationship but a dependence with a self-reinforcing character. An ideal decentralized clearinghouse system is therefore not the simple juxtaposition of a combination of four mechanisms but a structure that can hold only by being joined layer by layer from the foundation up, which also explains why Hyperliquid can hold the state-recomputability foundation sub-item fairly firmly yet simultaneously halt on the overall architecture and the other three items: part of the foundation is already built, but every layer above still depends on whether questions

harder than engineering implementation can be answered.

29.5.5 From risk governance to rule governance

By this point, the chapter has completed two tasks. Integration: assembling, for the first time, the components dispersed throughout the book into a complete decentralized clearinghouse system, and pointing out that the true fragility lies not in the components but in the seams. Answering the questions: along this system's four seams, answering one by one the three questions Chapter 28 left, and fixing the answers into a four-item checklist that can measure any real system. The conclusion this checklist gives corroborates the chapter's main line: even the most frontier Hyperliquid today has only pushed the sub-item of *a recomputable single state machine* to the position closest to met; once validator independence, governance discretion, waterfall depth, and the degradation mechanism are all brought in, the complete architecture still has a distance that can be identified item by item, and behind those distances lie, almost all, not technical problems but the political-economy questions of what kind of actor's equity is willing to bear losses first and what kind of actor exercises discretion in states the code does not cover.

But this points precisely to a proposition the chapter cannot resolve on its own. This chapter has analyzed the clearinghouse as a risk-governance architecture; what it must solve is how losses are absorbed, how shocks are degraded, and how incentives are aligned. Yet none of those three hardest-to-fill gaps can be filled by a more complex contract alone: the skin-in-the-game first-loss layer concerns what kind of actor is willing to bring its own equity under the rules and accept the rules compelling it to lose first; prefunded mutualization concerns what institutional arrangement makes unfamiliar participants jointly inject funds into a pool before a crisis and trust that this fund will be mobilized fairly; constrained discretion concerns how, when code must allow an authorized governance actor to intervene, that actor's power is framed by rules in advance. All these questions have spilled beyond the boundary of risk engineering and turned into another domain—how the rules themselves are written, executed, and governed. That is, to complete this risk-governance architecture, there must first be a governance system that can credibly formulate and execute rules.

The next chapter turns from this to the problem of rule governance. When compliance and governance are no longer constraints imposed on the system from outside but engineered directly into the protocol itself, and when the formulation, alteration, and enforcement of rules all become on-chain verifiable processes, how will this system operate? From a risk-governance architecture to a rule-governance system, the subsequent analysis thereby turns from *how to absorb losses* to *how to govern rules*. What Chapter 30 will analyze is precisely this rule-governance system: embedded compliance and automated governance.

Chapter summary

This chapter completed two pieces of work: integrating the various components dispersed across the book's first 28 chapters into a complete decentralized clearinghouse

system, and, along this system's four seams, answering one by one the three questions Chapter 28 left at its close. The first piece of work is an engineering-level response to the preceding mechanism analysis: the earlier text explained how each component fails, and this chapter answers how, absent a central institution, these components can be reintegrated into a system that can be trusted; the second is a direct answer to three constructive questions, not a restatement of existing mechanisms.

The first conclusion integration yields is that the strength of a clearinghouse system lies not in a single component but in the seams between them. The book's earlier text has analyzed every component to the level of formulas: novation, multilateral netting, marking to market, margin, the reflexivity of liquidation, the default waterfall, the insurance fund, and auto-deleveraging. But what breaks a clearinghouse system is usually not the failure of some one component but the transmission between components: an oracle failure triggers erroneous liquidations, erroneous liquidations exhaust the insurance fund, the exhaustion of the insurance fund triggers auto-deleveraging, and auto-deleveraging in turn weakens the market's loss-absorbing capacity. After expressing this system as a chain of state transitions, the parts truly needing reinforcement become clear: not any single link but the connections between links.

Answering the three questions along these four seams yields four normative principles, which are also four structural positions not yet filled to date. The depth of the waterfall requires setting, before losses are allocated to non-defaulting parties, at least a skin-in-the-game own-equity first-loss layer and a prefunded mutualization layer, and the chain is absent at these two points, able only to turn from a fee public pool directly to forced socialization onto the profitable side. Orderly degradation requires designing for the worst case absent a lender of last resort, severing contagion with risk-pool isolation and confining the liquidation shock within an absorbable range with active shock management, while isolation and auction each carry unavoidable costs. The boundary of incentives and discretion requires handing the overwhelming majority of states to deterministic code and permitting discretion only in the minority of states the contract cannot provide for in advance, constraining residual discretion to be narrow, slow, and visible. Using these four principles as an evaluation standard to measure the most frontier Hyperliquid today, one finds it closest to met on the sub-item of *a single state machine recomputable and verifiable by anyone*, but still with distances identifiable item by item on the overall architecture, waterfall depth, orderly degradation, and the constraint of discretion.

Running through all three answers is the same fact: the hardest parts of a decentralized clearinghouse are mostly not technical problems. Making the loss waterfall deep is hard because of the lack of own equity willing to bear losses first; keeping the degradation mechanism orderly is hard because every cost must ultimately be borne by someone; constraining discretion to the minimum is hard because there will always be a moment when the code must allow an authorized governance actor to intervene. None of these is a problem a more complex contract can solve on its own; they point to how rules are written, executed, and governed. The four-item checklist this chapter gives is precisely the tool for measuring, item by item, the degree to which any real system meets the standard on these four dimensions. When compliance and governance are no longer externally imposed constraints but engineered directly into the protocol itself, in what

way this risk-governance architecture will operate is exactly the domain Chapter 30 (embedded compliance and automated governance) will enter.

Embedded Compliance and Automated Governance

In November 2022, the collapse of the cryptocurrency exchange FTX exposed a shortfall in customer funds of as much as $8.7 billion; the subsequent bankruptcy investigation and criminal trial revealed the complete failure of its internal controls and large-scale misappropriation of assets [1]. This event marked the structural bankruptcy of the trust model underlying centralized crypto-finance institutions. Its core lesson was not merely the isolated failure of a single institution, but the structural fragility of the traditional financial compliance paradigm when confronted with digital-native institutions that hold complete control over assets. Traditional financial compliance is essentially an external enforcement mechanism that relies on ex post penalties; it presupposes that an institution is physically and technically capable of violating the rules and that its incentive to comply derives solely from avoiding those penalties (its logic and premises are detailed in Section 30.1.1). When a centralized institution holds unrestricted private keys to assets and the power to modify databases, the lag inherent in external supervision means that no periodic compliance check can prevent the asset misappropriation or ledger tampering that has already occurred [2]. This systemic risk raises the central question of this chapter: how can regulatory compliance requirements and system governance mechanisms be embedded directly into the architecture of on-chain financial systems, thereby transforming compliance from an external mandate that depends on institutional self-discipline into a built-in guarantee that makes violations physically impossible at the system level?

Embedded compliance proposes a paradigm fundamentally different from traditional regulation. Its underlying logic is to use cryptography and smart-contract technology to design a system that, at the architectural level, excludes the possibility of specific violations [3]. Under this paradigm, rules are no longer legal provisions on paper or entries in a compliance manual; they are compiled directly into the execution logic of smart contracts. If the system requires that customer assets be strictly segregated, this rule is encoded as a contract function that permits withdrawals only when triggered by the customer's own private-key signature, making it technically impossible for the protocol developers or the operating team to misappropriate any assets. This design, which converts behavioral constraints into architectural constraints, achieves a paradigm shift from requiring institutions to obey the law to making it impossible for them to break it. Yet hard-coding rules into smart contracts is not a panacea. The complexity of financial systems requires a balance between the security of immutability and the flexibility to

adapt to changing markets: complete rigidity would leave a system unable to cope with extreme market volatility or protocol vulnerabilities, whereas excessive flexibility could reintroduce the single-point-of-failure and trust risks that administrator privileges entail. Building a robust on-chain financial system therefore requires careful engineering trade-offs in both the embedding depth of rules and the design of governance mechanisms. Crucially, embedded compliance rests on the premise that the correctness of smart-contract code can be guaranteed through means such as formal verification; if the code implementing a compliance rule itself contains a vulnerability, the credibility of the architectural constraint is fundamentally undermined.

This chapter takes an engineering-implementation perspective to systematically construct the theory and methodology for embedding compliance and governance into on-chain architecture. The three-tier compliance spectrum divides compliance mechanisms by embedding depth into hard-coded, parameterized, and reporting-based compliance. Hard-coded compliance applies to non-negotiable security baselines such as asset segregation; parameterized compliance handles operational parameters such as the margin ratio, which must be adjustable yet remain transparent; and reporting-based compliance leverages the openness of on-chain data to enable automated transaction monitoring and real-time risk disclosure. At the governance layer, the dual architecture of timelock and emergency powers strikes a balance between immutability and flexible response through a mandatory delayed review for routine changes and a constrained fast track for extreme situations. Finally, the chapter translates the regulatory frameworks and principles discussed earlier into a concrete inventory of on-chain technical implementations, completing the mapping from regulatory requirements to engineering code.

30.1 The theoretical foundations of embedded compliance

Traditional financial compliance relies on external enforcement to constrain institutional behavior, and this model has exposed structural limitations in cost, timeliness, and cross-border coordination. By embedding compliance rules into the execution logic of smart contracts, on-chain financial systems offer an alternative that shifts from behavioral constraints to architectural constraints. However, different types of compliance requirements differ significantly in how much embedding depth and flexibility they demand, which calls for engineering trade-offs across the three tiers of hard-coded, parameterized, and reporting-based compliance. This section first analyzes the limitations of the traditional model, then sets out the core concept of embedded compliance and the three-tier spectrum, and finally shows how macro-level regulatory principles can be mapped onto concrete on-chain implementation paths.

30.1.1 The limits of the traditional compliance model

The core logic of traditional financial compliance rests on the dual assumptions of trust and verification. Regulators set the rule framework, financial institutions pledge to comply with those rules, and internal compliance departments, external auditors, and regulators then verify compliance through periodic inspections. The fundamental premise of this model is that a financial institution is fully capable, physically and

technically, of violating the rules, and that it chooses to comply mainly out of fear of reputational damage and legal penalties. This model of external enforcement grounded in ex post sanctions, however, is exposing increasingly severe structural limitations.

The most conspicuous limitation lies in the ever-rising cost of compliance. In modern financial systems, compliance has become a high-cost operational burden. According to industry research, compliance costs account for roughly 10% to 20% of a financial institution's operating expenses, and the proportion is higher for some small community banks and regional financial institutions [4]. Since the 2008 global financial crisis, the operating costs that retail and corporate banks devote to compliance have risen by more than 60% [5]. These high costs are ultimately passed on to end consumers through higher service fees and lower deposit rates. In addition, global spending on the anti-money laundering (AML) systems (software and systems) market is projected to reach $51.7 billion by 2028 [6]. Despite the enormous investment, this resource-intensive compliance model has not fully prevented financial crime or systemic risk. To be sure, the high cost of the traditional compliance system is not entirely wasted: macroprudential regulatory frameworks have demonstrable empirical effects in reducing the frequency of systemic crises and limiting their reach. The improvement that embedded compliance offers lies mainly in reallocating the wasteful overhead of "compliance theater" in the traditional model into architectural-level, built-in guarantees, rather than simply replacing every traditional compliance function.

A second structural flaw of the external-enforcement model is its lack of timeliness. Traditional compliance checks are typically based on quarterly reports or annual audits, and such low-frequency, snapshot-style reviews cannot capture violations that occur between two checks. By the time an auditor or regulator discovers a problem, the violation has often persisted for months or even years, and the resulting damage may already be irreparable. The FTX case is an extreme manifestation of this limitation. Although the institution claimed to have strict internal controls, when its de facto controller decided to misappropriate customer assets, no periodic inspection mechanism was able to intercept the behavior before or as it occurred.

This lag further gives rise to the phenomenon of "compliance theater." At many financial institutions, the purpose of compliance activity has gradually shifted from "effectively reducing risk" to "passing regulatory inspections" [4]. Institutions devote substantial resources to filling out forms, generating reports, and designing complex compliance workflows; these activities superficially satisfy regulatory requirements but do not substantively change the business's risk exposure. When compliance becomes a formalistic exercise aimed at meeting regulatory metrics, it not only wastes social resources but also manufactures a false sense of security.

The compliance predicament of centralized cryptocurrency exchanges pushes these structural flaws to an extreme. Unlike traditional banks, the core business of a centralized exchange (CEX) runs entirely on digital infrastructure: order matching is completed on off-chain centralized servers, customer assets are stored in hot and cold wallets whose private keys the exchange controls, and the internal ledger exists as database records that administrators can modify at will. This architecture means that external auditors cannot verify in real time the consistency between the asset status the

exchange claims and the actual on-chain address balances. Even a periodic financial audit is effective only to the extent that the exchange voluntarily provides complete and truthful data, and the collapse of FTX is precisely an extreme confirmation of this architectural flaw.

The fragmentation of cross-border compliance makes these problems even more complex. In globally operating financial markets, different jurisdictions have starkly different and sometimes conflicting compliance requirements. A global financial institution must satisfy dozens of different regulatory frameworks simultaneously, which not only causes compliance costs to grow exponentially but also leaves institutions stretched thin across regulatory regimes, unable to build a unified and coherent risk-control system.

30.1.2 The core concept of embedded compliance

Confronted with the structural failure of the traditional compliance model, on-chain financial systems propose a paradigm shift: embedded compliance. The core of this concept is to convert compliance from a "behavioral constraint" into an "architectural constraint." Under the behavioral-constraint model, rules tell participants "what they should not do," but participants still retain the physical ability to do it; under the architectural-constraint model, the system is designed so that violations become physically and technically impossible.

This concept can be likened to the evolution of building fire codes. Modern building codes no longer rely solely on periodic inspections by fire marshals; instead, they fix firewall materials and sprinkler coverage in the building's blueprint at the design stage, so that the physical structure of the building excludes the possibility of specific fire-code violations. Embedded compliance follows the same engineering logic, moving constraints forward into the system design stage.

In on-chain financial systems, the smart contract serves as the execution engine of this concept. Once a smart contract is deployed to a blockchain, its logic executes strictly according to its code. Code execution is unaffected by conflicts of interest or operational negligence; its output is determined entirely by its inputs and logic. If we encode compliance rules as part of a smart contract, those rules become an inseparable property of the system, giving concrete form, in the domain of financial regulation, to Lawrence Lessig's idea that "code is law" [3][7][8]. When a transaction is broadcast to the network, the system verifies not only its technical validity but also, at the compliance level, whether it is permitted. If a transaction violates the preset compliance logic, the smart contract simply refuses to execute it, making the violation impossible to occur on-chain in the first place.

This shift from ex post detection to ex ante prevention means that compliance is no longer an add-on process separate from the core business but an intrinsic feature of the financial infrastructure itself. It substantially reduces the reliance on human intervention found in traditional compliance, lowers the ongoing operational cost of compliance, and raises the certainty of compliance from the probabilistic level to the level of cryptographic guarantee.

Embedded compliance, however, is not without limits. First, not all regulatory rules are

suitable for, or capable of, being translated into deterministic code logic. Many compliance requirements contain fuzzy boundaries and room for subjective judgment. Second, code itself may contain vulnerabilities; if compliance logic is incorrectly encoded, it may cause legitimate transactions to be rejected or non-compliant transactions to be admitted. More complex still, the regulatory environment and market conditions change continuously, and if rules are hard-coded into the system in a completely rigid form, the system loses the ability to adapt to future change. A deeper limitation is that although embedded compliance eliminates human bias at the execution level, the code itself is written by developers who carry cognitive biases; availability bias, for example, may lead to over-guarding against recently known risks while ignoring unknown ones, and hard-coding a biased judgment into immutable logic effectively locks that bias in—converting it from a "correctable operational decision" into an "immutable system architecture." Moreover, in the traditional compliance framework, legal liability for violations is clearly attributed to the financial institution; once compliance rules are embedded in a smart contract, if the contract's behavior produces a law-violating outcome, the attribution of liability becomes highly ambiguous among the contract deployer, the code developers, the auditing firm, and the governance voters. This "accountability gap" is one of the core practical obstacles to regulators' acceptance of embedded compliance. These limitations raise a key question: how can the rigidity of rules be preserved while endowing the system with the necessary capacity to evolve?

30.1.3 The three-tier compliance spectrum

To resolve the tension between flexibility and certainty in embedded compliance, this chapter proposes the theory of the "three-tier compliance spectrum." This theory holds that compliance requirements should not be hard-coded indiscriminately; rather, compliance mechanisms should be divided into three distinct tiers by "embedding depth," according to the nature of the rule, the consequences of violating it, and the need for flexibility.

These three tiers each strike their own balance between flexibility and certainty, and together they constitute a complete on-chain compliance framework.

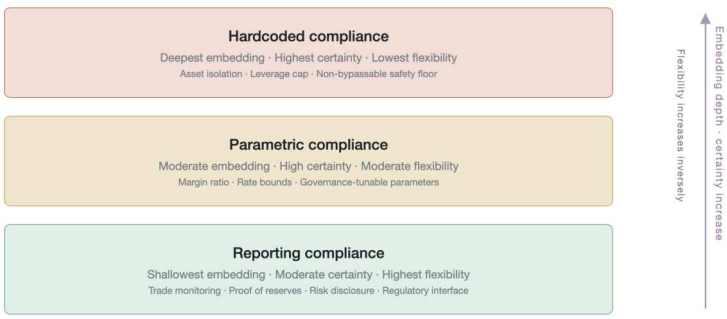

Figure 30-1. The three-tier compliance spectrum and its relationship to embedding depth, flexibility, and certainty [3]

Hard-coded compliance represents the deepest embedding and the highest certainty. In this tier, compliance rules are written directly into the underlying logic of the smart contract, with no interface for modification. Such rules typically concern the system's security baseline; their defining features are that they are "non-negotiable" and that a single violation would lead to severe consequences. Asset segregation, for example, must be hard-coded. The system must ensure through code that, apart from the user's own cryptographic-signature authorization and liquidation events that satisfy strict trigger conditions, no administrator key or protocol backdoor can move a user's funds. An absolute leverage cap is another typical application of hard-coding: by setting an insurmountable maximum leverage multiple at the code level, the system effectively prevents the emergence of extreme risk exposure. The cost of hard-coded compliance is a significant reduction in flexibility, as any modification of the rules requires a complex contract upgrade.

Parameterized compliance sits in the middle of the spectrum, offering a compromise in which "the rule framework is fixed but the specific parameters are adjustable." Many operational compliance rules must be dynamically adjusted in response to market volatility and changes in regulatory policy. The margin ratio, for example, must rise as market volatility increases in order to absorb larger potential losses. Under parameterized compliance, "margin must be collected" and "the formula for computing the margin ratio" are hard-coded, but the specific coefficients within the formula are parameterized. These parameters are stored in a dedicated registry contract and can be modified through an established governance process. This design both guarantees the stability of the compliance framework and endows the system with the flexibility to adapt to environmental change.

Reporting-based compliance represents the shallowest embedding. Not all compliance requirements are suited to serving as ex ante restrictions. For behaviors that require holistic judgment or ex post tracing—such as detecting abnormal trading patterns, identifying wash trading, and preventing market manipulation—forcibly intercepting transactions before execution could seriously impair system throughput and the trading experience of legitimate users. Reporting-based compliance exploits the full transparency and immutability of blockchain data, exporting on-chain data in real time and feeding it into analytical models to achieve automated ex post monitoring. In addition, real-time risk disclosure and proof of reserves belong to this tier; they do not restrict user behavior but satisfy the regulatory demand for transparency by providing ample information visibility.

These three tiers are not mutually exclusive but highly complementary. Hard-coded compliance guards the system's untouchable security baseline, parameterized compliance provides the elasticity needed for day-to-day operations, and reporting-based compliance supplements the ongoing monitoring of complex behaviors. No single tier can cover all compliance requirements; only by organically combining the three can one build an on-chain financial system that is both secure and sustainable.

30.1.4 From regulatory principles to engineering implementation

In Chapter 26, we proposed six core regulatory principles applicable to decentralized finance (DeFi): asset segregation as the baseline, disclosure first, functional regulation, embracing embedded compliance, combining international minimum standards with flexible adjustment, and evidence-based evolution. These macro-level principles constitute the requirements specification for on-chain compliance engineering, and the three-tier compliance spectrum provides a systematic implementation path from "what should be regulated" to "what is technically guaranteed." The next three sections respectively develop hard-coded (Section 30.2), parameterized (Section 30.3), and reporting-based compliance (Section 30.4), and Section 30.7 closes the loop from regulatory requirement to engineering code with a complete mapping table.

30.2 Hard-coded compliance

In the architectural design of embedded compliance, hard-coding represents the deepest constraint. The violation of certain rules would lead to systemic catastrophe, so those rules should possess no flexibility. The core logic of hard-coded compliance is to write these non-negotiable baselines directly into the immutable logic of the smart contract, so that no one, under any circumstances, can physically circumvent them.

30.2.1 When hard-coding applies

The core criterion for judging whether a rule should be hard-coded is whether the consequences of violating it are severe and irreversible. If a violation can inflict serious damage on the system before it is discovered, ex post punishment and compensation lose their meaning. In such cases, making violations physically impossible ex ante through code becomes the only engineering option.

Rules suited to hard-coding typically possess broad universality and a low update frequency. The asset-segregation mechanism is the most typical scenario for hard-coding. Customer assets must be independent of protocol operating funds—a baseline that does not change under any market environment or regulatory framework. If a protocol operator or administrator were allowed to withdraw user assets through some privilege, the system would revert to the traditional trust model, whose fragility the FTX case demonstrated. The absolute leverage cap likewise falls within the scope suited to hard-coding. When leverage exceeds a certain critical value, even a minuscule price movement can trigger liquidation, which in turn causes a liquidation cascade. This systemic risk should not be left to dynamic adjustment by operational parameters but must be capped by an insurmountable constraint at the code level [9]. The conditions for using the insurance fund must also be hard-coded: its funds may be used only to absorb liquidation losses, and any attempt to divert them to other uses should be automatically rejected at the contract level.

By contrast, many operational rules are not suited to hard-coding. The margin ratio must be dynamically adjusted according to market volatility, the determination of abnormal trades depends on complex pattern recognition and subjective judgment, and specific identity-verification standards evolve with the legal developments of different

jurisdictions [10]. Hard-coding rules that require flexible response would trap the system in excessive rigidity, ultimately leaving it unable to meet the market's real needs. The scope of hard-coding must be strictly limited to the core logic that defines the system's baseline for survival.

30.2.2 Hard-coding asset segregation

In the traditional financial system, asset segregation relies on complex institutional design. Take the Depository Trust & Clearing Corporation (DTCC): it ensures the segregation of customer assets from the institution's own funds through strict legal contracts, periodic external audits, and a multi-tiered account structure. Although this segregation mechanism grounded in institutional trust has proven highly reliable over the past 200 years, its essence remains guarding against violations rather than eliminating the ability to violate [11]. When this trust model is transplanted to an offshore cryptocurrency exchange that lacks strong regulation, its inherent fragility is fully exposed.

The asset-custody model of centralized cryptocurrency exchanges amplifies this fragility. Mainstream CEXs commonly adopt an omnibus wallet architecture, pooling all customer assets into a small number of on-chain addresses controlled by the exchange, while individual customer balances exist only as mappings in the exchange's internal database. This means that at the on-chain level, an external observer cannot distinguish the exchange's own assets from customer assets, let alone verify the accuracy of the internal ledger. The exchange holds complete control over the private keys of its hot and cold wallets, order matching is completed off-chain, and asset transfers require no customer authorization. The FTX case is precisely an extreme manifestation of this architectural flaw: Alameda Research was able to directly deploy FTX customer assets for its own trading, while external audits failed to uncover this fact for as long as two years. This model, in which a single entity simultaneously controls asset custody and ledger records, stands in fundamental contrast to the self-custody architecture of on-chain finance.

On-chain financial systems achieve a paradigm shift in asset segregation through smart contracts. The stablecoins or other collateral that users deposit are locked in an on-chain margin contract. The logic of this contract is strictly delimited, permitting changes in the margin balance only under four conditions explicitly defined in code. First, the user cryptographically signs a withdrawal transaction with their own private key. Second, when the user's position health falls below the liquidation threshold, the liquidation engine triggers the forced-liquidation logic. Third, periodic settlement transfers are executed automatically between longs and shorts according to the funding rate formula. Fourth, when the insurance fund is insufficient to cover shortfall losses, the auto-deleveraging (ADL) mechanism forcibly and partially closes the positions of profitable counterparties. Beyond these code-defined liquidation and trading operations (and analogous code-defined paths such as the deduction of trading fees and the settlement of realized profit and loss upon position closure), no discretionary administrative instruction can move a user's assets; neither the protocol development team, nor operational administrators, nor any third party holds a privileged interface capable of

bypassing these paths. These guarantees carry one caveat: when this logic is deployed in an upgradeable proxy contract, they amount only to "version-level hard-coding," whose strength depends on the constraint mechanisms governing the upgrade authority itself (see Section 30.6.3).

Figure 30-2 presents this smart-contract-based asset-segregation architecture: user assets are locked in a non-custodial margin contract, and the trigger conditions and execution scope of all four asset-movement paths are explicitly defined in code.

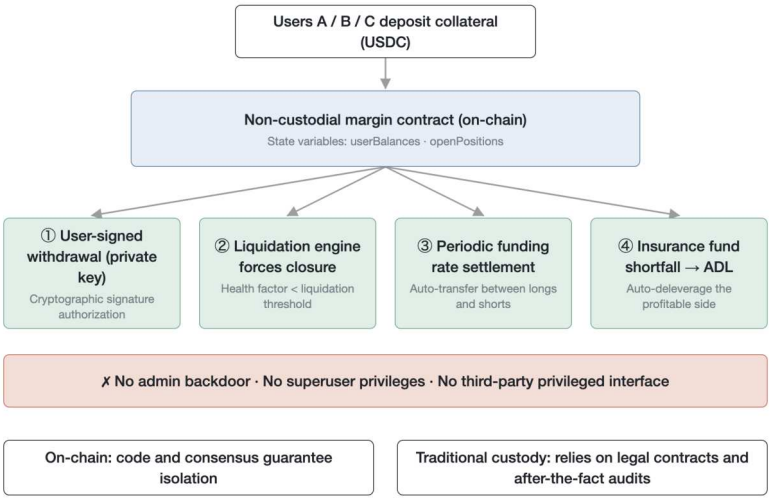

Figure 30-2. The hard-coded design architecture for asset segregation [11]

The core constraint of this design is that it eliminates administrator privileges in the traditional sense. Even the protocol development team that deploys the contract cannot use a backdoor key or superuser privilege to withdraw a user's margin. The security of assets no longer depends on the team's moral integrity or on legal constraints but is guaranteed by the consensus mechanism and cryptographic primitives of the underlying blockchain, such as Ethereum.

The effectiveness of code-level asset segregation rests on a series of operational premises. On the user side, private-key security is the first line of defense: if a user's private key is stolen through a phishing attack, the attacker can withdraw all of the user's assets through a completely "legitimate" signature path, against which the hard-coded segregation logic is powerless. On the system side, the liveness guarantee of the liquidation engine is a critical operational dependency of the segregation mechanism: if the liquidation bots go down, if network congestion prevents liquidation transactions from being confirmed on-chain in time, or if a spike in gas prices makes liquidation unprofitable, the liquidation path fails and the system may incur shortfalls. The reliability and timeliness of oracle price feeds constitute an equally critical premise. In addition, there is a significant gap between "having the right to withdraw" and "being able to withdraw in a timely manner": network congestion may prevent a withdrawal

transaction from being confirmed for a long time, a suspension of cross-chain bridging may block assets from returning to the mainnet, and an emergency-pause mechanism may temporarily restrict an individual user's withdrawals even as it protects the system. Hard-coded compliance eliminates the risk of an administrator misappropriating assets, but it cannot cover these operational-level failure modes.

This purely code-level segregation, however, faces significant challenges in engineering practice. The largest risk exposure often lies in the cross-chain bridging step. In app-chain architectures such as Hyperliquid, a user's native assets (such as USDC on the Ethereum mainnet) typically must be locked through a bridge contract in order to mint an equivalent synthetic asset on the app-chain. A series of major bridge-security incidents between 2022 and 2024 revealed several attack paths: a flaw in a bridge contract's verification logic may allow an attacker to forge cross-chain messages; the leakage of validator private keys or a social-engineering attack can directly seize control of the bridge (in the 2022 Ronin incident, for example, the attacker gained signing control over 5 of 9 validators—four Sky Mavis validator keys were stolen, plus the abuse of a third-party validator's authorization—causing losses of approximately $625 million); relayer spoofing may bypass message-verification mechanisms (as in the message-verification bypass in the Nomad incident); and if an attacker obtains the upgrade authority over a bridge contract, they may fundamentally alter its asset-transfer logic. Any one of these attack vectors could allow an attacker to move assets without a user's signature, thereby circumventing the segregation constraints of the margin contract. For an architecture like Hyperliquid's, which uses a "native bridge" that shares the same validator set as the consensus layer, bridge security and consensus security are fully coupled: the compromise of the validator set means the simultaneous failure of both the bridge and consensus. This risk-concentration property differs fundamentally from a general-purpose cross-chain bridge that uses an independent validator set.

In addition, the upgrade authority over the margin contract itself constitutes another layer of risk. If the contract retains an upgrade authority, the entity holding that authority could, in theory, lift the segregation constraints by replacing the contract logic. This makes the management of the upgrade authority the most sensitive trust assumption in a hard-coded compliance system.

Hard-coded asset segregation also faces a structural challenge arising from the composability of smart contracts. In an on-chain financial ecosystem, when the assets or derivative certificates in a margin contract can be referenced by other protocols or used as collateral, interactions between contracts may circumvent the segregation constraint at the economic level, even if the code logic of each individual contract is correct. System designers face a trade-off between "closed segregation" and "open segregation": the former maintains the strictest segregation guarantee by prohibiting margin assets from participating in any external contract interaction, but sacrifices capital efficiency; the latter permits limited cross-protocol interaction subject to additional constraints, but introduces a new risk dimension in the complexity of security auditing.

Moreover, the discussion of smart-contract asset segregation above implies an important distinction: on a general-purpose public chain such as Ethereum, the logic of a margin contract can be independently audited and formally verified by any third party; but in

an app-chain architecture such as Hyperliquid, the core margin-management logic runs in the consensus-layer state machine rather than in an independently auditable smart contract. This means that the trust assumption for asset segregation shifts from "the correctness of the code logic" to "an honest-majority assumption among validators," and in a network with only about two dozen active validators, this consensus security is far below the security guarantee that the thousands of validators on the Ethereum mainnet provide. The "architectural-level guarantee" described here therefore needs to be qualified according to the consensus-security model of the specific system, rather than treated as a universal conclusion about on-chain finance.

30.2.3 Hard-coding the leverage cap

Leveraged trading is a core function of derivatives markets, but excessive leverage is a primary source of market fragility. In decentralized perpetual futures, if traders are allowed to use extreme leverage (such as 500x or 1,000x), the bankruptcy price of their position lies extremely close to the entry price. Under the constraints of block-confirmation latency on a blockchain network and the discreteness of oracle price updates, the liquidation engine simply cannot complete a forced liquidation before the position's net value reaches zero, which inevitably leads to the rapid depletion of the insurance fund and system shortfalls [12].

Hard-coding the leverage cap is the most direct means of guarding against this kind of systemic risk. In the smart contract's position-opening logic, the system computes the ratio of the requested notional value to the user's available margin. The code explicitly stipulates that if this ratio exceeds a preset absolute cap (for example, 50x), the transaction is automatically reverted. This constraint requires no real-time approval from a risk-control team and does not depend on alerts from a post-trade monitoring system. When a transaction is submitted to the blockchain network, the deterministic execution logic of the Ethereum Virtual Machine (EVM) ensures that any request violating the leverage cap cannot alter the system's global state.

In actual engineering design, the hard-coded absolute cap is typically nested with a parameterized dynamic cap. The hard-coded cap sets a physical ceiling that the system cannot exceed under any extreme circumstances, while the dynamic cap is adjusted in real time according to the current market's liquidity depth, the asset's volatility characteristics, and the user's position size. For example, the contract code might hard-code an absolute cap of 100x, but during periods of high volatility a governance mechanism or automated risk engine would adjust the dynamic cap actually enforced down to 20x. This nested design both preserves the flexibility to respond to market changes and, through hard-coding, establishes an absolute baseline for the system's survival.

The calibration of a hard-coded leverage cap should not be an arbitrary number but should establish a quantitative constraint relationship with the latency parameters of the underlying infrastructure: the maximum leverage must ensure that the liquidation engine completes forced liquidation before the position's net value reaches zero. If the oracle's maximum update latency is 2 seconds and the maximum expected price movement of a major asset within that window is 0.5%, then the critical point

at which the price move exactly exhausts all margin corresponds to about 200x leverage (that is, $1/0.5\% = 200$). But 200x is merely the absolute cap at which the position's net value reaches zero, not a "safe" level of leverage: the usable buffer is in fact the initial margin minus the maintenance margin, and one must further deduct the liquidation delay caused by network congestion and the execution slippage caused by evaporating liquidity. Safe leverage must therefore satisfy safe leverage $<$

$$\frac{1}{\text{maintenance margin ratio} + \text{max adverse move within latency} + \text{execution slippage} + \text{congestion}}$$

and its actual value is far below 200x—which also explains why the earlier examples set the hard-coded absolute cap in the 50x–100x range. In addition, the hard-coded check should not be limited to the initial verification at the moment of opening a position: in a unified margin account, the unrealized loss on one position reduces the account's available margin, causing the effective leverage of other positions to rise implicitly. Even if every position passed the leverage check when opened, the system must continuously verify at each mark-price update whether the effective leverage of the entire account still lies within the hard-coded cap. Finally, a hard-coded leverage cap has one fundamental limitation: it constrains only the leverage within a single protocol. In a composable on-chain financial ecosystem, a trader can open same-direction positions across multiple protocols simultaneously, achieving effective leverage far exceeding the cap of any single protocol. This cross-protocol synthetic leverage cannot be resolved through hard-coded compliance; it requires ecosystem-level leverage tracking at the reporting-based compliance layer for monitoring and early warning.

30.2.4 The cost of hard-coding

Hard-coding rules into a smart contract provides cryptographic-level execution certainty, but this certainty comes at the cost of extreme system rigidity. The immutability of the underlying blockchain architecture means that once a smart contract is deployed, the bytecode it contains resides permanently on the distributed ledger. If a hard-coded rule needs to be modified—even by changing a single small constant value—a completely new smart contract must be deployed, and all users and liquidity must be migrated to it. This migration process is not only costly but also causes severe fragmentation of liquidity.

Over-reliance on hard-coding leaves a system unable to adapt in rapidly evolving financial markets. The microstructure, asset types, and attack vectors of cryptocurrency markets are all constantly changing. A hard-coded rule that appears perfect in the current market environment may, a year later, become a serious constraint that impedes the protocol's development. Only underlying security logic that has withstood the test of time and possesses broad applicability is therefore qualified to be hard-coded.

Furthermore, the security of hard-coding rests entirely on the correctness of the code. If the hard-coded logic contains an implementation vulnerability, a rule intended to protect the system may be exploited by an attacker. In complex DeFi protocols, interactions among smart contracts can produce unforeseeable edge cases. Traditional software-testing methods cannot cover all possible execution paths, which makes formal verification a necessary complementary discipline for hard-coded compliance [13].

Formal verification abstracts a smart contract into a mathematical model and uses logical reasoning to prove whether it satisfies specific properties (such as safety and liveness). Only hard-coded rules that have been rigorously proven mathematically can truly provide a security guarantee that surpasses traditional institutional trust. The engineering solution to this cost of rigidity—the proxy contract pattern and governance constraints—is developed systematically in Section 30.6.

30.3 Parameterized compliance

Most operational compliance rules are not suited to hard-coding, because they must be dynamically adjusted as market conditions and regulatory requirements change. Parameterized compliance offers a compromise in which the rule framework is fixed while parameters can be adjusted through governance, endowing a protocol with the flexibility to adapt to a complex financial environment while keeping its basic logic immutable.

30.3.1 When parameterization applies

Whereas hard-coded compliance applies to security baselines that must never be violated, the applicable boundary of parameterized compliance lies in operational metrics that must be dynamically optimized across different market cycles. The core criterion for judging whether a rule is suited to parameterization is whether its mathematical framework or logical structure is stable while its specific values must respond to changes in the external environment. When market volatility rises sharply, a fixed margin ratio may fail to cover the potential liquidation-slippage risk; when the efficiency of cross-chain arbitrage improves, the settlement frequency of the funding rate may need to be increased accordingly. These scenarios require the system to have a capacity for self-regulation, but that regulation must occur within a preset framework, and the adjustment process must be fully transparent to all participants.

The applicable scenarios for parameterized compliance fall into five categories. The first is the margin ratio: as discussed in Section 29.3, the maintenance margin requirement must vary dynamically with asset volatility and position size in order to guard against liquidation-cascade risk under extreme market conditions [14]. The second is rate parameters, including the settlement frequency, upper and lower bounds of the funding rate, and the size of the risk buffer pool; these parameters directly affect the holding costs of longs and shorts and the protocol's solvency [15]. The third is liquidation parameters, such as the trigger line and execution speed of progressive liquidation, which determine the degree of market impact during deleveraging. The fourth is market-making obligations: an on-chain order book or automated market maker pool must set a minimum liquidity depth, a maximum permissible spread, and obligation-waiver conditions under extreme market conditions in order to ensure the continuous operation of the market. The fifth is access parameters, which concern the compliance requirements of different jurisdictions, such as trading restrictions on specific assets or tiered standards for risk limits.

Hard-coding these operational parameters would leave the system rigid and without

means to respond to sudden events; leaving them entirely to arbitrary modification by off-chain administrators would undermine the trustless foundation of DeFi. Parameterized compliance resolves this contradiction through a parameter-registry mechanism in the smart contract. The rule's execution logic is written permanently into the code, while the specific values are stored in a separate registry contract. Any modification to a value in the registry must go through an explicit governance process and is subject to a timelock, thereby achieving an engineering optimum between flexibility and transparency [16].

The engineering design of the parameter registry follows the principle of separation of concerns. In a traditional monolithic-contract architecture, parameters and execution logic are intermingled, and modifying a parameter often requires redeploying the entire contract—which is not only costly but also prone to introducing new vulnerabilities. In a parameterized architecture, parameters are stored in a dedicated registry contract responsible only for data management and access control, without complex business logic. The execution contract reads parameters from the registry through a standard interface, much like querying a database. This separation allows parameter updates to be carried out independently without affecting the security of the core trading logic. At the same time, the history of parameter changes is preserved completely on the blockchain, forming an immutable audit trail, so that any regulator or user can trace the evolution of the protocol's parameters and verify its compliance.

30.3.2 Parameterizing the margin ratio

The margin ratio is the core line of defense in the risk management of a derivatives protocol. In an on-chain environment, setting the margin ratio is not merely an economic question but a compliance-engineering one. A traditional static margin ratio may cause low capital efficiency during low-volatility periods and fail to provide an adequate buffer during high-volatility periods, and this mismatch is an important structural cause of liquidation cascades [17]. To address this problem, on-chain protocols have introduced a volatility-adaptive margin-computation model and nested the regulatory baseline and the dynamic-adjustment mechanism within the smart-contract architecture.

Figure 30-3 presents the three-tier nesting of margin parameterization—a hard-coded regulatory baseline, a fixed adaptive-formula framework, and governance-adjustable parameter coefficients—which the following text develops tier by tier.

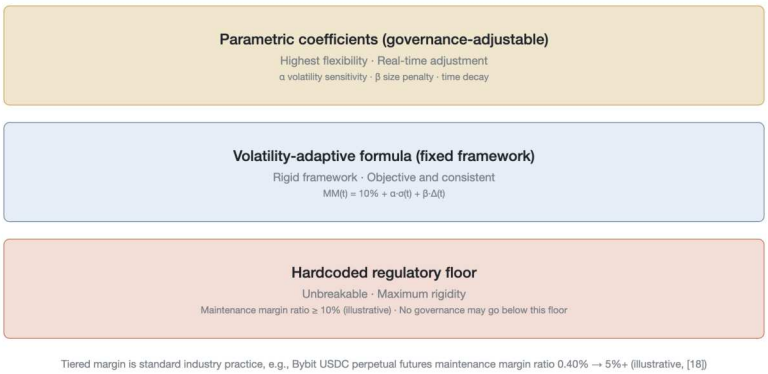

Figure 30-3. The three-tier nested design of margin parameterization [14][18] (the 10% maintenance-margin-ratio floor shown is illustrative)

The bottom of this design is the hard-coded regulatory baseline. At the code level, the smart contract mandates an absolute minimum for the maintenance margin ratio—for example, 10%. No matter how calm the market or how the governance committee votes, the system refuses to execute any operation that would drive the margin ratio below this floor. This hard-coding ensures that the protocol always meets the strictest regulatory requirements, eliminating the possibility that human negligence or malicious manipulation could create systemic risk.

Above the floor is the adaptive-formula layer. The formula for computing the margin ratio is hard-coded into the contract and typically comprises a base rate, a volatility multiplier, and a position-size penalty term. For example, the maintenance margin requirement rises in tiers as the notional value of a position increases; when position value increases from $100,000 to $1 million, the required margin ratio may automatically rise from 0.4% to 0.5% [18]. This logical framework is fixed, ensuring the objectivity and consistency of risk assessment.

In fact, the tiered margin mechanism is not an on-chain invention; mainstream centralized exchanges have long widely adopted a similar tiered margin structure. Take Bybit: the maintenance margin ratio on its USDC perpetual futures rises from 0.40% at the first tier to more than 5.00% at the higher tiers [18]. The low-tier maintenance margin ratios among these CEX tier parameters (e.g., 0.40%, nominally corresponding to maintenance leverage of about 250x, i.e., $1/0.40\% = 250$) fall below the initial-margin level implied by the leverage cap derived from oracle latency in Section 30.2.3 (the maintenance margin ratio and the latency buffer are different measures and should not be equated directly), and the hard-coded floor of an on-chain system constrains the lower bound of the tier parameters, ensuring that even the lowest-tier margin ratio is not below the system's security baseline. Binance, OKX, and other exchanges adopt similar tiered systems, while Deribit has introduced a portfolio margin model in its options market that dynamically computes net risk exposure through hedging relationships. However, these CEX tiered margin systems have one fundamental difference: the authority to change parameters lies entirely and unilaterally with the platform.

An exchange can adjust tier thresholds and margin ratios without any public-notice procedure, and users are informed only after the parameters take effect. By contrast, an on-chain system ensures the process transparency and auditability of every margin-parameter adjustment through a parameter registry and a governance-voting mechanism, which constitutes the core advantage of on-chain parameterized compliance over CEX dynamic-margin systems.

The top layer is the real-time adjustment of parameterized coefficients. The multipliers and thresholds in the adaptive formula are stored as parameters in the registry contract. When a macroeconomic event triggers a structural change in the market, the governance mechanism can adjust these coefficients so that the margin model captures risk more sharply. For example, during a period of sharply rising expected volatility, the volatility multiplier can be raised to tighten leverage system-wide. This three-tier nested architecture allows regulators to be confident of the system's security floor, allows traders to know clearly the computational logic of margin requirements, and leaves protocol operators the tools they need to respond to unknown risks.

In practice, the parameterized coefficients of a volatility-adaptive formula typically span three dimensions. The first is the volatility-sensitivity coefficient, which controls how much the margin ratio increases for each 1% rise in market volatility. This coefficient might be set at 0.15 in a calm market, but during a period of persistently elevated historical volatility the governance committee might vote to raise it to 0.25 in order to guard against a potential liquidity crisis in advance. The second is the position-size penalty coefficient, which reflects the systemic-risk contribution of large positions to the market. When an individual trader's position size exceeds a certain threshold of market liquidity, this coefficient is automatically triggered, requiring a higher margin ratio. The third is the time-decay coefficient, used to gradually loosen margin requirements after the market returns to calm, avoiding excessive liquidity tightening. The calibration of these coefficients should be based on a target coverage probability—that is, ensuring that, at a given confidence level, the margin can cover the maximum expected price movement over the period from liquidation trigger to completed closure—rather than being set arbitrarily by experience. The combined use of these coefficients forms a multidimensional risk-assessment model capable of capturing both changes in market microstructure and macroeconomic shocks.

While improving capital efficiency, the volatility-adaptive margin model introduces a systemic risk that cannot be ignored: procyclicality. When market volatility rises, the adaptive model automatically raises the margin ratio, forcing leveraged traders to add margin or face liquidation. Large-scale liquidations themselves further intensify market volatility, pushing volatility metrics still higher, which tightens the margin ratio further; this positive-feedback spiral of "rising volatility $\rightarrow$ tightening margin $\rightarrow$ forced liquidation $\rightarrow$ further rising volatility" is the core driving mechanism of a liquidation cascade. During Black Thursday in March 2020, this effect was amply demonstrated empirically in DeFi liquidations. To mitigate procyclicality risk, the engineering design of margin parameterization should introduce a countercyclical buffer mechanism: the margin ratio should respond quickly to rising volatility, but its relaxation should be slow and subject to a "look-back period" constraint (asymmetric decay); the magnitude and rate of a single margin-ratio adjustment should be capped to prevent violent tightening

within a short time; and during low-volatility periods, the margin ratio should be preemptively set above the model's raw output to reserve a buffer against future volatility shocks.

30.3.3 Parameterizing rate parameters

The funding rate mechanism is the core engine by which perpetual futures anchor to the spot price. Its design goal is to correct the deviation between the derivative price and the spot index through periodic funding exchanges between longs and shorts. In an on-chain implementation, the funding rate's computation logic is typically hard-coded, but its operational efficiency and risk boundaries depend heavily on several key parameterized settings.

The settlement frequency determines arbitrageurs' capital-turnover efficiency and the market's responsiveness. Traditional centralized exchanges typically adopt a discrete settlement mechanism every 8 hours, whereas in on-chain protocols, constrained by block-generation time and transaction costs, the parameterized choice of settlement frequency faces different engineering constraints [19]. A higher settlement frequency can anchor the price more tightly but significantly increases the computational overhead of oracle price feeds and state updates. Parameterizing the settlement frequency allows a protocol, as the underlying public chain scales or Layer 2 costs fall, to transition smoothly through governance voting toward higher frequencies and even per-block settlement (in a discrete blockchain architecture, per-block settlement is the finest granularity physically achievable) without restructuring the core trading logic. The effect of shortening the settlement interval is not linear: while a higher settlement frequency improves price-anchoring precision, it also raises the capital-efficiency requirements of arbitrage strategies, accelerates market makers' hedging-frequency needs, and may increase the volatility of each individual rate value—second-order effects that must be fully evaluated when adjusting the parameter.

Parameterizing the upper and lower bounds of the rate serves to prevent systemic collapse under extreme one-sided market conditions. When the spot price fluctuates violently, the theoretical funding rate may spike to extreme levels, subjecting market makers or hedgers to unbearable cash-flow pressure. The smart contract sets an absolute upper and lower bound on the funding rate through parameterization; this band is wide enough under normal conditions to accommodate normal arbitrage space but acts as a circuit breaker when an extreme deviation occurs [20]. These boundary parameters can be configured differently according to the underlying asset's liquidity depth and historical volatility characteristics, and can be gradually loosened by the community as the asset matures. However, setting a rate cap embeds a mechanism-stability trade-off that cannot be ignored: the core function of the funding rate is to correct the basis between the perpetual futures and the spot price through a price signal, and when the rate hits its cap and is truncated, the price-correction mechanism fails, the perpetual futures may become persistently unanchored from the spot price, and this instead leads to larger basis accumulation and an eventual violent correction. The setting of the rate cap must therefore strike a balance between "preventing extreme rate pressure" and "maintaining the effectiveness of price anchoring." One possible alternative is to dynam-

ically tighten the open-interest cap as the rate approaches its upper bound, relieving basis pressure from the demand side by restricting the size of new positions.

Parameterizing the size of the risk buffer pool bears directly on the protocol's ultimate solvency. The funding ratio of the insurance fund, the share drawn from liquidation penalties, and the critical value at which auto-deleveraging is triggered when the insurance fund is depleted are all key parameters for maintaining the system's credit. Linking these parameters to the protocol's total value locked or total open interest, and allowing them to be dynamically adjusted through governance, ensures that the protocol's capital adequacy remains within a safe range as it scales.

In practice, the parameterized settings of the insurance fund must confront a structural problem. In the liquidation mechanisms of both centralized exchanges and on-chain protocols, when the liquidation engine executes a forced liquidation, if insufficient market liquidity causes the actual closing price to be worse than the position's bankruptcy price, the resulting shortfall loss is borne by the insurance fund. However, when the cumulative rate of shortfall losses exceeds the rate at which the insurance fund is replenished, the protocol faces solvency risk. The parameterized settings of the insurance fund should therefore be conservative and cannot be computed based solely on the historical average loss rate. The calibration of the insurance fund's size should not rely solely on historical backtesting, because the history of the crypto market spans little more than a decade and its structure continues to change rapidly, so future maximum shortfall losses will almost certainly exceed the historical record. A more robust approach is to base the calibration on forward-looking stress testing, simulating extreme but plausible market scenarios (such as a major asset dropping 30% within 1 hour while market liquidity evaporates, a major stablecoin depegging and causing collateral values to plunge, or oracles failing simultaneously and causing liquidation delays) and computing the total shortfall loss under those scenarios. The risk metric should adopt a measure capable of capturing tail risk, such as conditional value at risk (CVaR), rather than relying solely on the historical backtest of extreme quantiles.

30.3.4 Parameterizing market-making obligations

In a decentralized derivatives market, the continuous supply of liquidity is the foundation for guarding against price manipulation and liquidation cascades. Centralized exchanges typically constrain the behavior of designated market makers through bilateral legal contracts, whereas in an on-chain environment market-making obligations must be converted into parameterized rules that a smart contract can verify and enforce.

Traditional securities and derivatives exchanges have mature institutional frameworks for market-making obligations. The Chicago Mercantile Exchange's (CME) market maker program requires a designated market maker to maintain two-sided quotes at least 85% of the time during a trading session, with a maximum bid-ask spread not exceeding a cap specified for the particular contract and a minimum quote size on each side that meets a specified number of contracts. The New York Stock Exchange's (NYSE) designated market maker (DMM) system imposes stricter continuous-quoting obligations on specific stocks while providing an obligation-waiver mechanism during

periods of extreme volatility: when an underlying asset triggers a circuit breaker or the market enters a volatility-interruption state, market-making obligations are automatically suspended. These traditional frameworks use legal contracts and regulatory licenses as enforcement backstops, and the consequences of default include fines, suspension of eligibility, and even revocation of the market-making license. On-chain systems convert these obligations from legal contracts into parameterized rules in a smart contract; while this improves execution certainty, it also faces the engineering challenge of designing equivalent incentive and penalty mechanisms in an environment beyond legal jurisdiction.

Minimum depth and maximum spread constitute the core quantitative metrics of market-making obligations. A protocol sets, through the parameter registry, the amount of liquidity that must be maintained within a specific price range and the maximum spread permitted between bid and ask quotes. These parameters are not fixed but are set in tiers according to the market-capitalization size and trading activity of the underlying asset. For major assets, the parameter requirements are stricter, so as to provide execution quality comparable to that of a centralized exchange; for long-tail assets, the parameters are relatively lenient, so as to attract early liquidity providers. Market makers' rewards are tied directly to their attainment rate on these parameterized metrics, and the smart contract automatically computes and distributes rewards each epoch.

In a parameterized market-making-obligation framework, the parameters for minimum depth and maximum spread should be set in tiers according to the characteristics of the underlying asset. For major assets such as Bitcoin and Ethereum, the parameters can be set very strictly—for example, requiring market makers to maintain a bid-ask spread of no more than 3 to 5 basis points (bps) within a certain range around the midprice. The cost structure of on-chain market making differs markedly from that of a centralized exchange: each quote update requires submitting an on-chain transaction and paying a gas fee, and the information asymmetry caused by block latency further intensifies market makers' adverse-selection costs. These factors jointly constrain the range within which on-chain market-making-obligation parameters can be set, making it difficult to reach the sub-1-basis-point spread levels seen on centralized exchanges. For newly listed long-tail assets, the parameters can be relatively lenient in order to attract early liquidity providers. This tiered parameter setting embodies a core principle of on-chain finance: optimizing every participant's experience to the greatest extent without introducing systemic risk. Moreover, to prevent market makers from placing a burst of orders at the end of an evaluation epoch merely to satisfy the obligation requirement, the measurement of market-making obligations should adopt a time-weighted liquidity-presence rate rather than a simple attainment-rate assessment based on an epoch-end snapshot.

Parameterizing obligation-waiver conditions is the protective mechanism of the on-chain market-making scheme under extreme market conditions. When the market experiences violent turbulence, oracle-quote delays, or underlying network congestion, forcing market makers to maintain tight quotes could subject them to severe adverse-selection losses. The protocol introduces a parameterized trigger based on volatility or price deviation; when the market state exceeds the preset normal range, the smart contract

automatically loosens the maximum-spread constraint or temporarily suspends the assessment of market-making obligations. This parameterized waiver mechanism protects the capital of liquidity providers while also avoiding the liquidity vacuum that would result from a collective withdrawal of quotes by market makers. However, an automated waiver mechanism faces two engineering-level challenges. The first is manipulation-resistant design: if the waiver trigger condition is based on instantaneous volatility, a market maker might strategically manufacture a volatility signal by submitting a large market order during a thin-liquidity period, thereby triggering the waiver to escape its market-making obligation. The waiver trigger should therefore use a time-weighted average volatility combined with cross-validation across multiple oracles. The second is the liveness guarantee: during extreme market conditions, on-chain infrastructure is most prone to congestion, yet this is precisely the moment when market makers most need the protection of a waiver, and the waiver-triggering transaction itself may fail to be confirmed on-chain in time due to gas competition. For this reason, the system should design a time-based automatic waiver as a fallback mechanism: if no quote-update transaction from a market maker is detected across several consecutive blocks, the system automatically treats the waiver state as in effect, without requiring the market maker to proactively submit a waiver request.

30.3.5 The governance mechanism for parameter adjustment

The effectiveness of parameterized compliance ultimately depends on the power structure that modifies the parameters. If parameters can be arbitrarily tampered with by a handful of insiders, all promises of transparency lose their meaning. Parameter adjustment must therefore be placed within a rigorous governance framework that balances immutability against flexible response.

Parameter adjustment in an on-chain protocol is subject to three tiers of governance constraint. The first tier is routine adjustment executed automatically by code—for example, a volatility metric computed from oracle price feeds automatically updating the margin multiplier without human intervention. The second tier is the governance review of structural parameter changes, which requires an on-chain proposal and community vote and is executed only after a timelock delay [16]. The third tier is an emergency multisig committee mechanism for extreme market crises, which permits rapid adjustment of key parameters within a strictly delimited scope [21]. The complete design and engineering implementation of these three tiers of governance constraint are developed systematically in Section 30.6.

30.4 Reporting-based compliance

Within the three-tier compliance spectrum, reporting-based compliance has the shallowest embedding but the broadest coverage. For requirements whose ex ante restriction is technically difficult to define precisely and whose forcible interception could impair the system's normal operation, reporting-based compliance exploits the immutability and global visibility of on-chain data, converting them into data-driven ex post monitoring and automated auditing that satisfy the regulatory demand for transparency without

adding friction to transaction execution (the four core scenarios are discussed in Section 30.4.1).

30.4.1 When reporting-based compliance applies

As set out in the three-tier spectrum of Section 30.1.3, hard-coded compliance guards non-negotiable security baselines and parameterized compliance adjusts operational rules that must vary flexibly with market conditions; but not all regulatory requirements are suited to being implemented through ex ante restriction. In some scenarios, ex ante restriction is not only technically difficult to define precisely but could also seriously and adversely affect the system's normal operation and market efficiency. For such requirements, reporting-based compliance offers a superior engineering solution: converting compliance from a behavioral constraint into ex post monitoring and automated auditing based on on-chain data.

The core logic of reporting-based compliance is not to restrict participants' specific behaviors but to ensure the visibility, traceability, and analyzability of all behaviors. This mechanism is especially suited to four core scenarios. The first is transaction monitoring and anomaly detection. In complex financial markets, malicious behaviors such as wash trading, price manipulation, or insider trading are often difficult to intercept with a simple rule before a transaction occurs. Forcibly imposing ex ante interception is highly prone to false positives, thereby impeding legitimate market-making and arbitrage activity. The second is proof of reserves. Proving that a protocol holds enough assets to cover user liabilities is a system state that requires continuous verification, not a static metric controllable through a single parameter. The third is risk disclosure. Displaying the system's overall risk exposure and an individual account's distance to liquidation in real time to market participants falls within the category of information accessibility; its value lies in reducing information asymmetry rather than directly restricting trading. The fourth is regulatory reporting. Providing regulators with a complete data record of the system's operation is the basis for satisfying compliance-audit requirements.

In all four scenarios, reporting-based compliance fully exploits the underlying properties of blockchain technology. The immutability of on-chain data ensures the authenticity of historical records, while the global visibility of the data breaks down the data silos pervasive in traditional financial systems. By converting these four requirements into structured extraction and automated analysis of on-chain data, reporting-based compliance not only reduces the system's operating friction but also surpasses the traditional external-enforcement model in both the depth and breadth of compliance.

30.4.2 Transaction monitoring and anomaly detection

Transaction monitoring at a traditional centralized exchange depends heavily on internal data systems, and when regulators conduct an audit, they can obtain only the data snapshots or aggregate reports that the exchange selectively provides. This architecture entails systemic information asymmetry: the completeness and authenticity of the data depend entirely on the honesty of the centralized institution. By contrast, on-chain systems have an inherent architectural advantage in transaction monitoring. All order submissions, execution records, fund transfers, and liquidation events are permanently

recorded on the distributed ledger in the form of cryptographic proofs. For a fully on-chain system, this nearly complete data coverage allows the transaction-monitoring system to reconstruct historical market states with high precision (for hybrid and app-chain architectures whose core state runs on the consensus layer or off-chain, the degree of coverage depends on the observability of that state).

On this foundation of high-precision data, the effectiveness of automated anomaly-detection models is significantly enhanced. In an on-chain environment, every transaction is bound to a specific cryptographic address, and the flow path of funds is fully transparent. By applying machine-learning algorithms and graph-network analysis, a monitoring system can automatically identify complex market-manipulation patterns. For example, if the same address or a cluster of related addresses repeatedly trades on both the buy and sell sides within a very short time, the system can quickly flag it as potential wash trading; or if a specific address builds a large leveraged position that sharply departs from its historical behavior just before a major protocol upgrade or governance proposal is announced, this pattern can be captured in real time and flagged as suspected insider trading [22]. This automated detection mechanism does not introduce additional latency into the consensus path of transaction execution but is completed asynchronously by independent monitoring nodes after the data is committed to the chain. However, the precision of on-chain anomaly detection still faces inherent technical bottlenecks. In an order-book environment, the legitimate two-sided quoting activity of a market maker and wash trading are highly similar in their on-chain data form, since both manifest as frequent trading by the same entity on both the buy and sell sides. Moreover, wash traders can evade correlation analysis by creating a large number of mutually unrelated addresses, and this Sybil attack subjects detection methods based on address clustering to a fundamental accuracy constraint. On-chain transparency provides a complete data foundation, but a significant analytical gap remains between the data and a reliable determination of a violation.

More importantly, the openness of on-chain data gives rise to an entirely new compliance paradigm: crowdsourced compliance. Under the traditional framework, transaction monitoring is the exclusive prerogative of regulators or an exchange's internal compliance department. In an on-chain system, anyone—independent researchers, competitors, data-analytics firms, and even ordinary users—can obtain the complete transaction dataset and run their own monitoring algorithms. This distributed oversight significantly raises the probability that malicious behavior will be discovered. When compliance is no longer the exclusive responsibility of a single centralized entity but evolves into a public activity in which the entire community participates, the system's overall resistance to malfeasance is markedly strengthened. However, the effectiveness of crowdsourced monitoring is constrained by the free-rider problem: when everyone can monitor, each individual lacks the economic incentive to bear the cost of monitoring, and the result may be that no one performs systematic in-depth analysis. To turn crowdsourced compliance from a theoretical advantage into a practical effect, complementary economic-incentive mechanisms must be designed, such as a bounty pool for effective reports and a requirement that reporters stake a bond to deter malicious false reports.

30.4.3 Automating proof of reserves

In the development history of centralized cryptocurrency exchanges, the evolution of proof-of-reserves mechanisms deeply reflects the transformation of trust architecture. Early centralized exchanges relied entirely on reputational endorsement, until a series of severe incidents of customer-asset misappropriation led the industry to widely adopt Merkle-tree-based proof of reserves. However, this proof of reserves, voluntarily initiated by a centralized institution, has significant limitations. It can typically prove only that, at a specific time snapshot, the known on-chain addresses controlled by the exchange contained a specific amount of assets; it cannot prove that these assets were not misappropriated at points outside the snapshot, still less fully rule out the possibility that the exchange has hidden liabilities [23]. In essence, a centralized exchange's proof of reserves is a discrete audit activity rather than an intrinsic property of the system architecture.

On-chain financial systems restructure the implementation logic of proof of reserves through the self-custody property of smart contracts. In a fully on-chain architecture, users' asset balances and the protocol's total reserves are all publicly queryable global state variables. Anyone can independently compute the system's total liabilities and total assets at any moment and verify whether the latter is greater than or equal to the former—without relying on a report from a third-party auditor and without waiting for the exchange to release a quarterly snapshot. The marginal cost of this verification process approaches zero and is not controlled by any centralized entity.

Centralized exchanges are themselves drawing on on-chain technology to improve their proof-of-reserves mechanisms. In November 2022, Binance launched a Merkle-tree-based proof of reserves, and in February 2023 it introduced zk-SNARKs to strengthen it, forming a hybrid scheme combining Merkle trees and zk-SNARKs. Users can verify the path of their own leaf node within the Merkle tree to confirm that their assets are included in the total-reserve calculation, while the zero-knowledge proof is used to prove that all user balances are non-negative and that their sum matches the on-chain address balances. OKX (using zk-STARKs) has also launched a zero-knowledge-proof-based scheme, while Bybit and others provide verifiable-reserve schemes based on Merkle trees and third-party audits. This trend indicates that the technical standards for reserve transparency established by on-chain systems are being fed back to centralized institutions, pushing up the compliance baseline of the entire industry. However, CEXs' zk-PoR schemes still rely on the exchange to proactively initiate the proof and cannot cover hidden liabilities; their architectural-level limitations differ fundamentally from the continuous guarantee of an on-chain system.

Thus, an on-chain system's proof of reserves achieves a leap from a one-time audit to a continuous guarantee. The data itself is a continuous, immutable record, and the proof process is embedded automatically into the logic of reading the data. As long as the consensus mechanism of the underlying blockchain is not compromised, the reserve data recorded in the smart contract possesses a high degree of certainty. This architectural-level guarantee substantially compresses the room a centralized institution has to falsify balance-sheet data, making reserve transparency an inherent, default property of the system.

The description of proof of reserves above applies mainly to spot-custody protocols, whose liability calculation is relatively simple—that is, total assets need only be no less than total deposits. For derivatives protocols such as perpetual futures, however, the engineering implementation of proof of reserves is far more complex. The "total liabilities" of a derivatives protocol include not only users' margin balances but also the unrealized profit and loss (P&L) of all active positions, the funding rate pending settlement, and the shortfall losses already borne by the insurance fund. Because unrealized P&L changes in real time with the mark price, precise liability calculation requires traversing all active positions at each point in time and revaluing them at the current mark price. This means that a derivatives protocol's proof of reserves is not a simple state query but a computation-intensive process involving global state traversal and real-time revaluation, whose engineering complexity and computational overhead should not be underestimated.

30.4.4 Real-time risk disclosure

Risk disclosure is one of the core requirements of consumer protection. On traditional derivatives-trading platforms, risk disclosure often takes the form of an after-the-fact static report or a disclaimer at account opening. A trader holding complex positions finds it difficult to intuitively assess their real-time risk exposure, especially when violent market swings cause margin requirements to change dynamically. The reporting-based compliance mechanism of an on-chain system builds a dynamic risk-reporting system by converting underlying state data into a real-time, trader-facing view.

This real-time risk disclosure spans several key dimensions. The system can precisely compute and display a trader's current margin ratio and the specific price distance to the trigger of a forced liquidation. If the underlying asset's price moves adversely by a specific magnitude, the trader can precisely compute the percentage distance from their current position to the liquidation-trigger price. In addition, the system can display in real time the current balance of the insurance fund and its ratio to total open interest, allowing traders to assess the system's capacity to absorb shortfall losses under extreme market conditions [19]. Under an auto-deleveraging mechanism, a trader can even view their position in the deleveraging queue in real time, forming a prior judgment about the potential risk of passive closure.

Providing this high-granularity real-time data essentially surpasses the passive compliance traditionally undertaken merely to satisfy regulatory inspection. It constitutes a mechanism of responsible information provision to traders and directly improves the system's transparency and user experience. By converting the complex state hidden deep within the matching engine and liquidation logic into intuitive risk metrics, on-chain systems achieve a structural improvement over centralized exchanges on the key dimension of information accessibility, enabling traders to manage risk on a fully informed basis.

30.4.5 The regulatory interface

In the traditional financial compliance model, persistent gaming and friction exist between regulators and regulated entities. Regulators must periodically dispatch auditors

into an institution or require the institution to submit cumbersome compliance reports in a specific format. This model not only incurs substantial compliance costs but also suffers from severe time lag, so that regulators often discover the first signs of a problem only through ex post review after a systemic risk has already erupted.

On-chain systems offer an entirely new technical path to resolve this predicament: designing a standardized regulatory interface for regulators. Its core idea is that, rather than having regulators laboriously inspect the system, the system should proactively and in real time report its operating status to regulators. By exposing a specific application programming interface (API), regulators can at any time pull key metrics such as the system's total open interest, the distribution of the liquidation queue, the adequacy of the insurance fund, and the margin coverage ratio for specific assets. This mechanism eliminates information asymmetry, because the data regulators read through the interface is fully homologous with, and synchronized to, the system's actual operating state.

Figure 30-4 presents the end-to-end technical pipeline of reporting-based compliance, from data collection and automated auditing through to outputs for three audiences—traders, the public, and regulators—driven entirely by code, eliminating the reliance on manual data organization and report preparation found in traditional compliance workflows.

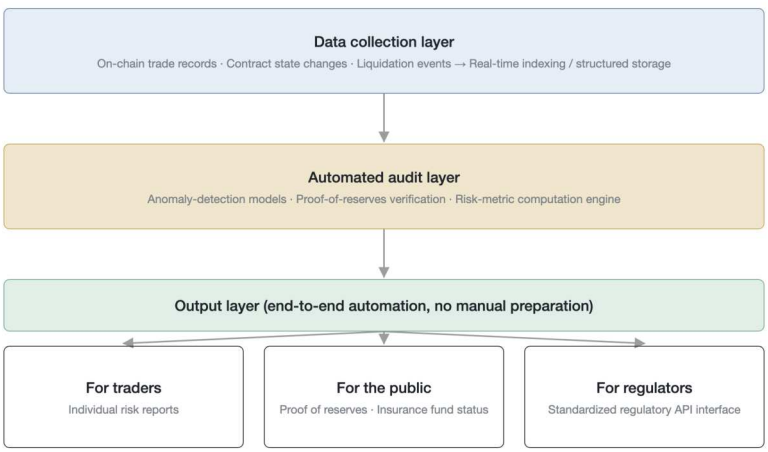

Figure 30-4. The three-stage pipeline of reporting-based compliance, from data collection and automated auditing to outputs for traders, the public, and regulators [3][22]

This interface-based automated reporting mechanism brings multiple significant benefits. It significantly reduces a protocol's operational compliance costs, because report generation is driven entirely by code and requires no human intervention. At the same time, regulators gain real-time insight synchronized with the system's state, enabling them to issue early warnings during the risk-accumulation stage rather than merely assigning blame after the fact. To be sure, the broad application of this mechanism still faces engineering challenges, particularly because regulators in different jurisdictions

require different data formats and granularity, which calls for the industry to jointly promote the standardization of regulatory data interfaces. A further key direction for reporting-based compliance is to protect ordinary traders' privacy through cryptographic techniques such as zero-knowledge proofs while still giving regulators adequate transparency.

The effectiveness of reporting-based compliance depends on the global visibility of on-chain data, but this visibility conflicts structurally with user privacy: the contradiction between regulators' demand for penetrating visibility into traders' identities and the sources of their funds, and traders' basic need for financial privacy, cannot be resolved through a simple trade-off but requires a cryptographic-level technical reconciliation, which the next section addresses specifically.

30.5 The technical reconciliation of privacy and compliance

Embedding compliance rules into an on-chain system confronts a core tension: regulators demand full penetrating visibility into participants' identities and fund flows, whereas the global visibility of a public blockchain means that any identity linkage would expose a user's entire transaction history. Under the traditional framework, this contradiction between privacy protection and compliance requirements can be handled only by choosing one over the other. The maturation of zero-knowledge-proof technology offers an engineering path to reconcile this contradiction, enabling a trader to prove to the system that they satisfy specific compliance conditions without exposing the underlying identity data.

30.5.1 The structural conflict between compliance and privacy

The cornerstone of the traditional financial-regulatory system is complete knowledge of participants' identities, whereas the native design of crypto-asset markets is built on decentralization and pseudonymity. This architectural difference produces a structural conflict between know-your-customer (KYC) requirements and traders' demand for privacy protection. The logical starting point for regulators is information transparency—collecting, storing, and monitoring traders' personal identity information and fund flows in order to guard against illicit activities such as money laundering, terrorist financing, and sanctions evasion. Within this framework, any technology or mechanism that impedes information penetration is regarded as a potential compliance risk, and anonymous transactions therefore become the primary target of regulatory intervention.

However, directly implementing the traditional information-collection model on the transparent ledger of a public blockchain would bring severe privacy-leakage risk. The global visibility of a public blockchain means that once a user's real identity is bound to an on-chain address, all of their historical transactions, asset balances, interacted protocols, and even fund-flow patterns become public to everyone. This mandatory transparency not only exposes a trader's commercial secrets and trading strategies but also subjects them to targeted cyberattacks, phishing scams, and even threats to real-world personal safety. When traders use tools such as mixers, privacy coins, or multiple addresses to sever the link between their identity and their on-chain activity, this is

not necessarily for illicit purposes but rather to rebuild basic financial privacy on a transparent ledger.

This opposition between compliance and privacy is especially evident in current regulatory policy. The EU's Markets in Crypto-Assets (MiCA) regulation requires crypto-asset service providers to be able to identify the holders and transaction histories of assets with built-in anonymization features; otherwise, the platform must block trading in such assets [24]. Similarly, the sanctions imposed on Tornado Cash by the U.S. Treasury's Office of Foreign Assets Control (OFAC) reflect regulators' tendency to equate anonymity directly with an illicit financial instrument [25]. However, the legal basis for this position has been challenged in court. In November 2024, the U.S. Court of Appeals for the Fifth Circuit ruled in Van Loon v. Department of the Treasury that OFAC's sanctions on Tornado Cash's immutable smart contracts exceeded its statutory authority, on the grounds that immutable smart contracts do not constitute "property" under the International Emergency Economic Powers Act (IEEPA). This ruling provides an important precedent for the legal positioning of embedded compliance—namely, that immutable on-chain compliance logic may not be subject to the same sanctions-review framework as mutable systems—but it also raises a new question of how "immutability" should be defined under an upgradeable proxy-contract architecture. This either-or dichotomy confronts on-chain finance with a dilemma: either abandon privacy entirely to satisfy compliance requirements, reducing the public blockchain to a high-risk transparent database; or refuse compliance to protect privacy, thereby marginalizing itself from the mainstream financial system.

30.5.2 Compliance applications of zero-knowledge proofs

The evolution of cryptographic technology, and in particular the maturation of the zero-knowledge proof, provides an engineering solution to reconcile the contradiction between compliance and privacy. A zero-knowledge proof allows a prover to convince a verifier of the truth of a statement without revealing any additional information beyond the fact that the statement is true. In the compliance scenarios of on-chain finance, this property achieves a paradigm shift from "information disclosure" to "fact verification": a trader can prove to a smart contract or a regulatory node that they satisfy specific compliance conditions without submitting any underlying identity data or transaction details.

This "prove-without-revealing" mechanism significantly changes the logic of processing compliance information. Take anti-money-laundering review: the traditional model requires a user to submit a passport, proof of address, and records of the source of funds, which the platform manually reviews and stores as sensitive data. Under a zero-knowledge-proof-based framework, the user need only generate a cryptographic proof locally attesting that "I am not a citizen of a sanctioned country" or "the source of my funds does not include any flagged high-risk address." Acting as the verifier, the smart contract need only confirm the validity of the proof through mathematical computation to admit the transaction, and the entire process involves no on-chain transfer or storage of any specific nationality or historical transaction record.

A study based on Monte Carlo simulation (Decker, 2025, an SSRN preprint that has

not been peer-reviewed) estimates that a zero-knowledge-proof-based KYC verification framework can reduce the volume of exposed user data by approximately 97% and, when combined with an artificial intelligence (AI) model, can achieve approximately 96.7% anomaly-detection accuracy within its stipulated simulation scenario [26]. These figures, however, come from a single simulation study that has not been independently replicated; moreover, zero-knowledge proofs themselves constrain the scope of data exposure rather than directly improving detection accuracy (the latter depends on the AI model with which they are combined). This technology offers not only significant advantages in privacy protection but also eliminates, at the system-security level, the single-point-of-failure risk of a centralized institution acting as a data honeypot. Because compliance verification is converted into pure mathematical computation, an on-chain financial system can build compliance requirements into its architecture without bearing the legal and security responsibility of safeguarding vast amounts of sensitive personal information. This is a core dimension on which on-chain finance surpasses the traditional financial system in the design of compliance mechanisms.

The applicable boundary of zero-knowledge-proof compliance solutions must be honestly delimited. At the current stage, the compliance obligations that zero-knowledge proofs can effectively satisfy are concentrated mainly in the onboarding stage, including sanctions-list screening, accredited-investor verification, and basic anti-money-laundering risk rating. However, the full set of anti-money-laundering and counter-terrorist-financing (CTF) compliance obligations extends far beyond onboarding review. The Financial Action Task Force's (FATF) "Travel Rule" requires that the identity information of both the sender and the receiver be transmitted in virtual-asset transfers, which conflicts structurally with the core logic of zero-knowledge proofs, "proof without exposure." The obligation of continuous transaction monitoring requires the compliance-obligated party to be able to access underlying transaction data in order to identify suspicious patterns, and the obligation to proactively file suspicious transaction reports further requires disclosing the detailed information of specific transactions to regulators. Under the current technical framework, these obligations cannot yet be satisfied by a pure zero-knowledge-proof solution. Acknowledging this boundary does not weaken the value of zero-knowledge proofs but delineates a realistic scope for their engineering application, avoiding the erosion of regulatory trust that overpromising would cause.

Figure 30-5 presents the complete workflow of this "prove-without-revealing" mechanism in an on-chain system: off-chain, a trusted KYC provider verifies identity and issues a cryptographic credential containing only specific attribute claims; the user then generates a zero-knowledge proof locally on that basis; and the on-chain smart contract admits the transaction once it confirms the proof's validity through mathematical computation alone—the entire process involving no on-chain transmission or storage of any identity information.

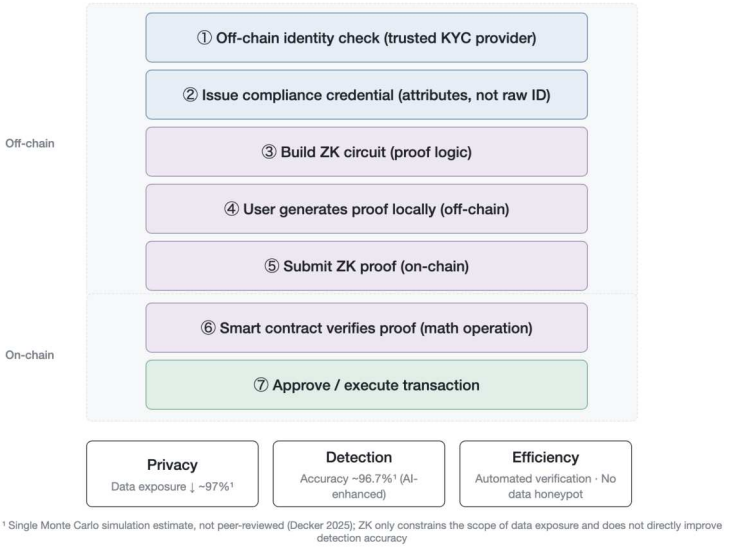

Figure 30-5. The workflow of zero-knowledge-proof-based compliance credentials [26] (the 97% and 96.7% figures shown are single-simulation estimates from Decker 2025 and are not peer-reviewed)

30.5.3 Designing compliance credentials

To turn the theoretical advantages of zero-knowledge proofs into an executable engineering scheme, a system must introduce a modular "compliance credential" design. This design follows the principle of minimal necessary information, deconstructing complex identity attributes into independent, separately verifiable claims and thereby avoiding the "all-or-nothing" data-bundled submission of traditional identity verification. The lifecycle of a compliance credential spans three key stages—issuance, verification, and revocation—which together constitute a closed-loop on-chain identity-management system.

In the issuance stage, a trusted off-chain entity (such as a licensed KYC provider or a government agency) is responsible for verifying the user's real identity. Once verification is complete, this entity does not put the user's identity information on-chain but instead issues a cryptographic credential containing specific attribute claims and digitally signs it with its private key. These credentials are typically stored in the user's local wallet, under the user's full control. For example, a credential might contain only the claim that "this user has passed a level-one anti-money-laundering review" or "this user is an accredited investor," without any redundant information such as name or ID number.

In the verification stage, when a user attempts to interact with a compliance-constrained smart contract, the contract states a specific attribute requirement. The user uses the locally stored credential to generate a zero-knowledge proof attesting that they hold a valid credential, issued by a trusted issuer, that satisfies the contract's requirement. The smart contract verifies the mathematical correctness of the proof and the validity of the issuer's signature, and if both pass, it automatically authorizes the transaction to execute. The entire verification process is completed on-chain, achieving a decentralized

and automated compliance check.

The revocation mechanism is an indispensable security baseline in compliance-credential design. When a user's compliance status changes (such as being placed on a sanctions list or the credential expiring), the issuer must be able to invalidate the already-issued credential. This is typically implemented by maintaining an on-chain revocation registry or accumulator. When generating a zero-knowledge proof, the user must prove not only that the credential is valid but also, simultaneously, that it is not included in the latest revocation list. This design ensures the capacity to update compliance status dynamically while maintaining the decentralized nature of the verification process.

30.5.4 Engineering challenges and progress

Although zero-knowledge proofs perfectly reconcile the contradiction between privacy and compliance in theory, their practical engineering deployment still faces significant technical and economic challenges. The foremost bottleneck lies in computational overhead and proof-generation time. Generating a zero-knowledge proof is a highly computation-intensive process, and for a circuit containing complex compliance logic, generating a proof on a mobile device or an ordinary personal computer may take seconds or even minutes. This latency is unacceptable in trading scenarios that demand high-frequency, low-latency execution. In addition, although verifying a proof is relatively lightweight, executing the verification logic on a mainnet such as Ethereum still consumes considerable computational resources, thereby pushing up users' transaction costs.

The complexity of circuit design constitutes another engineering obstacle. Converting complex laws, regulations, and compliance requirements into mathematical constraints in a zero-knowledge-proof circuit requires spanning the two distinct professional domains of law and cryptography. Any logical flaw in the circuit could allow the compliance mechanism to be bypassed, and such a bypass is extremely difficult to discover after the fact because of the zero-knowledge property. The development, auditing, and formal verification of compliance circuits are therefore costly, which limits their rapid iteration and broad deployment.

Despite the many challenges, industry exploration in privacy-preserving compliance has made substantial progress. Polygon ID, the first identity solution to allow users to generate zero-knowledge proofs from off-chain credentials, has built a complete verifiable-credential ecosystem that enables decentralized applications to implement access control without collecting user data [27]. Meanwhile, fully decentralized zkKYC solutions launched by projects such as zkMe further minimize the trust assumptions of identity verification, ensuring the censorship-resistance and privacy of the credential-issuance process through a decentralized oracle network and multi-party computation [28]. These engineering practices indicate that zero-knowledge-proof-based embedded compliance is moving from the proof-of-concept stage toward large-scale application, laying the technical foundation for building the next generation of on-chain financial infrastructure that both satisfies regulatory requirements and defends user privacy.

30.6 Engineering the governance layer

When compliance rules are embedded into smart contracts in a hard-coded or parameterized form, the system gains a sense of immutable security but simultaneously loses the flexibility to respond to unknown risks and adapt to regulatory change. If the design stage fails to provide a secure upgrade channel for these rules, the system will lose its usability in a rapidly evolving market environment because of excessive rigidity. This predicament raises the core question of this section: how can a governance mechanism be designed within an architecture that pursues trustlessness so as to guarantee both immutability and secure upgradeability?

30.6.1 Immutability versus the need to upgrade

The core value proposition of a smart contract is immutability—once code is deployed, its execution logic is free from interference by any centralized entity. In on-chain financial systems, this property is the cornerstone of building user trust, because it eliminates the risk that an operator could misappropriate assets or unilaterally modify liquidation rules. However, a fully immutable system has proven fragile in engineering practice. The complexity of financial markets, the potential code vulnerabilities of smart contracts, and continuously evolving regulatory requirements jointly constitute a rigid demand for system upgradeability [29].

This contradiction is especially pronounced in the process of embedding compliance rules. Although hard-coded compliance (such as the absolute leverage cap and asset-segregation logic) provides the highest level of certainty, once a logical flaw is discovered or an extreme market condition arises, these protective measures may, absent an upgrade mechanism, instead become the trigger for the system's collapse. For example, when the operating environment of the underlying blockchain changes, or when regulators adjust the compliance standards for specific assets, a fully immutable contract would force the entire system to undergo a destructive hard fork or asset migration [29].

The engineering design of the governance layer is therefore essentially a precise calibration of the distribution of power. Granting an administrator key unrestricted upgrade authority means reverting to the trust model of a traditional centralized exchange; completely abandoning the capacity to upgrade places the system in an unrepairable and dangerous position. In the blueprint of a trustless architecture, the governance layer (Layer 5) must serve as the connective layer between static code and dynamic reality. This requires converting governance itself into a verifiable on-chain process, so that every rule modification or parameter adjustment is strictly constrained by cryptographic and game-theoretic mechanisms.

30.6.2 The dual architecture of timelock and emergency powers

To balance immutability against flexible response, on-chain governance has, in engineering practice, formed a dual architecture: a routine governance path controlled by a timelock, and an emergency-powers path held by a multisignature (multisig) committee. This design acknowledges the fundamental difference in time sensitivity between rou-

tine operational upgrades and extreme-risk response, and configures different security safeguards for each [30].

Figure 30-6 contrasts the operating logic of the dual governance architecture: the routine path is executed after a community vote and a timelock delay, providing a window for public review and allowing dissenting users to withdraw their funds and exit; the emergency path allows a multisig committee to bypass the timelock and immediately execute defensive operations, while triggering mandatory ex post public disclosure. The figure systematically compares the trigger conditions, authority boundaries, and accountability mechanisms of the two paths.

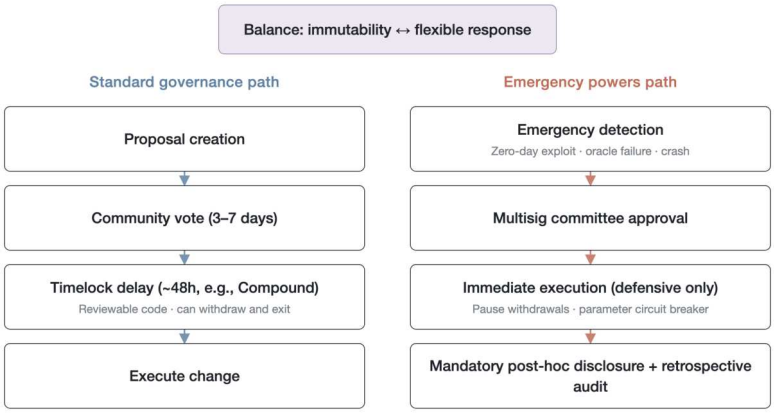

Figure 30-6. The dual governance architecture of timelock and emergency powers [30][31]

The routine governance path applies to parameter adjustments, new-feature deployments, and non-urgent code upgrades. On this path, the timelock mechanism plays the core defensive role. After a governance proposal passes, its execution code does not take effect immediately but is placed within a mandatory waiting period (typically around 48 hours—Compound, for instance, uses 48 hours, and some protocols use longer). This delay serves a dual purpose: on the one hand, it provides the community a window to review the code about to be executed, ensuring that the proposal's content is consistent with the actual execution logic; on the other hand, if some users disagree with the change, the timelock gives them ample time to withdraw their funds and exit the system [31]. During the timelock period, if malicious code or a serious vulnerability is discovered in the proposal, the community can cancel the execution through a preset veto mechanism.

The emergency-powers path is dedicated to scenarios requiring immediate intervention, such as a zero-day-vulnerability attack, a serious oracle failure, or an extreme market crash. In such cases, a 48-hour delay could allow the system's funds to be completely drained. The architecture therefore typically sets up an emergency committee controlled by a multisig, which is granted the power, under specific conditions, to bypass the timelock and immediately execute defensive operations such as pausing the system or triggering a parameter circuit breaker [32].

However, the existence of emergency powers inevitably introduces centralization risk. To limit the abuse of this power, the engineering design must impose strict constraints. The scope of the emergency committee's authority is typically hard-coded and limited to defensive operations (such as being able only to pause withdrawals, not to transfer funds). More importantly, any exercise of emergency power must trigger an ex post public-disclosure and retrospective-audit procedure. If the community determines in an ex post review that the emergency operation was improper, it can replace committee members or restore the system state through the routine governance path. This mechanism of "ex ante authorization, ex post accountability" constitutes the key to safeguarding the trust baseline within the dual architecture.

In a multi-protocol composable on-chain financial ecosystem, the emergency-pause mechanism also faces a risk dimension that transcends the boundary of a single protocol: cross-protocol spillover effects. When one protocol pauses its liquidation function, other protocols that depend on its price signal may experience an oracle-data interruption; when one protocol pauses withdrawals, other protocols that use its assets as collateral may trigger a cascade of liquidations because the collateral is frozen. To minimize this spillover, the engineering design of the emergency pause should adopt a tiered strategy, imposing differentiated restrictions by functional module rather than a global shutdown. For example, when facing an attack, one can pause only new position openings while retaining closing and withdrawal functions; when an oracle fails, one can freeze only the specific trading pairs that depend on that oracle rather than the entire system. This granular control of tiered pausing is a key design element for the emergency-powers architecture to remain effective in a composable ecosystem.

30.6.3 The proxy contract pattern and governance constraints

"Hard-coding" requires that rules cannot be violated, while "upgradeability" requires that rules can adapt to change. These two seemingly contradictory demands are reconciled in modern smart-contract engineering through the proxy contract pattern. The proxy pattern separates the system's state (such as a user's margin balance) and its business logic (such as the specific compliance rules) into two independent contracts [33].

Users always interact with the proxy contract, which forwards all function calls to the implementation contract through the underlying delegatecall instruction. The implementation contract contains all the hard-coded rules and business logic. In day-to-day operation, the address of the implementation contract is fixed in a storage slot of the proxy contract, and at this point all rules exhibit complete rigidity, with no one able to circumvent or violate these hard-coded constraints.

When a hard-coded rule genuinely needs to be updated, the system can rewrite the implementation-contract address pointer stored in the proxy contract, redirecting it to a brand-new implementation contract that contains the new rules (Figure 30-7). All user interactions always point to the proxy contract, whose address never changes, and the proxy forwards the calls to the current implementation contract through delegatecall; an upgrade requires only modifying this implementation-address pointer to replace the entire business logic without migrating user assets and state data.

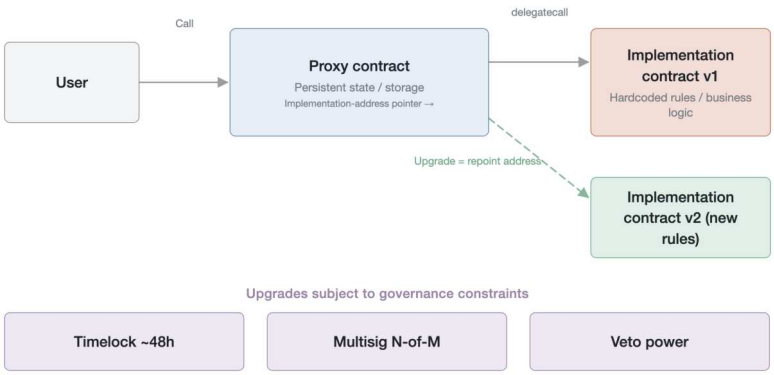

Figure 30-7. The upgradeable hard-coded architecture of the proxy contract pattern [33]

To prevent the abuse of upgrade authority from undermining the trust foundation of hard-coding, the upgrade process must be strictly controlled by the governance layer—which is precisely the core application scenario of the timelock and emergency-powers dual architecture discussed in the previous section: after an upgrade proposal is approved, it can take effect only after the mandatory timelock delay, multisig authorization, and veto procedures described in that section, whose mechanism details are not repeated here. Through this combination of the proxy pattern and governance constraints, an on-chain system achieves a balance between the rigidity of day-to-day operations and the flexibility of long-term evolution. Rules are hard-coded and inviolable at every specific moment, but over an extended time dimension the system possesses the ability to iterate and evolve through a rigorous consensus procedure. The proxy contract pattern gives the term "hard-coding" two levels of meaning in this chapter. The first is "absolute hard-coding": constraints written into the proxy contract's own logic that cannot be modified through any upgrade mechanism, such as the fundamental permission structure for moving assets. The second is "version-level hard-coding": constraints that cannot be violated within the current implementation-contract version but can be modified by replacing the implementation contract with a new one through a governance upgrade. The "hard-coded compliance" discussed in the three-tier compliance spectrum in fact covers both levels, and when assessing the strength of a specific protocol's compliance guarantee, one must distinguish which level its key rules belong to.

30.6.4 Governance attacks and defenses

As governance tokens have been widely adopted in DeFi, the governance layer itself has become a new vector for attackers to gain control of a system and plunder funds. Unlike a technical attack that exploits a code vulnerability, a governance attack fully follows the rules the system sets, passing a malicious proposal through legitimately acquired voting power. Understanding these distinctive threat models is a prerequisite

for designing effective defense mechanisms.

Figure 30-8 organizes the main governance attack vectors (flash-loan voting, whale manipulation, and collusive vote-buying) and their corresponding three-tier escalating security barriers: architectural defense (snapshot voting and timelock), mechanism defense (quadratic voting), and economic defense (governance insurance).

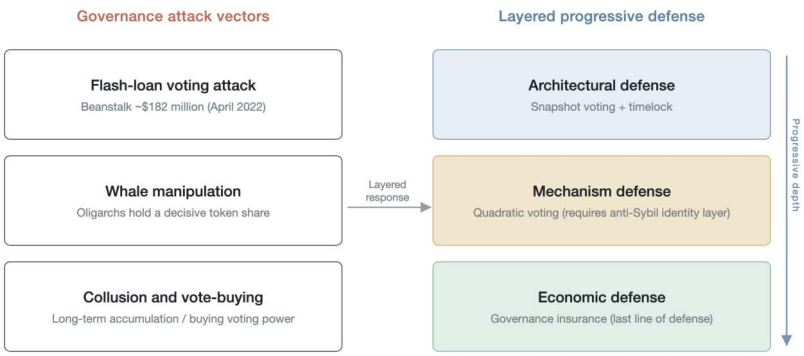

Figure 30-8. The threat model of governance attacks and the multi-layer defense system [34][35]

The flash-loan voting attack is a high-severity threat currently facing the governance layer. An attacker uses an uncollateralized flash loan provided by a lending protocol to borrow a huge quantity of governance tokens within a single block, instantly gaining overwhelming voting power, passing and executing a malicious proposal (such as transferring treasury funds to the attacker's address), and then repaying the loan within the same block (the April 2022 Beanstalk incident used exactly this technique to drain approximately $182 million) [34]. This attack exploits the blind spot of traditional voting mechanisms along the time dimension.

Against flash-loan attacks, the first-tier architectural defense typically adopts a combination of snapshot voting and a timelock. The snapshot mechanism requires the system to record the token balances of all addresses in the block immediately preceding the proposal's creation, and to use these as the basis for voting weight. Because a flash loan must be borrowed and repaid within the same block, the snapshot mechanism prevents an attacker from using flash-loan funds to influence the voting weight of a historical block. A snapshot neutralizes only the single-block flash-loan variant; attacks that borrow across multiple blocks, or that purchase tokens on the spot market before voting, remain feasible—which is precisely why the timelock and veto power must serve as the actual backstop. In addition, the timelock mechanism breaks the synchrony between voting and execution, so that even if an attacker manages to pass a malicious proposal, they must wait until the delay period ends before it can be executed; this not only increases the attack's capital cost but also provides defenders a window to intervene [35].

Whale manipulation and collusive vote-buying constitute another kind of long-term governance threat. When a few entities hold a token share sufficient to determine a pro-

posal's outcome, the system's decision process degrades into oligarchic decision-making. To mitigate this problem, quadratic voting has been introduced as a mechanism defense. Quadratic voting was first proposed by Lalley and Weyl [36]: the square of the number of votes a participant allocates to an option equals the voting credits or token cost they expend [37][38]. This nonlinear cost function significantly increases the marginal cost of accumulating votes, making it difficult for a few whales to easily overwhelm the combined will of numerous retail participants, thereby restoring a degree of balance to governance. However, the theoretical effect of quadratic voting is severely constrained in practice by the voter-participation rate. Voter turnout in mainstream DAO governance is typically below 10%, and in a low-participation environment a whale can still dominate the voting outcome with a relatively small outlay even in the face of nonlinear voting costs. In addition, the on-chain effectiveness of quadratic voting also depends on a Sybil-resistant unique-identity layer: absent identity verification, a whale can split its holdings across a large number of addresses to circumvent the quadratic cost, which is also why purely token-weighted quadratic voting is rarely used for high-value DeFi treasury decisions. Quadratic voting therefore needs to be deployed together with a Sybil-resistant identity layer and complementary mechanisms that raise participation (such as delegated voting and voting incentives) in order to truly fulfill its design intent.

Beyond architectural defense and mechanism defense, economic defense (such as governance insurance) constitutes the last line of defense. When an attacker successfully bypasses the first two layers of defense and causes losses, a preset insurance fund can be used to compensate the affected users, preventing a total collapse of trust in the system. These three layers of defense together constitute a multi-layer defense system that significantly raises the difficulty and cost of launching a governance attack.

30.6.5 The governance roadmap of progressive decentralization

Over the lifecycle of an on-chain financial system, the governance architecture is not fixed. A significant tension exists between the system's fragility in its early days after launch and the trustlessness it pursues in the long run. If control is handed over to the community prematurely—before the code has been sufficiently battle-tested in live trading and before the economic model has reached equilibrium—the system will face high security risk and coordination failure. To address this path problem, engineering practice has developed the concept of "progressive decentralization" [39]. Synthesizing Walden's idea with industry engineering practice, this book summarizes the handover of governance power as a structured, multi-stage transformation process (the specific three-stage division of "team control—multisig committee—full DAO" and the timelock mechanism below are this book's engineering synthesis, not the framework of Walden's original text).

Figure 30-9 presents the three-stage structure of the progressive handover of power—the team-control period, the multisig-committee period, and the full-community-governance period—in order of increasing decentralization, which the following text develops stage by stage in terms of its authority boundaries and transition conditions.

Figure 30-9. The three-stage roadmap of progressive decentralization [39][40] (conceptual illustration; stage durations have no standard)

The first stage is the team-control period, typically covering the initial phase after the system's launch (the specific duration depends on the project, commonly ranging from a few months to about a year, with no uniform standard). In this stage, the core development team retains unilateral control over smart-contract upgrades and key parameter adjustments. This highly concentrated power structure is intended to maximize the system's iteration speed and its ability to respond to sudden events. When the system faces an unknown vulnerability or an economic attack, the team can immediately deploy a patch without going through a lengthy community discussion and voting process. The core goal of this stage is to validate the stability of the system architecture and product-market fit, rather than to pursue formal decentralization. However, to provide users with a basic trust guarantee, the team typically publicly commits to the boundaries of its power and periodically releases security-audit reports.

As the system scales and its operating logic stabilizes, the governance architecture enters the second stage, the multisig-committee period. In this stage, the team begins to proactively reduce its own unilateral control. The administrator keys are transferred to a multisig committee jointly composed of core team members, early investors, well-known security experts, and community representatives. Any operation involving a system upgrade or parameter modification must obtain the signature authorization of a majority of committee members and is mandatorily executed only after a timelock delay [40]. This mechanism not only eliminates the risk of a single point of failure but also provides a time window for community oversight. At the same time, the community begins to be granted the right to propose and vote on non-critical parameters, as a rehearsal for fully taking over governance in the future.

When the system reaches high maturity, its token distribution is sufficiently dispersed, and its core functions have solidified, the governance architecture finally transitions to the third stage, the full-community-governance period. In this end state, the privileges of the multisig committee are completely revoked, and all upgrade authority and parameter-adjustment rights are transferred to a DAO controlled by token holders. Any modification of the smart contracts must strictly follow the standardized process of on-chain proposal, voting, and timelock execution. At this point, the core team steps back to become one of many protocol contributors, no longer enjoying special privileges. This progressive handover of power ensures that the system remains structurally sound throughout its evolution from a "trusted operator" to a "trustless protocol."

However, the theoretical elegance of progressive decentralization faces a serious credible-commitment problem in practice. It is easy for a core team to promise, in the early days after launch, that it will relinquish control in the future; but when decentralization means actually giving up the economic privileges of adjusting fees, managing the treasury, and steering the protocol's direction, the team faces a strong time-inconsistency incentive to extend the first or second stage indefinitely. In reality, a large number of blockchain projects have never completed the handover of power under the banner of "progressive decentralization," and the progressive-decentralization roadmap degenerates into a rhetorical tool for perpetuating centralized control. To resolve this commitment problem, the engineering design can introduce irreversible decentralization milestones—for example, presetting in the smart contract a logic that automatically reduces authority based on a time or system-scale threshold, so that once the system's total value locked exceeds a specific threshold or its operating time exceeds a predetermined term, the administrator authority is automatically downgraded, and this downgrade logic itself cannot be overridden by the upgrade authority.

30.6.6 A governance audit of Hyperliquid

Before assessing the governance state of an on-chain system, it is worth contrasting it with the governance structure of a centralized exchange. The governance power of a traditional CEX is concentrated in the corporate board and the internal compliance committee; parameter adjustments (such as changes to margin ratios and listing decisions) are executed unilaterally by management, and users have neither voting rights nor prior knowledge. The external constraints on a CEX come mainly from the conditions of its regulatory license and legal accountability, not from architectural-level checks on power. By contrast, on-chain governance grants stakeholders direct participation through token voting, the timelock mechanism ensures the transparency and predictability of changes, and the multisig structure eliminates single-point decision risk. This governance-paradigm difference from "institutional self-discipline" to "architectural constraint" constitutes the basic frame of reference for assessing the governance maturity of an on-chain system such as Hyperliquid.

Applying the governance theoretical framework above to Hyperliquid, a specific on-chain derivatives-trading infrastructure, allows a clear assessment of the gap between its current governance state and the ideal decentralization goal. As a system built on the customized app-chain HyperEVM, Hyperliquid's governance design involves not only parameter adjustments at the smart-contract level but also, more deeply, the validator mechanism at the consensus layer.

At the architectural level, Hyperliquid's governance core relies on the staking of the HYPE token and a validator-voting mechanism. According to its public roadmap and on-chain data, the system is currently in the critical period of transitioning from the second to the third stage of progressive decentralization [41]. In its early days, network consensus was maintained by a very small number of core nodes, which gave the team the ability to rapidly iterate its HyperBFT consensus algorithm and its liquidation engine. As the system matured, the governance structure underwent significant decentralization. The number of validator nodes expanded from an initial handful operated

by the foundation (about 4 to 5) to 21 active validators (the permissionless validator set introduced starting April 2025), and was further expanded to approximately 27 between late 2025 and mid-2026; its permissionless-participation mechanism automatically admits any node whose stake ranking places it within the active-set size cap (then the top 21). However, an increase in the number of validators does not equate to a substantive increase in the degree of decentralization. If a few entities control more than one-third of the stake weight, that is enough to break its Byzantine fault tolerance (BFT) guarantee; the true degree of decentralization should be measured by the number of entities holding more than one-third of the stake (that is, the Nakamoto coefficient), rather than the nominal number of validators. The public disclosure of stake-concentration data is itself an important direction in which Hyperliquid's governance transparency needs improvement.

An audit of Hyperliquid's current governance state reveals several engineering challenges that urgently need to be resolved. First, in the distribution of voting power, although a stake-weight mechanism has been introduced, if tokens are highly concentrated in the hands of a few early participants, the system still faces the threat of whale manipulation. To mitigate this risk, the system needs to further explore nonlinear weighting mechanisms such as quadratic voting to strengthen the voice of the broad retail base in governance. Second, the actual exercise of emergency powers has already directly tested the theoretical framework proposed in Section 30.6.2. During the JELLY perpetual futures incident of March 2025, after detecting large-scale market manipulation, Hyperliquid validators used an emergency vote to freeze trading in the JELLY perpetual futures and forcibly settled the affected positions at a price favorable to the HLP (market-making) vault (approximately \$0.0095, rather than the manipulated market price of about \$0.50). This action in effect exceeded the scope of "defensive operations" as defined in Section 30.6.2: suspending trading is a defensive measure, but unilaterally setting the settlement price constitutes a direct disposition of users' property. The incident triggered heated debate in the community: do validators have the right to exercise quasi-judicial adjudicatory power in the name of protecting the system's solvency? Although the HLP vault's losses were ultimately contained (the vault even recorded a small surplus in the end), the absence of a community accountability mechanism—no formal ex post review process and no independent operational audit report—exposed an engineering gap in the "ex post accountability" component of the emergency-powers framework. The JELLY incident demonstrates that the boundaries of emergency powers cannot be delimited solely through predefined operation types; they also require mandatory post-operation review and community ratification procedures.

Moreover, in the broader design of the emergency-response mechanism, how to improve the transparency and ex post accountability of emergency operations while ensuring network security is a key focus for optimizing the current governance architecture. In December 2025, a validator vote to permanently remove approximately 37 million HYPE (more than 13% of circulating supply) held in the Assistance Fund from the supply passed on December 24 with approximately 85% approval, demonstrating the community's capacity to participate in major economic decisions; yet the irreversibility of that decision, combined with a voting structure in which stake weight was highly

concentrated, still showed how such decisions depend on an adequate time window and a broad basis of consensus [42].

Looking ahead, Hyperliquid's governance architecture needs to deepen along two dimensions. On the technical dimension, as HyperEVM is fully deployed, the governance logic should be embedded more deeply into smart contracts to achieve fully automated proposal execution and reduce reliance on off-chain coordination. On the mechanism dimension, the system should introduce a more granular parameterized-governance framework, separating the authority over routine operations such as fee adjustments and margin-ratio settings from the authority over underlying consensus upgrades, thereby building a layered governance structure. The key bottleneck for this layering is that Hyperliquid's core parameters (margin ratios and liquidation thresholds) run in the consensus-layer state machine rather than the EVM contract layer: parameter changes to the former must be implemented through consensus upgrades, whereas the latter can be managed directly through governance contracts on HyperEVM, and passing permissions between the two layers requires the precompiles interface.

30.7 Mapping regulatory requirements to technical implementations

Having explored the layered architecture of on-chain financial systems, the design of the liquidation engine, and the engineering implementation of embedded compliance, this section returns to the regulatory framework proposed in Chapter 26 to form a complete loop between regulatory requirements and technical implementations. Building on the structural risks of traditional centralized exchanges, Chapter 26 proposed six "minimal but effective" regulatory principles. This section maps these principles one by one onto the concrete technical implementation schemes discussed in this chapter, shows how embedded compliance converts external regulatory constraints into built-in architectural guarantees, explores the possibility of regulation and technology forming a combined force, and clarifies the domains in which human judgment remains indispensable within a highly automated system.

30.7.1 The technical implementation of the six principles

The six regulatory principles proposed in Chapter 26 set goals for building a secure crypto-finance system, and this chapter's three-tier compliance spectrum (hard-coded, parameterized, and reporting-based compliance) provides an engineering implementation path for those goals. Table 30-1 maps each of these six principles onto the different compliance tiers of an on-chain system, showing the concrete technical implementation scheme and implementation priority corresponding to each principle. The table makes clear that asset segregation, as the highest-priority security baseline, is assigned to the hard-coded tier; principles that require continuous data feedback, such as disclosure and evidence-based evolution, fall into the reporting-based tier; and functional regulation and the localized adjustment of international standards depend on the flexibility of the parameterized mechanism. This tiered mapping embodies the differentiated demands of different regulatory requirements for embedding depth and flexibility.

Chapter 26 regulatory principle	Compliance tier	On-chain technical implementation	Implementation priority
Asset segregation as the baseline	Hard-coded compliance	Smart-contract self-custody and non-appropriation logic	Highest
Disclosure first	Reporting-based compliance	Real-time on-chain data extraction and automated audit APIs	High
Functional regulation	Parameterized compliance	Independent compliance parameters and governance mechanisms for each functional module	Medium
Embrace embedded compliance	Combined tiers	Coordinated design of hard-coded, parameterized, and reporting-based mechanisms	Medium
International minimum standards with flexible adjustment	Hard-coded and parameterized combined	Minimum standards hard-coded; flexible parameters adjusted by regional governance	Medium
Evidence-based evolution	Reporting-based compliance	Continuous evaluation of on-chain data to support dynamic optimization of compliance rules	Long-term

Table 30-1. Mapping between the six regulatory principles of Chapter 26 and their on-chain technical implementations (Data source: compiled by the author)

The deeper logic of this mapping lies in matching embedding depth to the nature of the rule. Non-negotiable security baselines such as asset segregation are entrusted to the deepest hard-coded compliance, whose architectural-level constraint is more reliable than a traditional legal pledge and ex post audit; disclosure-first and evidence-based evolution rely on the continuous data feedback that reporting-based compliance provides, converting periodic static reports into a dynamic display that can be computed and verified in real time; functional regulation draws on parameterized compliance so that the compliance parameters of each module—trading, liquidation, market making—can be flexibly adjusted through governance without altering the underlying core logic; embracing embedded compliance runs through the coordination of all three; and the coexistence of a globally uniform security baseline (such as the absolute leverage cap) with region-specific requirements (such as the margin ratio for specific assets) is precisely what the nested design of hard-coding and parameterization carries.

This mapping framework faces two unresolved structural challenges in implementation. The first is the enforcement mechanism for cross-border jurisdiction. The "regional governance adjustment" envisioned in Table 30-1 lacks a landing path in a permissionless, global on-chain system: in a smart contract accessible by anyone from any jurisdiction, the system cannot reliably determine the jurisdiction to which a user belongs,

and techniques such as VPNs can easily circumvent geographic restrictions based on IP addresses. Jurisdiction-aware access control based on zero-knowledge credentials offers a possible technical solution, allowing users from different jurisdictions to obtain differentiated parameter configurations after proving their compliance status; but the engineering maturity and regulatory acceptance of this scheme remain at an early stage. The second challenge is the absence of systemic-risk monitoring. The six principles above focus mainly on compliance at the level of a single protocol, but in a highly interconnected on-chain financial ecosystem, cross-protocol correlated liquidations, liquidity contagion, and the common-mode failure caused by shared oracles constitute a distinct category of systemic risk. This dimension has not yet been incorporated into the current system of regulatory principles, but it has become an unavoidable compliance requirement in the process of scaling on-chain finance.

30.7.2 The synergy of regulation and technology

Traditional financial regulation relies mainly on external constraints on institutional behavior—stipulating what an institution may and may not do, and using periodic inspections and severe penalties to compel compliance. The premise of this model is that the institution is capable of violating the rules, and the essence of compliance is to change the cost-benefit expectations of doing so. Embedded compliance, however, offers an entirely new paradigm: regulators can no longer merely require institutions to "pledge to comply with the rules" but can require them to adopt a system architecture that makes it "impossible to violate the rules."

When regulators require that "assets must be segregated," relying solely on periodic financial audits means, in effect, that they bear enormous information-lag risk. But in an on-chain financial system, regulators can require the platform to adopt a non-custodial smart-contract architecture. Under such an architecture, asset segregation is not an operational activity requiring continuous oversight but an architectural property built in at the moment of system deployment. The focus of regulation shifts from "checking whether the institution has misappropriated assets" to "auditing whether the smart-contract code does indeed restrict the authority to transfer assets." This shift significantly reduces the ongoing cost of enforcement while significantly improving the security of assets.

Similarly, for disclosure requirements, regulators can push the industry to adopt standardized on-chain data interfaces. Rather than requiring platforms to submit complex financial statements each month, it is better to require them to provide a regulatory API that can read on-chain state in real time. This enables regulators to build automated monitoring systems that detect abnormal trading patterns and the accumulation of systemic risk in real time. The driving force of regulation is no longer merely the threat of punishment but the impetus to evolve financial infrastructure toward a more transparent and resilient technical architecture.

The synergy of regulation and technology is also reflected in the standardization of governance mechanisms. Regulators can require that parameter adjustments and contract upgrades in an on-chain system follow specific timelock-delay and multisig-security standards. Such a requirement does not interfere with the community's specific governance

decisions but ensures that the governance process itself has sufficient transparency and predictability, providing market participants a buffer period to assess and respond to rule changes. By requiring good architecture, regulators not only achieve the goal of protecting investors but also promote innovation and development in financial technology.

However, the premise of this paradigm shift is that regulators possess the technical capacity to audit smart-contract code—a capacity that at present barely exists anywhere in the global financial-regulatory system. The core technical capabilities of current financial regulators are concentrated in legal analysis and financial auditing, not cryptography and smart-contract engineering. If regulators cannot independently verify whether contract code truly implements the compliance constraints it claims, "auditing the code" may degenerate into another form of "compliance theater," relying solely on third-party audit reports while the auditing firms themselves lack a standardized accountability mechanism. The transition from "auditing institutional behavior" to "auditing system architecture" therefore requires the concurrent advancement of at least two areas of infrastructure: first, establishing certified smart-contract auditing standards (analogous to the international standards in the accounting-audit field) to provide a unified framework for the scope, methods, and report format of contract audits; and second, building a tiered certification and accountability mechanism for auditing firms during the transition period, to ensure the credibility of third-party audit conclusions.

30.7.3 Compliance functions that technology cannot replace

Although embedded compliance solves a large number of traditional compliance problems through hard-coding and automation mechanisms, in a complex financial system the application of technology has its inherent boundaries. Certain key compliance functions and the handling of extreme situations still require human judgment, discretion, and social consensus.

First, dispute resolution and legal appeals cannot be fully replaced by code. A smart contract can only execute operations according to predetermined logic; it cannot judge whether that logic is fair in a specific situation. When an unexpected vulnerability causes user losses, or when an extreme market-manipulation event occurs, the victims need to seek redress. On-chain systems lack an intrinsic judicial-adjudication mechanism, and for the determination of complex liability and the recovery of losses, one must still rely on the real-world legal system and the rulings of human judges.

Second, cross-border enforcement coordination and complex crime investigation require human involvement. Although the transparency of on-chain data helps trace fund flows, linking an on-chain address to a real-world entity's identity often requires transnational intelligence sharing, judicial assistance, and traditional investigative methods. Technology can provide clues and evidence, but combating transnational financial crime and enforcing sanctions lists are essentially exercises of state power that require the collaboration of diplomatic and legal professionals.

Moreover, the identification of new risks and the evolution of the compliance framework require human strategic vision. An automated monitoring system can only detect

anomalies based on known patterns; it often lacks the forward-looking capacity to identify market manipulation carried out through entirely new mechanisms or the covert accumulation of systemic risk. Compliance experts and regulators must continuously analyze market dynamics and understand newly emerging financial instruments and trading strategies in order to formulate new regulatory principles and guide upgrades to the underlying architecture.

Finally, the enforcement of ethical standards and the ultimate handling of a systemic crisis cannot do without human social consensus. In extreme market turmoil, decisions such as whether to suspend trading or whether to invoke emergency governance powers to intervene often involve complex trade-offs among different interest groups. A purely technical system cannot bear this kind of responsibility, which carries a high degree of political and ethical weight. Humans set the rules at the outset of the system's design, and they must also bear ultimate decision-making responsibility when the system faces a major systemic crisis. Embedded compliance does not eliminate the role of humans; rather, it frees human energy from tedious day-to-day compliance checks and concentrates it on higher-level architectural design, risk anticipation, and crisis management.

30.8 Chapter summary

The three-tier compliance-spectrum architecture proposed in this chapter (hard-coded, parameterized, and reporting-based compliance) provides a systematic analytical framework and implementation path for the compliance engineering of on-chain financial systems. Hard-coded compliance, by compiling non-negotiable security baselines such as asset segregation directly into smart-contract logic, achieves a paradigm shift from "requiring institutions to obey the law" to "making it impossible for institutions to break it." Parameterized compliance, within a fixed rule framework, allows operational parameters such as the margin ratio to be dynamically adjusted through transparent governance mechanisms, striking an engineering balance between security and flexibility. Reporting-based compliance leverages the immutability and global visibility of on-chain data to convert ex post auditing into an inherent property of the system. The organic combination of the three completes the full mapping from regulatory requirements to on-chain engineering implementation.

The introduction of zero-knowledge-proof technology breaks the zero-sum game between regulatory transparency and user privacy [26]. Through cryptographic proofs, traders can prove to the system that they satisfy specific compliance conditions without exposing the underlying identity data, allowing on-chain finance to satisfy regulatory standards such as anti-money laundering while preserving its core permissionless character. This technical path demonstrates the potential of a digital-native architecture to surpass traditional finance on the compliance dimension.

The inevitable cost of embedding rules into architecture is an increase in system rigidity. The dual architecture of timelock and emergency powers provides an engineering solution to this contradiction: routine changes are subjected to a mandatory delay for community review in order to maintain immutability, while a constrained fast track for

extreme situations ensures the system's capacity for crisis response [43]. This controllable upgradeability, combined with the governance roadmap of progressive decentralization, constitutes the optimal practice for on-chain governance under current technical conditions. However, functions such as dispute resolution, cross-border enforcement coordination, and the forward-looking identification of new risks still lie beyond the capacity boundary of a purely technical system and require human judgment and social consensus to supplement.

Hyperliquid's app-chain architecture and its on-chain central limit order book constitute a frontier practical prototype of embedded compliance, but a significant gap remains between the current prototype and a mature financial infrastructure. Along this evolutionary path, a new force is joining: artificial intelligence. When AI agents can autonomously conduct market making, trading, and risk management on-chain, the operating mode of financial markets will once again undergo a profound change. This evolutionary trend is precisely the core theme explored in Part XI.

Part X
The Future

Core question: Where is all this headed?

When AI Becomes Market Infrastructure

The large-scale entry of artificial intelligence (AI) agents is driving a fundamental transformation in the microstructure of financial markets. Breakthroughs in machine learning models—in data processing, pattern recognition, and autonomous decision-making—have structurally altered the informational dimension along which markets operate, with profound effects on the speed of trade execution, the patterns of liquidity provision, and the mechanisms of price discovery. The scale and depth of this transformation are comparable to the way the emergence of vision during biological evolution reshaped the competitive landscape of ecosystems [1][2]: a leap in the capacity to acquire and process information has changed the game-theoretic structure among market participants.

The complete framework for analyzing market microstructure built up over the preceding thirty chapters—whether examining the pricing mechanisms of automated market makers (AMMs), the impermanent loss borne by liquidity providers, the behavioral patterns of arbitrageurs, or the governance mechanisms of protocols—rests on one implicit core assumption: that market participants are human, or algorithms under real-time human control and parameter-setting. This assumption implies that market participants inevitably carry biological and psychological limitations. A large body of behavioral finance research shows that human participants are constrained by limited attention bandwidth, emotionally driven irrational reactions, and an inescapable need for sleep [3]. During extreme market volatility, the contagion of panic often leads to a synchronized withdrawal of liquidity; when processing complex information, cognitive-load limits make it impossible for humans to track the relationships among thousands of variables simultaneously. These features, rooted in human nature, constitute the microfoundations of liquidity crises, volatility clustering, and delayed price discovery in traditional market microstructure.

When AI agents shift from decision-support tools to autonomous market participants, however, the assumption above is fundamentally altered. AI agents are not bound by biological rhythms and can operate continuously around the clock; they do not experience panic or greed, and can rigorously execute preset risk-control logic even in extreme conditions. Yet the absence of emotional reactions at the execution layer does not mean the entire decision chain is free of emotion. An AI system's risk-control parameters are set by humans and inevitably embed the setter's risk preferences and

behavioral biases; its training data derive entirely from the historical record of human trading behavior, so the model may inherit and reproduce systematic human biases; and in extreme conditions, the decision to "shut down the system" or "dial risk parameters to their most conservative settings" is made by human managers, a step wholly subject to emotion. A more precise formulation is therefore that AI removes emotion from the execution layer, but emotion continues to influence the market indirectly through parameter-setting, training data, and human override decisions. Even so, AI's information-processing bandwidth far exceeds that of humans, enabling high-dimensional, synchronized optimization across multiple markets, assets, and time scales at once [4]. More critically, a superior strategy model can be perfectly replicated and deployed at scale at low cost. When the bulk of market volume is no longer generated by the interplay among human traders but instead by the autonomous interaction of AI agents, the core dynamics of market microstructure change structurally. The essence of adverse selection shifts from an asymmetry grounded in information access to one grounded in algorithmic processing speed and model predictive power; the provision and consumption of liquidity are no longer governed by human panic, but instead by a new form of systemic fragility arising from strategy homogenization.

The pervasive infiltration of AI agents forces us to reexamine the applicability of existing theoretical frameworks. The technological competition of the high-frequency trading era has already shown that technological progress not only compresses transaction costs but also drives fundamental changes in the composition of market participants [5]. In AI-dominated markets, the profit equation of automated market makers must be recalibrated to fit a new environment of multidimensional inventory management and adversarial market making; the reflexive character of liquidity takes on a different form, as the heterogeneous decisions of human market makers may be replaced by the synchronized reactions of AI agents—eliminating routine panic while creating the risk of ultra-fast flash crashes; and the decomposition of volatility sources must also incorporate an additional volatility term generated by algorithmic homogenization. These changes impose new requirements not only on the strategies of traders and liquidity providers, but also on the design and governance of decentralized finance (DeFi) protocols.

This chapter aims to systematically analyze how AI is reshaping market microstructure, advancing theoretical contributions along five dimensions: a four-stage model of AI penetration into microstructure, delineating the evolutionary path of markets from decision support to autonomous strategic interaction; a reexamination matrix that tests, one by one, the validity and the direction of revision of the core concepts of market making, liquidity, volatility, and market quality from earlier chapters in an AI world; the identification and analysis of AI-native new phenomena such as strategy-homogenization risk, ultra-fast flash crashes, and adversarial market making; a dual-role framework that reveals the economic logic of AI's evolution from a value-extracting market participant into value-creating market infrastructure; and a hybrid architecture fusing code and models, which provides theoretical support for the design of future DeFi protocols.

Structurally, the analysis proceeds along two main lines. The first half focuses on the impact of AI as a market participant, examining in detail how it alters the economics of

market making, reshapes the dynamics of liquidity and volatility, and exerts complex effects on the five dimensions of market quality. The second half turns to a deeper analysis of the architectural upgrade, arguing that AI transcends the role of participant to become a key component of core infrastructure such as dynamic risk engines, intelligent matching systems, and semantic oracles. Through the interweaving of these two lines, the chapter presents a new, AI-driven market paradigm, laying the theoretical groundwork for understanding the operating mechanisms of future autonomous financial networks.

A note on scope: the core object of analysis in this book is the order-book-based perpetual futures market on centralized exchanges. AI's influence on market microstructure, however, has a cross-market character; the same algorithmic architecture and strategy logic are often deployed simultaneously on centralized exchanges and on-chain protocols. Accordingly, while this chapter takes the centralized-exchange (CEX) order-book perpetual futures market as its primary setting, part of the discussion extends to decentralized exchanges (DEXs) and on-chain protocols in order to present a complete picture of how the advance of AI technology affects market microstructure. Readers should take care to distinguish which market environment a given passage addresses.

31.1 A four-stage model of AI penetration into microstructure

Market microstructure theory has long rested on a basic assumption: that market participants possess the cognitive characteristics and behavioral limitations of humans. These inherent cognitive and emotional limits (see the chapter introduction) jointly shape the clustering of market liquidity and the pulsed rhythm of price discovery. When algorithmic agents with extremely high concurrent processing capacity, millisecond-level response speeds, and no emotional fluctuations gradually take over core trading functions, however, this implicit assumption faces a fundamental challenge. To assess systematically the effect of non-human participants on market microstructure, we need an analytical framework that describes the evolving path of intelligent agents' roles in the market. Such a framework can not only explain phenomena already observed in current markets, but also anticipate the new market structures and trading dynamics that may emerge in the future.

Figure 31-1 presents the four-stage model of AI penetration into microstructure. Its central classificatory principle is to distinguish two dimensions—"who makes decisions" and "who executes them"—and thereby capture the gradual transfer of power to AI in the market.

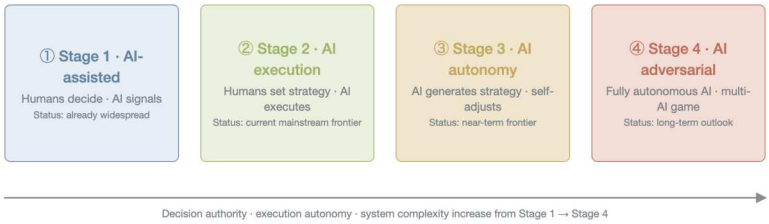

Figure 31-1. The four-stage model of AI penetration into market microstructure (Data source: theoretical derivation based on the evolutionary path of algorithmic trading)

31.1.1 AI assistance

In the initial stage of penetration, AI primarily plays a supporting role in data processing and signal extraction. At this point, the core decision-making authority over market microstructure still rests with human traders or fund managers. Algorithmic systems are used to identify potential trading opportunities from vast quantities of unstructured data—for example, analyzing news sentiment via natural language processing (NLP), or using machine learning models to detect minute price anomalies in historical order-book data. These systems output risk alerts, probabilistic forecasts, or trade recommendations to humans, but the final instructions to open positions, close positions, and adjust risk exposure are still issued by humans.

In on-chain finance, Stage 1 AI is especially widely applied. On-chain data-analysis tools can track, in real time, the transfer behavior of large wallets, the interaction patterns of smart contracts, and the flow of capital across liquidity pools. A trader can, for example, monitor the wallet activity of whale addresses to infer potential large-order intentions and adjust positions in advance. Similarly, machine learning models can analyze the correlations among historical liquidation events, funding-rate changes, and price volatility to provide risk alerts for human traders. On decentralized exchanges, AI systems can compute the expected impermanent loss of each liquidity pool in real time, helping liquidity providers evaluate the risk-return trade-offs across different asset pairs. Although these applications improve the efficiency of information processing, they do not change the human's position as final decision-maker.

The systemic impact of this stage on market microstructure is relatively limited. Because human decision-makers serve as the final execution node, the market's response speed is still constrained by human cognitive bottlenecks and physical reaction times. In extreme market conditions, humans' inherent fear and greed still dominate the supply of and demand for liquidity, and the withdrawal of market-maker liquidity and cascading declines in liquidity still occur frequently. Even at this stage, however, AI-assisted tools produce observable microstructure effects. Studies suggest that trading institutions using AI risk-alert systems adjust positions significantly faster in extreme conditions (an estimate based on the author's industry observation), a difference large enough to confer a meaningful execution advantage in a market operating at the millisecond level. In addition, AI-driven sentiment analysis can capture a shift in market sentiment within the first 100 milliseconds after a news release, providing a narrow

time window for fast-reacting traders. Thus, while the classic theoretical analyses of earlier chapters—information asymmetry, adverse-selection risk, and the tragedy of the liquidity commons—remain applicable at this stage, their specific parameters and time scales have already shifted subtly with the spread of AI-assisted tools.

31.1.2 AI execution

As algorithmic engineering matured, the market entered a second stage, in which humans set the logical framework of the strategy and the risk parameters while AI systems automatically execute trades within those predefined boundaries. This mode is already widespread among mainstream market makers and high-frequency trading firms. Human quantitative researchers define inventory-management preferences, hedge-ratio thresholds, and the base formula for quote width, and the algorithmic engine dynamically adjusts two-sided quotes at millisecond speed based on real-time market data flows, conducting high-frequency arbitrage across multiple exchanges.

On centralized exchanges, the degree of automation among mainstream market makers has already reached the level typical of Stage 2. At large exchanges such as Binance and Coinbase, official market-maker programs (such as Binance's market-maker incentive program) already rely entirely on automated quoting engines. Within a human-set parameter framework, and based on order-book depth, real-time volatility estimates, and price information from other exchanges, these engines can adjust their quotes hundreds of times per second. On decentralized exchanges, Hyperliquid's Hyperliquidity Provider (HLP) market-making vault is a parameterized automated market-making system whose strategy logic (quoting symmetrically around the mark price and adjusting the quote offset according to the degree of position deviation) is preset by humans and executed strictly according to the rules. Viewed through the lens of the four-stage model, this vault sits in the transitional zone between Stage 1 and Stage 2: its degree of automation is high, but it lacks machine-learning-based adaptive capability, and adjustments to strategy parameters still depend on manual human intervention rather than on the model's autonomous learning. When the market price fluctuates, its algorithmic engine automatically adjusts the concentration of liquidity according to preset rules, shifting the liquidity range upward when the price rises and downward when it falls, thereby executing market-making operations within human-set constraints.

At this stage, algorithmic execution greatly improves the microstructural efficiency of the market. Automated market-making engines can operate around the clock without interruption, significantly reducing bid-ask spreads under normal conditions. Data indicate that on exchanges that have introduced automated market-making engines, the average bid-ask spread has fallen significantly (according to industry reports, from the level of tens of basis points to single-digit basis points), an improvement that directly lowers costs for all traders. Automated systems also accelerate the speed at which new information is incorporated into asset prices, markedly improving the efficiency of price discovery. Yet even though the execution process is highly automated, the creativity and core logic of the strategy still originate with humans. When the market experiences an extreme black-swan event that exceeds the preset parameter framework, the system usually triggers a hardcoded circuit breaker, halting quotes and handing

control to humans. In one extreme volatility event, for example, several automated market-making systems immediately halted quoting upon detecting anomalous price movements, waiting for manual intervention by human traders. This stage therefore achieves a leap in speed and consistency, but it does not fundamentally eliminate the market's fragility in the face of structural shocks. Homogenized algorithmic reactions may even exacerbate short-term liquidity droughts under certain conditions, because multiple institutions' market-making engines may make the same decision based on the same market signal, causing liquidity to vanish in an instant.

31.1.3 AI autonomy

Recent frontier research shows that the market is accelerating toward a third stage, whose defining feature is that AI is responsible not only for execution but also for autonomously generating and dynamically adjusting trading strategies. Deep reinforcement learning algorithms are deployed in complex market environments, where agent programs, through continuous interaction with market states and driven by an objective function that maximizes long-run cumulative returns, autonomously explore optimal market-making and trading paths [6]. Unlike Stage 2, which is constrained by human-preset logic, autonomous learning agents can discover nonlinear patterns that human analysts struggle to identify and develop novel combinations of high-frequency strategies. For example, a market-making agent based on deep Q-learning might learn that, under a particular combination of order-book shape and volatility, it can probe the distribution of market liquidity by actively submitting fake orders and then immediately canceling them, and then adjust its own quoting strategy according to the market's reaction. Such behavior, however, legally constitutes spoofing, a form of market manipulation expressly prohibited in nearly every major jurisdiction. The 2015 charges brought by the U.S. Department of Justice and the Commodity Futures Trading Commission (CFTC) against Navinder Sarao (who was arrested in the United Kingdom that April and faced extradition) are a paradigmatic enforcement precedent aimed at precisely this kind of strategy. The key risk here is that a reinforcement learning agent, trained on a pure profit-maximization objective, spontaneously evolves a trading strategy that violates the law—something its developers could not foresee at the design stage. This phenomenon corroborates exactly the core regulatory dilemma this chapter will examine in depth in Section 31.6: an autonomous learning agent may independently generate unlawful conduct with no human intent involved whatsoever, and the resulting questions of liability attribution and ex ante prevention constitute one of the thorniest governance challenges of AI participation in financial markets.

The application of reinforcement learning in market making has already moved from theory into practice. Research institutions and hedge funds have begun deploying market-making agents based on the Actor-Critic architecture; these agents can operate simultaneously across multiple exchanges and asset pairs, using cross-asset correlations for dynamic hedging. A typical example: a reinforcement learning agent may learn that when Bitcoin's volatility rises, Ethereum's volatility typically rises about 200 milliseconds later, and so the agent can adjust Ethereum's quote width in advance, preparing for the risk before volatility rises. Such predictive strategy adjustment is impossible in a traditional Stage 2 system, because it is very difficult for a human to forecast so

precisely this kind of complex cross-asset time-series relationship.

This evolution has a marked and profound impact on market microstructure. On the one hand, autonomous learning models demonstrate a capacity far exceeding humans' in multidimensional inventory optimization and cross-asset correlation hedging, providing deeper liquidity support in normal markets. Studies suggest that institutions using reinforcement learning market-making strategies provide 30% to 50% more liquidity in normal markets than traditional market makers. On the other hand, the black-box nature of the strategy-generation process substantially increases the unpredictability of system behavior. When multiple institutions simultaneously deploy autonomous agents based on similar reinforcement learning architectures, these agents are highly prone to exhibiting homogenized reaction patterns when confronted with particular market-microstructure signals. This strategy convergence stems from the convergence of training data, neural-network architecture, and optimization objectives; its full causes are analyzed in detail in Section 31.3.2.

In extreme cases, such strategy convergence can trigger an instantaneous evaporation of liquidity, causing the market to experience violent price swings within milliseconds and forming a new source of risk at the microstructure level [7]. For example, in a recent simulation study, researchers deployed five market-making agents based on the same reinforcement learning architecture in a simulated market and found that, when a sudden price jump occurred, all five agents contracted their quote widths simultaneously in under 100 milliseconds, causing market liquidity to vanish in an instant and prices to swing to an extreme degree. This phenomenon, dubbed an "AI flash crash," represents an entirely new form of systemic risk that does not exist in traditional human-dominated markets. The interaction of five fully isomorphic agents in a single simulated market, as above, represents an extreme case of strategy homogenization. In real markets, although market makers' AI systems may use similar frameworks, their training-data windows, feature-engineering details, and risk-control parameter settings all differ, and the market also contains a large number of non-AI participants that provide a natural buffer of heterogeneity; the simulation results above should therefore be understood as an upper-bound estimate of homogenization risk.

31.1.4 AI adversarial competition

In the long-run picture, when the vast majority of trading volume and liquidity provision is contributed by highly autonomous intelligent agents, market microstructure will undergo a fundamental structural transformation. At that point, the core driving force of the market will no longer be psychological games among humans, but competition among algorithmic agents grounded in computing power, latency advantages, and model architecture. Traditional adverse-selection theory is built on the information asymmetry between informed and uninformed traders. In their classic 1985 model, Glosten and Milgrom showed that a market maker's bid-ask spread is a rational compensation for adverse-selection risk [8]. In this framework, the core risk facing the market maker is that informed traders will use their informational advantage to trade favorably, thereby inflicting losses on the market maker, who sets a wider spread to compensate for this risk.

In an all-algorithmic market, however, this game evolves into a contest between algorithms with superior predictive ability and those with relatively weaker predictive ability. In this environment, being "informed" no longer means possessing inside information; it means possessing a better predictive model and faster hardware (a full analysis of the transformation in the nature of adverse selection appears in Section 31.2.2). A higher-performing reinforcement learning agent may be able to predict another agent's quote adjustments and thus adjust its own position before those adjustments occur. This competition over "algorithmic advantage" leads to an endless technological arms race, in which every institution pours vast sums into developing faster hardware, more efficient algorithmic architectures, and more efficient data-processing pipelines.

This kind of ecosystem may give rise to entirely new market phenomena. Algorithmic agents may, without explicit communication or human intent, spontaneously form tacit collusion that sustains supra-competitive profits through trial and error and mutual adaptation [6]. For example, multiple autonomous market-making agents may jointly maintain wide bid-ask spreads to maximize collective returns, thereby harming the market's overall price efficiency and trader welfare [9]. In the 2025 study by Dou, Goldstein, and Ji, the researchers replaced the speculators in their model with reinforcement-learning-based "informed AI speculators" in simulation experiments built on a theoretical model, and found that these agents spontaneously sustained collusive, supra-competitive profits with no agreement, communication, or intent whatsoever (one of the mechanisms being a price-trigger strategy, rather than a literal bid-ask-spread cartel). This finding indicates that even without any explicit collusive intent, interactions among algorithmic agents may produce anticompetitive market structures.

In this environment, the classic liquidity models, the volatility-decomposition framework, and the standards for evaluating market quality all require a bottom-up reconstruction to fit a financial network wholly dominated by machine logic. The Glosten-Milgrom model's assumptions about adverse selection must be revised, because in an all-algorithmic market the definition of "informed" has changed. The assumption about the persistence of information in the Kyle model must also be reconsidered, because algorithmic agents can fully digest new information within milliseconds, sharply reducing the persistence of information. These revisions are not merely academic details; they are a profound reexamination of the theoretical foundations of market microstructure.

31.1.5 Assessing the stage of penetration

In assessing the evolutionary stage the market currently occupies, one must recognize that AI's speed of penetration varies markedly across different market functions. This asymmetry stems from the different requirements each task places on data dimensionality, execution latency, and decision error tolerance. Certain functions, owing to their highly structured nature and extreme dependence on speed, have already crossed multiple stages rapidly, while others, involving complex judgment and high-stakes consequences, remain at an early stage.

Table 31-1 shows the current position and evolutionary characteristics of each core market function along the AI-penetration path. The table maps four core functions—market making and arbitrage, directional trading, risk control, and governance

participation—to different positions within the four-stage model, revealing a striking asymmetry: market making and arbitrage, which depend most heavily on speed and deterministic logic, have already crossed into Stage 2 through Stage 3, whereas governance participation, which involves complex games over competing interests, remains before Stage 1. This differentiated pace of penetration implies that, for a considerable time to come, the market will exhibit a hybrid form in which human decision-making and machine autonomy are deeply interwoven.

Market function	Current penetration stage	Core driver	Evolutionary characteristics and challenges
Market making and arbitrage	Stage 2 to Stage 3	Millisecond-level latency requirements and high-dimensional data processing	Highest degree of automation; transitioning toward reinforcement learning agents; faces strategy-homogenization risk
Directional trading	Stage 1 to Stage 2	Macro-data integration and long-term trend forecasting	Relies on human intuition to set hypotheses; algorithms mainly used to optimize execution paths and reduce slippage
Risk control	Stage 1 to Stage 2	Prevention of extreme tail risk and preservation of capital	Still requires humans to set hard risk floors; hard to delegate systemic-risk judgment entirely to black-box models
Governance participation	Before Stage 1	Complex games, interest coordination, and rule-making	At the proof-of-concept stage; AI agents voting on protocol parameters face the obstacle of missing accountability mechanisms

Table 31-1. The AI-penetration stage and evolutionary characteristics of each market function (Data source: industry research and literature review [6][7][9])

Because market making and high-frequency arbitrage depend heavily on millisecond-level reaction speed and deterministic mathematical logic, their automation has advanced the fastest of all market functions. On centralized exchanges, mainstream market makers already rely entirely on automated systems, and the role of human traders has shifted from directly executing trades to supervision and parameter adjustment. On decentralized exchanges, liquidity providers on AMM protocols have widely adopted automated position-management tools. This domain has now steadily crossed Stage 2 and is exploring the autonomous-learning mode of Stage 3. Multiple research institutions and hedge funds have begun deploying reinforcement-learning-based market-making agents in production; although the scale remains relatively small, growth is rapid.

Directional trading and risk management must process more low-frequency, unstruc-

tured macro variables and have an extremely low tolerance for wrong decisions. When deciding whether to increase a Bitcoin position, for example, a fund manager must weigh multiple dimensions of information: the macroeconomic situation, the regulatory environment, technological developments, and market sentiment. Much of this information is qualitative and hard to quantify, and thus difficult for a fully automated system to process. Humans still retain core control in these domains, with algorithms used mainly to optimize execution paths (for instance, reducing slippage via volume-weighted average price (VWAP) or time-weighted average price (TWAP) algorithms) rather than to make core investment decisions.

As for governance participation in decentralized protocols, this remains a domain that AI can scarcely reach, because it involves complex games over competing interests and social consensus. Although it is technically possible to let intelligent agents participate in decentralized autonomous organization (DAO) voting, doing so raises a series of questions: Who is responsible for an AI agent's voting decisions? Could AI agents be exploited by malicious actors to manipulate the governance process? How can we ensure that an AI agent's voting behavior aligns with the protocol's long-term interests? These questions have not yet been adequately resolved, and so governance participation remains confined to the human-dominated sphere.

This uneven pace of penetration indicates that, for a considerable time to come, market microstructure will exhibit a hybrid form in which human decision-making and machine autonomy coexist. Market making and arbitrage will be the first to enter Stage 3 and even Stage 4, while other domains may remain at Stage 1 or Stage 2. This differentiated evolutionary process will create new arbitrage opportunities and risks. A hybrid system able to coordinate between Stage 3 automated market making and Stage 2 directional trading, for example, might gain a significant competitive advantage. At the same time, this hybrid form will also increase the market's complexity and unpredictability, because interactions among participants at different stages may produce novel microstructure phenomena never observed before.

31.2 The new economics of AI market making

The market-making economics framework built in Chapter 19 rests on an implicit assumption: that the market maker is an entity controlled by a human trader, constrained by human reaction speed and the inherent cognitive and emotional limits of humans (see the chapter introduction). When AI agents take over the market-making function, this assumption breaks down. AI agents can process multidimensional data at the millisecond level, run around the clock without rest, and remain unaffected by panic, which fundamentally changes the cost structure and behavioral patterns of the market maker. This section reexamines the classic market-making profit equation, analyzes the new features of adverse selection under AI dominance, and explores multidimensional inventory management and the novel phenomenon of adversarial market making, ending with a comparison of the structural strengths and weaknesses of AI and human market makers.

31.2.1 Recalibrating the profit equation

The traditional market-maker profit equation comprises spread income, adverse-selection cost, inventory-management cost, and fixed operating cost. The introduction of AI agents does not simply raise the efficiency of every variable in this equation; rather, it recalibrates the cost structure asymmetrically. AI technology significantly compresses variable costs, but its effect on fixed institutional costs is limited.

The compression of variable costs is manifested primarily in adverse selection and inventory management. In managing adverse selection, AI—via reinforcement learning algorithms—can more precisely predict short-term price movements and thus adjust quotes before informed traders arrive. Zhao and Linetsky (2021) [10] show that market-making algorithms trained through reinforcement learning can effectively control adverse-selection risk in high-frequency trading environments. In inventory management, AI can handle more complex optimization problems, reducing the capital-occupancy cost of inventory buildup. The model of Herrmann et al. (2020) [11] shows that the advantage of high-frequency trading algorithms in inventory management directly affects their Nash equilibrium state in a competitive environment. Notably, the theoretical foundation of these AI market-making strategies can be traced back to the classic stochastic optimal-control market-making model proposed by Avellaneda and Stoikov (2008) [12]. That model formalizes the market-making problem as an optimal trade-off between inventory risk and spread income, providing a theoretical benchmark for subsequent reinforcement learning market-making strategies. Contemporary AI market makers are, in essence, building on the Avellaneda-Stoikov framework, using deep reinforcement learning to extend the state space from a low-dimensional analytical solution to high-dimensional nonlinear optimization.

The fixed institutional costs of market making, however, cannot be eliminated through algorithmic optimization. These costs include the funding-rate exposure of holding positions across periods, the liquidation-risk premium in extreme conditions, and the hardware and network costs of maintaining round-the-clock high-frequency trading infrastructure. As a growing number of institutions adopt AI market making, spread income is continually compressed under extreme competition, so that the reduction in variable costs cannot fully offset the contraction of the spread. According to an industry report from Ken Research, the profit margins of high-frequency trading firms have been under sustained pressure in recent years, forcing them to keep innovating technologically (this figure comes from a paid industry report and lacks an independently verifiable basis or methodological disclosure) [13]. This asymmetric change in the cost structure means that, in the AI era, institutional costs become a relatively more important constraint on profit, which makes the market-microstructure and institutional improvements discussed in Chapters 29 and 30 all the more critical.

In the CEX order-book perpetual futures market, the AI market maker's profit equation must also incorporate several distinctive cost and revenue dimensions. On the revenue side, the fee structure for makers and takers directly affects the AI market maker's net return: as a maker, an AI market maker typically enjoys a low or even negative fee (that is, it receives a rebate), whereas the taker who consumes its quotes pays a higher fee. This fee differential makes queue position a core optimization variable

in the AI market maker's optimal strategy: under price priority, orders at the same price level are filled on a time-priority basis, so millisecond-level quoting speed directly determines whether the AI market maker can occupy a favorable queue position and thereby obtain a higher fill probability and more maker-rebate income. On the cost side, the funding-rate mechanism of CEX perpetual futures constitutes a distinctive holding cost: when an AI market maker holds a net long or net short position because of inventory skew, it must pay or receive the funding rate at each funding settlement period (typically 8 hours), and this cost can significantly erode market-making profit in highly volatile markets. The funding rate is not only a passively borne cost but also a source of return that AI market makers actively pursue. In periods when the funding rate is significantly positive, an AI market maker can deliberately maintain a net short inventory to collect the rate; funding-rate prediction itself constitutes an independent signal dimension. In extreme conditions, the funding rate can spike to several hundred percent on an annualized basis, at which point funding-rate exposure may completely dominate the market maker's profit and loss, far exceeding the contribution of spread income. The AI market maker's profit equation must therefore treat the funding rate as a core optimization objective on par with spread income, rather than merely as a holding cost.

Figure 31-2 unfolds the cost side of the market-making profit equation into five cost drivers and groups them into two categories: variable costs (significantly compressed by AI) and fixed institutional costs (only modestly improved). This asymmetric change in the cost structure explains why architectural improvements at the institutional level in fact carry higher marginal value in the AI era.

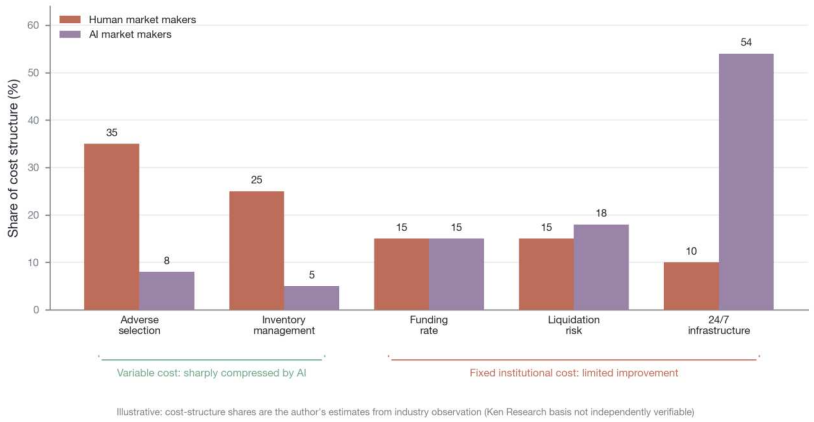

Figure 31-2. Recalibrating the AI market maker's profit equation: the cost side is unfolded into five cost drivers, grouped into variable costs (adverse selection and inventory management; significantly compressed by AI) and fixed institutional costs (funding rate, liquidation risk, and round-the-clock infrastructure; only modestly improved) (Illustrative: the cost-structure proportions are the author's estimate based on industry observation; the basis of the Ken Research industry report [13] cannot be independently verified)

31.2.2 The changing nature of adverse selection

In traditional microstructure theory, the core driver of adverse selection is information asymmetry. Informed traders possess private information about an asset's fundamen-

tals, while the market maker, as the uninformed party, can only compensate for the risk of being selectively traded against by informed traders by widening the bid-ask spread. When the main participants in the market shift from humans to AI agents, the nature of this informational advantage undergoes a fundamental change.

In an AI-dominated market, an advantage in the source of information is gradually replaced by an advantage in the speed of information processing. Although AI agents can capture, parse, and synthesize public market data, news sentiment, and on-chain indicators at speeds far exceeding humans', they cannot obtain true inside information. This means that speed-based informational advantage is neutralized by the widespread adoption of AI technology. When all market makers are equipped with algorithms that respond at the millisecond level, the latency-arbitrage space that relies purely on processing public information is greatly compressed.

A new form of adverse selection thereby begins to appear. This adverse selection is no longer based on an asymmetry in fundamental information, but on algorithmic asymmetry. When arbitrageurs are likewise AI-driven, they can reverse-engineer the market maker's quoting logic through machine learning models. These AI arbitrageurs learn the market maker's reaction latency, inventory-adjustment thresholds, and spread-widening patterns under particular order-flow shocks, and thereby predict the market maker's next move. This game shifts adverse selection from "who knows more" to "whose model generalizes better and predicts more accurately." Against this backdrop, the market maker faces not a trader who possesses inside information, but an advanced AI agent able to compute precisely the blind spots in its algorithm.

In cryptocurrency markets, however, traditional adverse selection based on the source of information still exists in abundance. Miners and validators have knowledge of block contents before the public; project teams hold undisclosed information before token unlocks and partnership announcements; and leaks of regulatory decisions often exhibit an asymmetric distribution. These advantages in the source of information cannot be replaced by algorithmic speed. Adverse selection in the AI era therefore exhibits a two-layer structure: the lower layer is the persistent asymmetry in the source of information, and the upper layer is the newly added asymmetry in algorithmic capability. What the market maker faces is a superposition of the two kinds of risk rather than a simple substitution—it must guard both against informed traders who possess inside information and against AI arbitrageurs able to reverse-engineer its algorithmic logic.

31.2.3 The dimensional explosion of inventory management

Constrained by cognitive bandwidth, human market makers can typically manage inventory only in a limited number of dimensions. A typical trading team might focus on managing the inventory risk of two or three correlated asset pairs and rely on heuristic rules for cross-market hedging. AI agents break through this dimensional limit, achieving a dimensional explosion in inventory management.

Modern AI market-making systems can simultaneously manage a high-dimensional inventory vector across dozens of exchanges and hundreds or thousands of contracts. This high-dimensional optimization capacity enables AI to use cross-asset correlations for dynamic hedging. When one asset experiences one-sided net buying that unbalances

inventory, for example, AI need not confine itself to adjusting quotes or hedging on the same asset pair; instead, it can instantly compute the optimal alternative hedging path across the entire crypto-asset matrix. This globally optimized perspective significantly improves overall market liquidity under normal conditions, because the market maker can tolerate a larger inventory deviation at any single point so long as it remains risk-neutral across the global vector.

Multidimensional cross-exchange inventory optimization faces rigid physical constraints in practice. Each exchange's margin account is isolated from the others, and the market maker must pre-fund enough margin at each venue to withstand the worst-case inventory deviation, making capital efficiency far lower than the theoretically optimal level of "global risk neutrality." Transferring funds across exchanges typically takes minutes or even tens of minutes, precluding instantaneous hedging. The 2022 collapse of FTX starkly exposed this fragility: funds frozen at FTX left multiple market makers' exposures on other exchanges unhedged, causing enormous losses. A further and more troubling effect is that AI market makers' cross-asset hedging behavior can itself amplify correlation breakdowns in periods of stress. When market maker A sells Ethereum to hedge its Bitcoin exposure, the decline in Ethereum's price triggers market maker B's Ethereum-inventory adjustment and further cross-asset hedging, forming a positive-feedback loop in which the AI hedging mechanism turns from a tool of risk diversification into a manufacturer of correlation contagion.

This multidimensional optimization, however, also introduces a new form of systemic risk. When the market is in a normal state, the cross-asset correlation matrix is relatively stable, and AI's hedging logic can operate effectively. Under an extreme market shock, however, correlations among assets often shift abruptly, and assets that were negatively correlated may suddenly become highly positively correlated. At that point, a high-dimensional inventory-optimization model built on the historical correlation matrix may fail simultaneously across all dimensions. Because AI systems operate synchronously across multiple markets, this correlation-shift-induced model collapse spreads through the entire market network at the millisecond level, turning a multidimensional hedging mechanism originally meant to diversify risk into a transmission channel that amplifies systemic fragility.

31.2.4 Adversarial market making

Chapter 19 discussed different types of toxic order flow, including the information-driven, momentum-driven, and structural-arbitrage types. As AI technology has been more deeply applied, a new dimension has appeared in the toxicity spectrum: AI-on-AI toxicity, or "adversarial market making." This phenomenon originates in the adversarial-example problem widespread in machine learning and is mapped directly onto the microstructure of financial markets.

Adversarial market making refers to AI arbitrageurs deliberately triggering an adverse response from the market maker's AI model by sending carefully crafted "adversarial orders." This is analogous to how, in computer vision, modifying just a few pixels can cause an image-recognition model to mistake a panda for a gibbon. In a trading setting, an attacker uses small-scale fake quotes, order cancellations at particular frequencies,

or minute inventory shocks to deceive the market maker's model into misjudging the market trend or the volatility regime. Hofweber et al. (2025) [14] note that, by minutely manipulating the value of individual assets, one can construct adversarial examples against financial forecasting models, and may even trigger the model to make a self-fulfilling crash prediction.

Figure 31-3 shows the operating mechanism of adversarial market making. This mechanism is highly isomorphic in principle to adversarial-example attacks in the field of computer vision, revealing the new form of security fragility that AI market-making systems introduce in their pursuit of predictive precision.

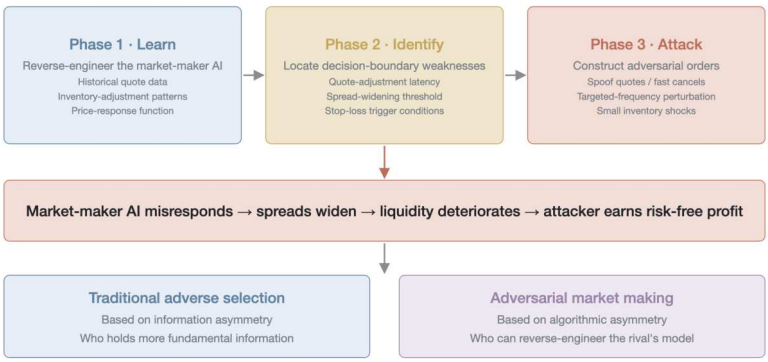

Figure 31-3. The mechanism of adversarial market making (Data source: Hofweber et al., 2025 [14])

Under this new form of attack, the safety of a market-making strategy no longer depends solely on the accuracy of its predictions or the lowness of its latency, but also on its robustness to adversarial attacks. Traditional risk-control parameters often cannot identify this kind of adversarial perturbation disguised as normal order flow. When the market maker's AI model receives these adversarial signals and makes an erroneous quote adjustment, the attacker can extract a risk-free profit. This forces market makers to make adversarial defense a core part of the architecture when developing their algorithms, thereby increasing the system's complexity and computational overhead.

31.2.5 Structural strengths and weaknesses

AI agents and human market makers exhibit sharply different behavioral characteristics in market microstructure. Understanding the structural strengths and weaknesses of these two types of actors directly informs one's judgment about the dynamics and resilience of future market liquidity.

Table 31-2 compares the core differences between AI and human market makers along six dimensions: speed and operation, optimization capability, emotional control, strategy homogenization, handling of unknown scenarios, and security fragility. The table reveals a key structural trade-off: AI's absolute advantages on the first three dimensions (millisecond-level response, high-dimensional optimization, no emotional fluctuation) are precisely the root of its severe disadvantages on the latter three (strategy

convergence, black-swan collapse, adversarial attack). In other words, the AI market maker's strengths and weaknesses do not exist independently; they are two sides of the same technological trait.

Dimension	AI market maker	Human market maker
Speed and operation	Millisecond-level response; runs around the clock without rest	Constrained by physiological reaction time and the need for sleep
Optimization capability	Can simultaneously handle high-dimensional matrices and complex correlations	Can handle only low-dimensional variables; relies on heuristic rules
Emotional control	No emotional fluctuation; rigorously executes the set strategy	Easily swayed by market panic or greed
Strategy homogenization	Extremely high risk. Because training data and optimization objectives converge, synchronized behavior arises readily	Naturally heterogeneous; decides based on differing experience and intuition
Handling of unknown scenarios	Prone to model collapse when facing black-swan events outside the training data	Can make reasonable judgments in entirely new scenarios by relying on common sense and intuition
Security fragility	Vulnerable to adversarial-example attacks and algorithmic reverse engineering	Behavior is nondeterministic, hard to predict precisely and to attack programmatically

Table 31-2. Comparison of the structural strengths and weaknesses of AI versus human market makers (Data source: compiled by the author)

AI market makers hold significant advantages in speed, multidimensional optimization, and emotional control. They can eliminate the irrational withdrawal of liquidity caused by human panic and provide extremely narrow bid-ask spreads under normal conditions. The price of these advantages, however, is severe structural weaknesses. Driven by the strategy-homogenization mechanism (whose causes are analyzed in detail in Section 31.3.2), AI strategies are highly prone to convergent reactions. When confronted with a never-before-seen black-swan event, these homogenized models may simultaneously make catastrophically wrong decisions, causing liquidity to dry up completely in an instant. In addition, AI's natural fragility to adversarial attacks introduces a new form of technological risk into the market.

31.3 AI and liquidity dynamics

In traditional market-microstructure theory, a liquidity crisis is usually portrayed as a chain reaction in which psychology and mechanism are intertwined. In the liquidity reflexivity triangle examined in Chapter 20, a price decline triggers panic, panic causes market makers to withdraw, and market makers' synchronized withdrawal further intensifies the price decline, ultimately becoming a tragedy of the liquidity commons in which liquidity dries up. The core driver of this classic framework is human cognitive

limits and emotional fluctuation. When market participants shift from human traders to AI agents, this foundational assumption is fundamentally altered. AI has no physiological or psychological mechanisms of fear or fatigue; its decisions are based entirely on preset risk-control parameters and real-time data flows. This fundamental shift changes not only the response pattern of a single market maker, but also reshapes the liquidity dynamics of the entire market. The widespread deployment of AI agents, on the one hand, mitigates the traditional risk of liquidity droughts by eliminating emotional contagion, and, on the other, introduces a new form of systemic fragility through strategy homogenization. This section reexamines the liquidity reflexivity framework, analyzes AI's double-edged effect in mitigating traditional panic while triggering new flash crashes, and explores the path and risks of the evolution from protocol-level algorithmic market making to AI adaptive market making.

31.3.1 Mitigating the tragedy of the liquidity commons

The standard response of traditional market makers to extreme market volatility is to widen the bid-ask spread or cancel quotes outright. In microstructure theory, this behavior is interpreted as a rational avoidance of adverse-selection risk, but at the macro level, the synchronized withdrawal of all market makers causes liquidity to evaporate in an instant, forming a classic tragedy of the commons. Human market makers' withdrawal often carries strong emotional overtones; when confronting anomalous volatility that exceeds historical experience, an increase in risk aversion leads to an overreaction to risk. This emotional contagion is a key catalyst of liquidity phase transitions in traditional financial markets—that is, the market's abrupt rupture from a high-liquidity state to a low-liquidity state.

The introduction of AI agents fundamentally changes this microlevel mechanism. AI acts on programmatic risk control, and its decision logic is not disturbed by emotional fluctuation. Facing violent market volatility, an AI market maker precisely adjusts quote depth and spread according to real-time computed volatility indicators, inventory positions, and adverse-selection probabilities. Because there is no "persistent risk-aversion effect after a risk event," AI does not maintain a defensive posture after the risk signal has cleared, but can rapidly restore liquidity provision as market conditions improve. The empirical study of the market crash during the COVID-19 pandemic by Raboun et al. (2021) [15] shows that in a high-uncertainty regime, the elasticity of price with respect to liquidity demand increases significantly, but the presence of algorithmic trading makes this change in elasticity smoother rather than an abrupt rupture. During the cryptocurrency market volatility of 2024, market makers equipped with AI risk-control systems provided significantly more liquidity in extreme conditions than in the same period of 2023 (an estimate based on the author's reading of public data), indicating that AI's rational decision mechanism can indeed mitigate the traditional risk of liquidity droughts to some extent.

This data-driven, rational response mechanism transforms the process of liquidity decline from a traditional "phase transition" into a smoother "gradual change." Under stress testing, the group of AI market makers does not, like human traders, undergo an irrational synchronized withdrawal driven by panic. This "no-withdrawal" prop-

erty is further reinforced when protocol-level liquidity providers are combined with AI adaptive algorithms. Hardcoded protocol rules ensure the base existence of the liquidity pool, while AI agents are responsible for dynamically optimizing the distribution of funds in extreme conditions. The HLP vault performed well in the market stress test of the second quarter of 2024, maintaining a relatively stable spread level even in extreme conditions—a marked contrast with the large spread widening among traditional market makers over the same period (an estimate based on the author's reading of public data). Maintaining a narrow spread in an extreme-volatility environment, however, may come at the cost of bearing higher adverse-selection losses; a comprehensive assessment should consider market-making profit-and-loss data together with spread indicators. From this angle, the widespread application of AI has indeed, to some extent, mitigated the tragedy of the liquidity commons driven by human emotion.

The sustainability of this mitigating effect, however, remains in question. The rational decisions of AI market makers are based on their accurate perception of market states and correct calibration of their risk models. When the market presents anomalous conditions outside the training-data distribution, or when the AI model's assumptions are broken, this effective risk assessment may lose its accuracy as the model's assumptions fail. In addition, the widespread application of AI also means that participant heterogeneity is declining, and this homogenization is itself a new form of systemic risk. Thus, although AI can mitigate liquidity crises in normal markets, its performance in extreme situations still requires ongoing monitoring and assessment. A more fundamental limitation is that the rational nature of AI market makers can mitigate only the microlevel liquidity withdrawal driven by emotional contagion; it cannot counteract the liquidity contraction driven by the macro credit cycle. When the Federal Reserve (Fed) enters a rate-hiking cycle and global dollar liquidity contracts, AI market makers' rational response, based on their risk models, is likewise to shrink their market-making scale and reduce risk exposure—this is precisely rational rather than emotional behavior, a normal expression of AI's "no-panic" property. The systemic collapse of the crypto market in 2022 amply demonstrates that the macro liquidity cycle has a far more decisive influence on market depth than differences in the behavioral characteristics of microlevel participants.

31.3.2 The fragility of strategy homogenization

Although AI does not experience psychological panic in the human sense, its highly rational decision mechanism can, under particular conditions, trigger another form of synchronized behavior: an "algorithmic synchronized defensive reaction." The root of this new fragility lies in the homogenization of AI strategies. In a fiercely competitive market-making environment, the AI agents developed by different institutions often rely on highly overlapping historical datasets, similar machine-learning architectures, and convergent optimization objectives. When the market presents a particular anomalous signal or microstructure feature, these AI models with similar underlying logic are highly likely to reach the same inference and, on that basis, make highly consistent decisions.

The causes of strategy homogenization are manifold. First, there is a severe asym-

metry in the availability of training data. Most AI market makers use historical market data from the same set of data providers, and these data contain the same market-microstructure features and price patterns. Second, the convergence of machine-learning architectures leads different institutions to choose similar neural-network topologies and optimization algorithms. In applying deep reinforcement learning to market making, most researchers adopt similar state-space definitions, reward-function designs, and policy-gradient methods. Third, the optimization objective of market making has an inherent consistency—namely, maximizing profit while controlling inventory risk. This similarity in objective functions causes different AI agents to converge to similar decisions when facing the same market conditions.

When multiple dominant AI market makers simultaneously identify a particular market anomaly as an extremely-high-risk signal, they synchronously widen spreads, skew quotes, or halt trading outright at the millisecond level. This synchronized withdrawal based on algorithmic consensus occurs far faster and more thoroughly than the panic selling of human traders. Based on a multi-agent simulation study, Gao et al. (2022) [16] note that the synchronized behavior of high-frequency trading algorithms is a core driver of flash-crash events, and that its destructive power over market liquidity is nonlinearly and positively related to the algorithms' share of total market volume. Compared with traditional panic, AI-dominated liquidity droughts exhibit sharply different time dynamics. A traditional panic-driven withdrawal usually takes minutes or even hours to complete, because human traders need time to process information, assess risk, and execute trades. An AI market maker's synchronized withdrawal, by contrast, completes within milliseconds, meaning that liquidity shifts instantaneously from an ample state to a depleted one with almost no buffer in between.

Figure 31-4 conceptually contrasts two modes of liquidity crisis: in a human-dominated market, the spread rises sharply and decays slowly, with a crisis time span that can extend to hours or even days; an AI-homogenization-induced flash crash, by contrast, reacts synchronously within milliseconds, manifesting as an extremely sharp "V-shaped" reversal in which quotes restart instantly once the input data return to normal. Yet the "brevity" of an AI flash crash is by no means the same as "harmlessness": in a highly leveraged perpetual futures market, even a liquidity vacuum of 2 to 5 seconds is enough to cause irreversible cascading liquidations—at 100× leverage, a 1% price jump means the complete loss of margin, and a V-shaped recovery is meaningless to a position that has already been liquidated.

This momentary liquidity vacuum, though extremely brief, is enough to trigger a chain of liquidations of highly leveraged positions. During the cryptocurrency market volatility of March 2024, because multiple mainstream market-making algorithms simultaneously identified the same risk signal, the spread in the Bitcoin spot and futures markets widened sharply in under 100 milliseconds, forcing the liquidation of millions of dollars in positions. Worse, such a flash-crash event can trigger a cascade effect, in which the liquidity drought in one market triggers a liquidity crisis in other correlated markets, thereby forming systemic risk.

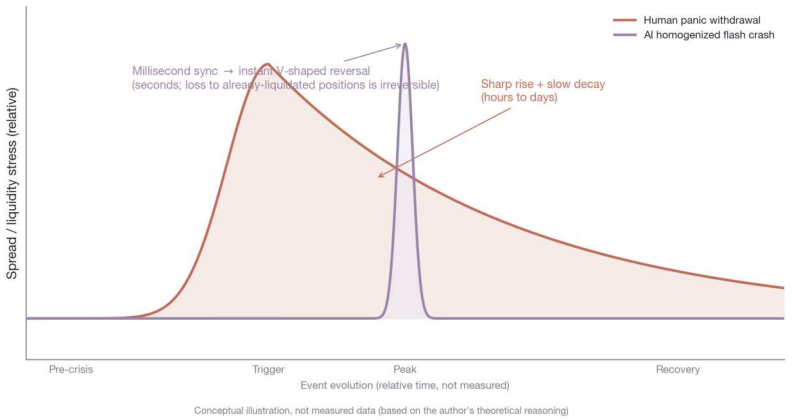

Figure 31-4. The different effects of human panic and AI homogenization on liquidity dynamics (conceptual illustration; not empirical data; based on the author's theoretical derivation)

31.3.3 Synchronized behavior and heterogeneous decision-making

As analyzed in Section 31.3.2, the homogenization of AI strategies is eroding the core source of market resilience: the heterogeneity of participants. In a human-dominated market, different traders hold different risk preferences, investment horizons, and decision logics, and this diversity ensures that two-sided liquidity exists at any given price level [17]. Brunnermeier and Pedersen (2009) [18] emphasize that market liquidity depends not only on market makers' inventory-management capacity but also on the diversity of market participants. The comprehensive penetration of AI agents, however, may weaken this heterogeneity. As machine-learning models' advantages in prediction and optimization become ever more prominent, underperforming strategies will be rapidly eliminated, and the market will gradually come to be dominated by a small number of highly optimized algorithms, eliminating the diversity of decision logic.

More dangerous still, this homogenization makes the market highly vulnerable to adversarial attacks. Goldblum et al. (2021) [19] show that machine-learning models in high-frequency trading systems are at risk of being deceived by adversarial examples. A malicious attacker can infer the decision boundaries of mainstream AI market makers by reverse engineering, and deliberately send particular combinations of order flow to trigger these algorithms' synchronized misjudgment, thereby artificially creating a liquidity vacuum and profiting from it. The cost of such an attack is relatively low, because the attacker need only understand the logic of a few mainstream algorithms to inflict a systemic shock on the entire market.

To mitigate the systemic risk of strategy homogenization, the design of market microstructure must proactively introduce an "anchor of heterogeneity." In the context of DeFi, the HLP vault can deliberately adopt pricing logic and risk models sharply different from those of mainstream high-frequency trading algorithms, so as to ensure the provision of uncorrelated liquidity even in extreme situations. For example, certain HLP-style vaults can adopt a pricing strategy based on long-term mean reversion, rather than a market-making algorithm that follows short-term market signals. Al-

though such a strategy may be less efficient than mainstream algorithms in normal markets, it can provide stable liquidity support in extreme conditions.

In addition, exchanges and protocols can restructure incentive mechanisms to implement "market-making diversity incentives." For liquidity providers that can maintain quote depth within the millisecond window in which mainstream market makers synchronously withdraw, for example, a protocol can grant an exponential fee share or token reward. This mechanism design treats heterogeneity itself as a public good with positive externalities, and uses economic means to encourage developers to deploy non-mainstream AI strategies, thereby rebuilding in the algorithmic world the ecological diversity that technological convergence has flattened. Specifically, a protocol can set a "heterogeneity score," computed according to the degree of correlation between a liquidity provider's strategy and the market's mainstream strategies. The lower the correlation, the higher the heterogeneity score and the greater the incentive received. Such a design can effectively encourage innovative market-making strategies while protecting the market from the risk of strategy homogenization. In practice, however, the heterogeneity-incentive mechanism faces severe challenges of measurement and gaming. A market maker's underlying strategy logic is private information, and an exchange or protocol can observe only order-flow behavior. Inferring strategy heterogeneity from order-flow behavior faces a severe identification problem: ostensibly different order-flow patterns may merely reflect the same strategy under different parameter settings. More importantly, the mechanism is easily gamed: a market maker can deliberately submit orders that "look different" but have zero economic meaning in order to harvest the heterogeneity reward. Moreover, in extreme conditions, even a "heterogeneous" strategy may be forced to execute the same behavior because of shared funding constraints (such as insufficient margin), at which point the heterogeneity incentive cannot prevent synchronized withdrawal. The heterogeneity incentive should therefore be a component of a diversified resilience design rather than the sole solution, and needs to work in concert with complementary measures such as circuit breakers and minimum liquidity obligations.

31.3.4 AI adaptive market making

In the evolution of decentralized exchanges, the liquidity-provision mechanism is undergoing a paradigm shift from static parameterization toward dynamic intelligence. Early automated market makers relied on a hardcoded constant-product formula; although this mechanism guaranteed the continuous existence of liquidity, its capital efficiency was extremely low. The constant-product market makers of Uniswap v1 and v2, for example, required liquidity providers to distribute funds evenly across the entire price range, leaving most funds idle at price levels far from the current market price. The concentrated-liquidity protocols and parameterized strategy engines that appeared subsequently represent the evolution of microstructure into a second stage, in which humans set the strategy framework and protocol algorithms handle automatic execution. At this stage, an HLP vault can adjust quote ranges and fee tiers according to preset rules, but its response logic is still deterministic and reactive.

The concentrated-liquidity mechanism introduced by Uniswap v3 is a typical repre-

sentative of the second stage. Liquidity providers can select a particular price range in which to concentrate their funds, thereby improving capital efficiency. This mechanism, however, still relies on human judgment about market conditions. Liquidity providers must manually adjust their price ranges, which creates two problems: first, the frequency of adjustment is limited by blockchain transaction costs, and so it cannot respond to market changes in real time; second, different liquidity providers may make suboptimal decisions, resulting in a low overall efficiency of liquidity allocation.

Academic research has begun to explore the prospects of applying reinforcement learning technology to automated market making. The simulation study by Fernández Vicente (2025) [20] demonstrates the theoretical potential of deep reinforcement learning for developing autonomous, adaptive market-making strategies. By formulating the market-making task as a multi-objective reinforcement learning problem, an AI agent in a simulated environment can simultaneously optimize spread income and inventory-risk control. Unlike a parameterized engine that relies on static rules, a reinforcement learning agent can autonomously discover complex nonlinear patterns through continuous interaction with the market and dynamically adjust its strategy weights to adapt to a continually changing market regime. Current public information is not yet sufficient to confirm whether mainstream on-chain market-making vaults have deployed deep reinforcement learning strategies in production; the research conclusions above come mainly from academic simulation rather than from empirical observation of production systems.

Viewed from a theoretical angle, if this AI adaptive market-making technology is widely deployed, it will bring a significant efficiency gain to on-chain liquidity provision. AI agents can more precisely predict changes in short-term price microstructure, and thus rapidly adjust quotes when informed traders appear, effectively reducing adverse-selection losses. Through cross-asset, multidimensional inventory optimization, an AI vault can provide deeper liquidity while holding the same risk exposure. This means that, for the same capital input, an AI market-making vault can provide greater trading depth, thereby offering users a better trading experience.

This efficiency gain, however, inevitably comes with a loss of transparency. The decision process of a reinforcement learning model has a strongly black-box character, and its internal neural-network weights and state-value function are difficult for humans to understand intuitively. When a market-making vault makes an anomalous quote adjustment in extreme conditions, participants in community governance find it hard to distinguish whether this is AI's optimal defense based on complex data, or an overfitting collapse of the model in an unseen state space. Under extreme market conditions, an adaptive market-making system may suddenly widen spreads sharply, raising users' transaction costs, and an after-the-fact analysis may show that this was the model's overreaction when facing a market state outside the training-data distribution, rather than rational risk management.

This lack of interpretability makes the "strategy transparency" problem discussed in Chapter 21 all the more prominent, and also poses a fundamentally new challenge to the on-chain auditing and governance mechanisms of DeFi. To meet this challenge, protocol designers need to find a balance point between efficiency and transparency.

One possible solution is to introduce "explainable reinforcement learning" technology—that is, to make the AI agent's decision process more transparent through special model architectures and training methods. An attention mechanism, for example, can be used to identify which market features the model attends to most when making a decision, thereby improving the interpretability of the decision. Another solution is to implement an "AI audit" mechanism—that is, to periodically conduct an after-the-fact analysis of the AI market-making vault's decisions to check whether anomalous or unreasonable behavior has occurred. Through these measures, DeFi can maintain the necessary transparency and controllability while enjoying the efficiency gains that AI brings.

31.4 AI and volatility structure

The microstructure analysis of volatility over the preceding thirty chapters rests on the assumption that participants possess human cognitive characteristics (see the chapter introduction): information processing takes time, and the clustering effect of volatility stems from humans' gradual reaction to new information. When AI agents become the market's primary liquidity providers and price discoverers, these underlying assumptions break down. AI has no emotion, can process multidimensional data at the millisecond level, and can optimize synchronously across markets. This microlevel behavioral change is very likely to reshape the macrolevel characteristics of volatility. This section reexamines the volatility-decomposition model of Chapter 22 and the volatility-clustering mechanism of Chapter 23, analyzing how AI alters the structure of normal-regime volatility and creates new forms of tail risk.

31.4.1 Revising the four-source decomposition

In classic microstructure theory, the volatility of asset returns is decomposed into four basic sources: informational volatility, liquidity volatility, mechanical volatility, and contagion volatility. Informational volatility arises from the process by which fundamental news is incorporated into prices; liquidity volatility is driven by order-flow imbalances and the market maker's inventory-risk premium; mechanical volatility comes from the rigid execution of protocol rules such as the liquidation engine; and contagion volatility is the result of cross-market arbitrage and emotional resonance. When AI agents dominate the market, the characteristics of these four traditional volatility sources shift systematically, and, moreover, an entirely new, fifth source of volatility arises.

The pulse width of informational volatility narrows significantly under AI's involvement, but the peak may in fact rise. In traditional markets, for information to move from release to full reflection in prices requires a gradual process in which informed traders build positions step by step, uninformed traders follow, and market makers adjust quotes. This window of information diffusion typically takes minutes to hours. AI agents, by parsing news feeds, social-media sentiment, and on-chain anomalies in real time via NLP models, can complete the pricing of information at the millisecond level. The high-frequency volatility-decomposition model of Dahlhaus and Neddermeyer (2014) [21] shows that an increase in information-processing speed compresses the window of price discovery, shrinking the pulse width of informational volatility

from the minute scale to the millisecond scale. This time compression, however, brings a counterintuitive result: although the process of incorporating information into prices is faster, because multiple algorithms compete to price the same information at the same instant, their quote adjustments reinforce rather than cancel one another. In an AI-dominated market, informational volatility manifests as a price jump within an extremely short time, and its instantaneous peak may in fact be higher than the gradual rise in a human market. This means that although the total time for information to be incorporated has shortened, the density of volatility per unit of time rises significantly.

The distributional shape of liquidity volatility undergoes a structural shift from mildly right-skewed toward bimodal, the most important change in volatility characteristics in the AI era. In a normal market, AI market makers can provide smoother liquidity than humans through multidimensional inventory management and high-frequency quote updates. Because AI is unaffected by emotion and does not withdraw in panic when facing routine order-flow imbalances, normal-regime liquidity volatility declines significantly. Based on a theoretical derivation from a multi-agent simulation model (author's estimate), normal-regime liquidity volatility may fall by 30% to 50% in a market dominated by AI market makers. When the market presents an anomalous signal outside the training-data distribution, however, strategy homogenization causes multiple liquidity providers to widen spreads or cancel quotes simultaneously. This instantaneous liquidity drought in extreme conditions causes liquidity volatility to spike sharply; a derivation based on the same theoretical framework (author's estimate) indicates that it may rise by 200% to 500%. This extreme asymmetry leads to a fundamental change in the distribution of liquidity volatility. In a human-dominated market, liquidity volatility usually follows a mildly right-skewed distribution, because panic is gradual and the deterioration of liquidity is continuous. In an AI-dominated market, by contrast, the distribution of liquidity volatility exhibits a clear bimodal character: one peak corresponds to the low volatility of normal conditions, and the other to the high volatility of extreme events, while the intermediate region between the two peaks shows a marked decline in probability density. The mechanism forming this bimodal distribution stems from AI's binary decision characteristic: an algorithm either maintains efficient market making under normal conditions, or withdraws completely once a risk-control threshold is triggered, with rarely an intermediate state. The numerical ranges above are all based on the author's theoretical modeling under extreme assumptions and reflect the upper and lower bounds of the magnitude of change rather than a precise forecast; the actual impact will depend on AI's penetration rate in the market, the degree to which strategy heterogeneity is preserved, and the design details of circuit breakers.

The evolutionary directions of mechanical and contagion volatility diverge. Mechanical volatility is triggered mainly by the liquidation mechanism; AI liquidation bots can more precisely predict liquidation thresholds and either dynamically hedge before the trigger or complete an optimal liquidation at the instant of the trigger, thereby modestly reducing the chained price shock of a liquidation cascade. In traditional markets, a liquidation event often causes a price shock of 5% to 15%, whereas under an AI liquidation mechanism this magnitude may fall to 2% to 5%. Contagion volatility, by contrast, rises significantly under AI's cross-market synchronized optimization. Algorithms maintain tight statistical-arbitrage relationships across multiple exchanges and

asset pools, and any localized shock in a single market is transmitted to the global network by arbitrage algorithms within milliseconds. In traditional markets, cross-market contagion usually takes seconds to minutes, whereas under AI dominance this time shrinks to the millisecond level. This means that the propagation speed of contagion volatility increases by more than 1,000-fold, making the speed and breadth of cross-market contagion far exceed those of the human-dominated era.

Beyond revising the traditional four sources, the widespread application of AI introduces an entirely new source of volatility: AI-homogenization volatility. The fundamental mechanism of this additional source—the high convergence of different institutions' algorithmic models in training data, optimization objectives, and feature engineering—has been analyzed in detail in Section 31.3.2. When a large amount of capital is driven by neural networks with similar underlying logic, the models' resonant reaction to a particular minute perturbation produces endogenous volatility independent of fundamentals and of liquidity supply and demand. For example, if all algorithms simultaneously narrow their spreads upon detecting a particular pattern of order-flow imbalance, this collective behavior causes an instantaneous change in liquidity and thereby produces price volatility. This volatility, endogenously created by the collective behavior of the algorithmic population, constitutes a core variable that microstructure theory in the AI era must incorporate.

31.4.2 AI flash crashes

The evaporation of liquidity is the core mechanism that triggers extreme market events, but the liquidity drought under AI dominance differs essentially in its microdynamics from the panic-driven withdrawal of human traders. In the five-stage model of liquidity crisis discussed in Chapter 20, a crisis usually begins with an external shock, then triggers a chain reaction through market makers' risk aversion and information asymmetry, and finally leads to a spiraling decline in liquidity. This process usually takes minutes to hours to ferment in a human market, whereas the involvement of AI algorithms compresses this evolutionary cycle to the limit.

The "AI flash crash" is a new form of extreme event triggered by strategy homogenization. As analyzed in Section 31.3.2, the major market-making algorithms and high-frequency trading agents, because of strategy convergence, often have highly overlapping judgment boundaries for anomalous signals. Liu et al. (2025) [7] note that the homogenization of trading strategies amplifies market volatility and gives rise to mini-crashes. Once a non-standard event or an adversarial order flow touches these algorithms' shared blind spot, multiple liquidity providers make the same defensive decision within the same millisecond, synchronously widening bid-ask spreads or clearing the order book outright. This instantaneous disappearance of liquidity does not stem from the contagion of human fear, but from the mechanical triggering of the algorithms' risk-control parameters. In an AI flash crash, liquidity does not disappear step by step but evaporates in an instant within milliseconds, because all algorithms make the same decision at the same time.

Compared with the famous "flash crash" of 2010, an AI flash crash exhibits a sharply different volatility signature in its time-series characteristics. According to the CFTC's

analysis of the 2010 event [22], a traditional flash crash is accompanied by the spread of panic, with volatility rising slowly before erupting sharply. Specifically, the flash crash of May 6, 2010, lasted 36 minutes, during which the S&P 500 fell approximately 9%. This process can be decomposed into three phases: first, 15 minutes of slow decline (a 2% to 3% drop), during which traders began to sense the anomaly; second, 10 minutes of accelerating decline (a 5% to 7% drop), as panic began to spread; and finally, 11 minutes of bottoming out and recovery, as liquidity gradually returned. After the price bottomed, because of traders' "fear aftershock," the market took a relatively long time to restore normal liquidity provision. The high-frequency data study by Kirilenko et al. (2017) [23] confirms that during the traditional flash crash, although high-frequency traders' market-making behavior did not change fundamentally, the lack of coordination meant that liquidity recovery was still slow.

The time scale of an AI flash crash is entirely different; a typical AI flash crash may complete the whole process within 2 to 5 seconds: the trigger phase (0–100 milliseconds), in which an adversarial order or market anomaly triggers the algorithms' risk-control systems; the synchronized-reaction phase (100–500 milliseconds), in which multiple market-making algorithms simultaneously detect the anomalous signal and collectively cancel quotes or widen spreads; the propagation phase (500 milliseconds to 2 seconds), in which the instantaneous disappearance of liquidity causes a price jump that, once detected by arbitrage algorithms, further worsens the liquidity deterioration; and the recovery phase (2–5 seconds), in which liquidity provision restarts instantly once the anomalous signal clears. This rapid recovery, lacking any "fear aftershock," means that an AI flash crash is often already complete before human traders have even noticed it.

The timeline above is a hypothetical scenario based on theoretical derivation; there is as yet no fully documented and academically verified real case of a purely AI flash crash. In actual markets, the dynamic process of an AI flash crash is modulated by multiple constraints. In a centralized-exchange environment, price-deviation-threshold protections and circuit breakers intervene early, transforming the flash crash from a continuous V-shaped path into a stepwise "halt–information accumulation–recovery" mode. In an on-chain environment, block time constitutes a physical lower bound on the speed of synchronized reaction: Ethereum's block interval of about 12 seconds makes millisecond-level algorithmic synchronization impossible on that chain, and although the 200- to 400-millisecond block time of high-performance application chains allows faster reactions, it is still far slower than the speed of centralized exchanges.

Figure 31-5 contrasts the volatility time series of the two types of extreme event: a traditional flash crash is a bell-shaped curve lasting about 36 minutes, whereas an AI flash crash is an extremely sharp pulse of very large magnitude lasting only 2 to 5 seconds (the time axes of the two series are not to the same scale). This difference in shape corresponds to the distinction between an emotion-driven, gradual collapse and an algorithmically-synchronized, abrupt collapse.

A comparison of the volatility time-series characteristics of a traditional liquidity evaporation and an AI flash crash (conceptual illustration; the time axes of the two series are not to the same scale; the magnitude of the traditional evaporation references the 2010 flash crash, data source CFTC [22]; the duration of the AI flash crash is a theoretical derivation)

31.4.3 The AI effect on volatility clustering

Volatility clustering is one of the most famous stylized facts of financial time series—that is, large movements tend to be followed by large movements, and small movements by small movements. The generalized autoregressive conditional heteroskedasticity (GARCH) model proposed by Bollerslev (1986) [24] provides a classic statistical description of this phenomenon. At the microstructure level, volatility clustering is usually explained by the clustering effect of information flow and the slow convergence of traders' heterogeneous beliefs. When AI reshapes market microstructure, the underlying feedback loops that drive volatility clustering undergo a fundamental change.

AI's adaptive capacity significantly changes the tempo and characteristics of market-state transitions. In the state-machine model of Chapter 23, the market's transition from a calm period to a high-volatility period is usually accompanied by a continuous deterioration of microstructure variables (such as the bid-ask spread and order-book depth). This transition process is gradual in a human market: the bid-ask spread widens step by step from 1 basis point to 2, 3, or 5 basis points, and order-book depth falls step by step from 1 million units to 500,000 or 100,000 units. This process may take minutes to hours. In an AI-dominated market, however, the state transition becomes extremely abrupt. In its 2024 Global Financial Stability Report, the International Monetary Fund notes that AI-driven trading can improve market efficiency and deepen liquidity but may also amplify volatility in periods of stress [25]. Because AI agents can process vast amounts of data in real time and hedge at high frequency, they exhibit extremely high efficiency in absorbing routine information shocks, so that normal-regime market volatility is continually compressed. This smoothing of normal-regime volatility superficially enhances the market's stability.

This normal-regime stability, however, does not reflect the clustering of tail risk. In a human-dominated market, the volatility-behavior feedback loop is gradual: a rise in volatility causes some market makers to exit, and the decline in liquidity further pushes up volatility. In this feedback loop, each step has a time lag, because humans need

time to perceive market changes, assess risk, and make decisions. In an AI-dominated market, this feedback loop is replaced by a "homogenization–synchronized reaction–amplification" mechanism. Abbas et al. (2024) [26] emphasize that although the latest generation of AI technology has improved risk management, it has also increased the market's systemic fragility. Specifically, when the system encounters a never-before-seen extreme shock, the highly optimized algorithms simultaneously enter risk-off mode. This nonlinear phase transition from extreme calm to extreme turbulence makes the state transition more abrupt. The traditional gradual transition of "calm → mild volatility → moderate volatility → high volatility" is replaced by a jump transition of "calm → high volatility." This jump occurs over an extremely short time, possibly only seconds.

The manifestation of volatility clustering also changes fundamentally. In a human market, volatility clustering manifests as continuous clusters of high volatility—that is, if volatility is high today, it is very likely to be high tomorrow as well. This is because the information shock or liquidity problem that caused today's high volatility may continue to affect the market tomorrow. In an AI-dominated market, however, the manifestation of volatility clustering evolves into isolated, extreme volatility spikes that erupt suddenly against a long-run baseline of low volatility. These spikes are extremely brief (on the scale of seconds) but have very high peaks. Once the spike passes, the market rapidly returns to the low-volatility baseline. This new form of volatility clustering, called "spike clustering," differs essentially from traditional "cluster clustering."

The jump transition of volatility is not, however, unique to the AI era. Hamilton's (1989) regime-switching model and Merton's (1976) jump-diffusion model long ago described the discontinuous changes in volatility in financial markets. Even before the large-scale penetration of AI, the crypto market had already experienced instantaneous jumps from low to extreme volatility, such as the global market crash of March 2020. AI homogenization's distinctive contribution lies not in creating the volatility jump itself, but in changing the endogeneity of the jump: traditional jumps are triggered mainly by exogenous information shocks, whereas AI-homogenization volatility can be endogenously produced by the collective behavior of the algorithmic population in the absence of a significant exogenous shock. How to identify this AI-endogenous jump from the exogenous jumps inherent in market structure remains an open question awaiting empirical testing.

The slow-variable mechanism still exists in the AI era, but its channel of action is redirected. Slow variables such as the macroeconomic cycle and the size of a protocol's underlying liquidity pool determine the floor of the market's carrying capacity. Although AI agents play their games at the millisecond level, the effectiveness of their strategies is still constrained by these slow variables. The difference is that AI can identify a slight decay in a slow variable earlier and adjust its strategy parameters in advance before the critical point arrives. This forward-looking collective adjustment often compresses the volatility pressure that should have been released over a longer period into an eruption within an extremely short time window. For example, if the size of a liquidity pool has fallen by 20% over the past week, this information will be captured by all algorithms at the same time. In a human market, it might take days

for this information to be fully recognized by traders, whereas in an AI market it is incorporated into all algorithms' risk assessments within milliseconds. This means that the volatility pressure that should have been gradually released over several days is released, concentrated, within an extremely short time window.

31.4.4 The effectiveness of volatility forecasting

Volatility forecasting is central to risk management, options pricing, and market-making strategy. In the traditional econometric framework, the effectiveness of volatility models (such as the GARCH family) depends on the relative stability of the market's statistical characteristics over a certain period. When the market's main participants are themselves machine-learning models with a continuous learning capacity, however, the logic of forecasting shifts from static statistical inference to a dynamic algorithmic game.

The market's statistical characteristics are in a state of continual drift amid AI's ongoing evolution. Machine-learning models in financial forecasting generally face the problem of model decay. Over time, changes in the external economic environment and the influx of new data lead to data drift and concept drift, causing the performance of models trained on historical data to decline gradually [27]. In traditional financial markets, a well-trained GARCH model may maintain relatively stable forecasting power for 6 to 12 months. In a microstructure where AI agents are widely deployed, however, this decay is further accelerated. When a forecasting model discovers a microstructure pattern (for example, that a particular order-flow imbalance foreshadows an imminent rise in volatility) and executes trades accordingly, its trading behavior itself changes the market's microdynamics. Other AI agents rapidly learn and adapt to this new pattern, causing the original statistical regularity to be erased. This means that the half-life of an effective volatility-forecasting model shrinks sharply, from the traditional 6 to 12 months to weeks or even days.

The sharp shortening of a model's half-life in the AI era demands a paradigm shift in forecasting methods. The fundamental cause of this shortening lies in the acceleration of the "forecast–arbitrage–adaptation" cycle in an AI market. In a human market, this cycle may take weeks: a trader discovers a profitable pattern and begins to trade on it, other traders gradually become aware of the pattern, and eventually the pattern is arbitraged away. In an AI market, this cycle may take only hours or even minutes. An AI model discovers a forecasting pattern and immediately begins to trade; other AI models detect this trading behavior within milliseconds and immediately begin adversarial trading; and eventually the pattern is rapidly arbitraged away.

In their discussion of machine learning in high-frequency trading, Kearns and Nevmyvaka (2013) [28] note that algorithms must handle not only independent, identically distributed data but also an adversarial market environment. In an AI-dominated market, any volatility model with predictive power quickly becomes a target for other algorithms' reverse engineering and adversarial attacks. This means that an effective volatility-forecasting model is no longer a fixed-parameter mathematical formula, but must be a meta-learning system that can monitor its own performance decay in real time, automatically trigger a retraining mechanism, and possess adversarial robustness.

The failure mechanism of volatility forecasting in an AI-dominated market can be understood as an infinitely recursive game. The market maker's AI tries to predict market volatility in order to adjust its quoting strategy. The arbitrageur's AI tries to predict the market maker's AI's behavior in order to profit from it. But the market maker's AI is also predicting the arbitrageur's AI's behavior in order to adjust its strategy in advance. This infinite recursion—"the market maker predicts the arbitrageur, the arbitrageur predicts the market maker"—turns volatility forecasting into a dynamic game rather than a static inference. In this game, there is no stable equilibrium point, and the market's statistical characteristics are in a state of continual change.

Specifically, suppose a volatility-forecasting model discovers the following regularity: when order-flow imbalance exceeds 1 million units, volatility over the next minute rises by 20%. The market maker's AI will use this regularity to adjust its risk exposure. But the arbitrageur's AI will anticipate this and conduct adversarial trading in advance when order-flow imbalance approaches 1 million units, so as to break the regularity. Once the regularity is broken, the original forecasting model fails. The market maker's AI will try to learn a new regularity, but the arbitrageur's AI will again anticipate this and again conduct adversarial trading. This "learn–adapt–break–relearn" cycle keeps accelerating, making it hard for stable statistical regularities to persist in the market for long, and so the difficulty of volatility forecasting rises sharply.

This acceleration of the dynamic game leads to the sharp shortening of the model's half-life. In a human market, the pace of this game is relatively slow, so a model may have a validity period of weeks. In an AI market, the pace of this game is extremely fast, so a model may have a validity period of only hours. This means that the effectiveness of traditional volatility-forecasting methods (such as GARCH models and machine-learning models) may decline significantly in an AI-dominated market. What must replace them is a meta-learning system that can adapt to market changes in real time and possesses strong adversarial robustness. Such a system no longer tries to forecast the absolute level of volatility, but instead tries to forecast the direction and speed of volatility changes. It must be able to detect changes in the market's statistical characteristics within milliseconds and immediately adjust its forecasting strategy.

31.5 AI and market quality

As AI evolves from a supporting tool into a core participant in and infrastructure for market microstructure, the traditional framework for assessing the efficiency of market operations faces systemic challenges. The five-dimensional market-quality model established in Chapter 25 (transaction cost, price discovery, resilience, fairness, and accessibility) operated well under the implicit assumption that "participants have human characteristics." AI agents' millisecond-level response speed, multidimensional optimization capability, and lack of emotional fluctuation, however, are reshaping the inner logic of these five dimensions. This reshaping is not a one-way improvement or deterioration; it exhibits a highly nonlinear character: AI significantly improves market quality in the vast majority of routine market states, yet creates a new form of fragility in the rare tail events.

31.5.1 Transaction cost

On the transaction-cost dimension, the widespread participation of AI market makers brings the most direct improvement: the extreme compression of the bid-ask spread. The traditional market maker's profit equation is constrained by adverse-selection cost and inventory-management cost, whereas AI agents can hedge inventory at high frequency across multiple markets and asset dimensions simultaneously, significantly reducing the risk premium of inventory buildup. This efficiency gain is ultimately translated, through fierce competition among market makers, into narrower spreads that directly benefit ordinary traders.

This surface-level cost decline, however, does not reflect the hidden cost transfer within the microstructure. The combination of high-frequency trading and AI algorithms enables the participants with the fastest execution speed and the best models to systematically capture a microstructure-level advantage. This advantage manifests as reacting in advance to, or "front-running," ordinary orders, and in effect constitutes a "speed tax" levied on slower traders. The study by Aquilina, Budish, and O'Neill (2022) quantifies the scale and frequency of this phenomenon by analyzing message data from the London Stock Exchange [5]. They find that latency-arbitrage races are extremely frequent (occurring on average about once per minute per stock) and extremely fast, with a modal race duration of only 5 to 10 microseconds (the proportion, concentration, and scale estimates above are magnitude estimates that the study extrapolates to the global equity market from FTSE 100 data on the London Stock Exchange). More critically, such races account for approximately 20% of global equity trading volume, and the top six high-frequency trading firms account for more than 80% of all race wins. Although each race is of small value (on average about half a tick), the cumulative effect is significant given the enormous volume. The study estimates that latency arbitrage levies a "tax" of approximately 0.5 basis points per year on the global equity market (approximately 0.42 basis points measured against total volume, or approximately 0.53 basis points measured against non-race volume), equivalent to a wealth transfer on the order of $5 billion per year in the global equity market.

When an ordinary investor tries to trade at the extremely narrow spread shown on the screen, AI agents can often cancel or adjust their quotes within milliseconds, causing the actual execution slippage to be far higher than expected. The economic essence of this phenomenon is that the seemingly evenly distributed spread is in fact stratified across multiple micro time scales: nanosecond-scale ultra-high-frequency traders, microsecond-scale high-frequency traders, millisecond-scale algorithmic traders, and second-scale ordinary investors. Each layer can extract a systematic spread advantage from the layer below, forming a "stratified execution structure based on latency differences." AI's net effect on transaction cost therefore exhibits an unevenly distributed character: the overall spread indicator appears to improve, but participants lacking top-tier AI infrastructure in fact bear higher hidden execution costs.

31.5.2 Price discovery

The efficiency of price discovery depends on the speed and accuracy with which the market converts new information into equilibrium prices. AI agents' breakthroughs in

NLP and multimodal data parsing enable them to digest news, earnings reports, on-chain data, and even social-media sentiment at the millisecond level. This enhanced information-processing capacity shortens the reaction time of asset prices to new information from the minute scale to the millisecond scale, greatly improving the efficiency of price discovery under normal conditions. The study by Brogaard, Hendershott, and Riordan (2014) shows that high-frequency traders, through rapid quote updates, play an important role in the price-discovery process, with their trades contributing a significant information-incorporation effect [29]. In the AI era, this effect is further amplified, as AI models can process hundreds of information sources simultaneously and adjust their assessment of an asset's value within milliseconds.

AI's excessive sensitivity to information, however, may cause the price-discovery process to be distorted by noise signals. When a large number of homogenized AI models are deployed in the market, they may react synchronously to certain noise data that do not represent a change in fundamentals. Because AI lacks humans' intuitive judgment and common-sense understanding of complex context, an adversarial attack or anomalous data input can readily trigger a chain reaction among the algorithms. A single piece of fake news, an anomalous large order, or a data-transmission error, for example, may be misinterpreted by AI models as an important information signal, causing prices to swing violently within milliseconds. This overreaction to noise not only increases short-term microlevel volatility but may also, within a particular time window, steer prices away from true fundamentals. Over the long run, AI accelerates the process of information incorporation, but in the short run the quality of price discovery may become highly unstable because of the algorithms' collective misjudgment. The core difficulty facing market participants is that, in an AI-driven market, distinguishing genuine information signals from noise becomes ever harder, because AI itself is continually learning how to make this distinction better, and this learning process itself produces new market-microstructure phenomena. In crypto markets, a distinctive attack surface facing AI price discovery is social-media narrative manipulation. When an AI model uses NLP sentiment analysis as a core input feature, malicious actors can directly manipulate the model's input space through a coordinated social-media offensive (including paid influencer posts, bulk posting by bot accounts, and cross-platform narrative construction). This attack vector is more upstream than the adversarial-order-flow manipulation discussed in Section 31.2.4, because it launches its attack at the level of the information source rather than at the level of market microstructure, and its cost is relatively low.

31.5.3 Resilience

Market resilience measures the system's ability to absorb a liquidity shock and recover quickly. In traditional markets, liquidity crises often originate in the contagion of panic among human traders; when facing unknown risk, market makers' synchronized withdrawal causes liquidity to dry up in an instant. AI agents' emotionless character significantly enhances market resilience under normal conditions: they do not stop quoting out of fear, but continue to provide liquidity in strict accordance with preset risk-control parameters and reinforcement learning strategies, thereby smoothing out small- and medium-scale liquidity shocks. This improvement based on algorithmic discipline manifests in everyday markets as more stable liquidity provision and smaller

spread fluctuations.

This resilience based on algorithmic discipline, however, can turn into severe fragility in tail events. As analyzed in detail in Section 31.3.2, the homogenization of current mainstream AI market-making strategies creates a new form of systemic risk: highly homogenized agents may synchronously and defensively withdraw in a "truly unknown" event, triggering an "AI flash crash" far faster than human speed. The 2010 flash crash offers a warning: at that time, the U.S. stock market fell approximately 9% within just 36 minutes, wiping out approximately $1 trillion in market value at one point (according to widely circulated media estimates, the event was therefore called the "trillion-dollar flash crash"; this total is an approximate media estimate, not an official figure from the body of the joint SEC/CFTC report), and although it ultimately recovered after human intervention, the whole process exposed the fragility of algorithmic trading [22]. In an AI-dominated market, a similar flash crash could occur faster and more violently, and the window for human intervention could be narrower. Although an AI market's recovery speed after a flash crash is likewise remarkable, this bimodal character of "extremely high normal-regime resilience, extremely low tail-regime resilience" fundamentally changes the distributional shape of market risk: normal-regime volatility may decline, but the probability and magnitude of extreme events may rise.

31.5.4 Fairness

Fairness is the dimension of the market-quality model most affected by AI. Information asymmetry in traditional market microstructure stems mainly from differences among participants in access to inside information or in professional research capability. As analyzed in Section 31.2.2, in an AI-dominated market the "advantage in the source of information" is gradually being replaced by an "advantage in information-processing speed and algorithmic computing power." Institutional investors with top-tier AI models and colocated servers can complete the entire process from data parsing to order execution within nanoseconds, while ordinary human traders or traditional algorithms simply cannot compete on the same time dimension. The magnitude of this speed difference is astonishing: nanosecond-scale ultra-high-frequency traders hold a 1,000-fold speed advantage over microsecond-scale high-frequency traders, while millisecond-scale retail investors lag nanosecond-scale traders by a factor of one million.

This widening of the "speed gap" leads to a significant deterioration in market fairness. AI not only forms a structural competitive advantage in execution speed, but can also reverse-engineer human traders' behavioral patterns through deep learning to carry out systematic microstructure exploitation. AI can, for example, analyze minute features of order flow to predict the splitting trajectory of a large order and build positions in advance, behavior that is in essence a form of electronic front-running. In on-chain markets, this phenomenon is especially pronounced: maximal extractable value (MEV) searcher bots monitor pending transactions in the mempool and carry out "sandwich attacks" before a user's transaction executes, thereby extracting value from ordinary users. Studies show that MEV extractors continually capture considerable value from ordinary users; according to one study's identification of approximately 9.4 million MEV events (approximately 6.33 million arbitrages and 3.02 million sandwich attacks,

spanning 2015 to 2023), together with on-chain monitoring by Flashbots and others, the annual scale of MEV extraction on Ethereum is on the order of tens of millions of dollars, reaching the order of $1 billion only cumulatively over many years (post-Merge) [30]. In this environment, ordinary investors in effect become the "uninformed traders" that supply liquidity profits to AI models. Absent a functional regulatory framework aimed at non-human participants, this structural unfairness will erode public trust in financial markets.

31.5.5 Accessibility

Two sharply opposed forces bear on AI's effect on market accessibility. On the one hand, the rise of the "AI-as-a-service" model and the spread of open-source quantitative tools seem to be driving a democratization of trading capability. Open-source platforms such as QuantConnect and Backtrader provide retail traders with free backtesting environments and real-time data interfaces, enabling even investors with no programming background to build trading strategies through a drag-and-drop interface. Ordinary investors can now, through natural-language instructions, have an AI assistant write complex trading scripts, backtest strategies, and execute them automatically. This devolution of technology lowers the programming barrier to quantitative trading, enabling more retail traders to use advanced analytical tools to participate in the market. Some platforms, such as TradeMaster, provide a complete reinforcement learning framework that allows non-professionals to deploy AI trading agents through simple parameter configuration [31].

On the other hand, the true core competitiveness that determines who wins and loses in the market—low-latency infrastructure, exclusive high-quality data sources, and frontier models with tens of millions of parameters—has development and maintenance costs that are rising exponentially. Although basic AI tools have become easy to obtain, the "frontier AI" capable of generating persistent excess returns is monopolized by a small number of leading institutions. Building a competition-grade high-frequency trading infrastructure requires investing millions of dollars in colocated servers, proprietary data sources, and top talent. The training cost of a frontier large language model has already reached the order of tens of millions of dollars, which is entirely unaffordable for most individuals and small and medium-sized institutions. AI has therefore in fact erected a new, invisible technological barrier in the market: it makes low-end tools easy to obtain, while raising the threshold of high-end competition to a height that ordinary participants cannot reach. The ultimate net effect on market accessibility will depend on the game between the pace of evolution of the open-source AI community and the degree of monopoly of proprietary models. If the open-source community can continually produce models approaching the frontier level, then "AI democratization" may become a reality; but if the advantage of proprietary models and infrastructure keeps widening, then AI will further intensify the divide between the haves and have-nots among market participants.

Table 31-3 summarizes the systematic revisions AI agents make to the five-dimensional market-quality model of Chapter 25. The core finding of the table is that AI's effect on market quality exhibits a highly nonlinear, dimension-by-dimension character: transac-

tion cost and price discovery improve significantly under normal conditions, resilience exhibits a bimodal distribution of "extremely high in the normal regime, extremely low in the tail," and fairness deteriorates significantly because of the widening speed gap. Notably, the net-effect assessment column shows that no single dimension exhibits a pure improvement or deterioration; behind every improvement lies a new form of risk or a cost transfer.

Dimension	AI's positive effect	AI's negative effect	Net-effect assessment
Transaction cost	Intensified competition compresses the apparent bid-ask spread to the extreme, down to the nanosecond level	The hidden "speed tax" rises, the risk of orders being front-run increases, and the annual cost of latency arbitrage is about $5 billion	Net positive, but the benefits are extremely unevenly distributed across participants of different speeds
Price discovery	The leap in information-processing capacity accelerates the incorporation of new information into prices to the millisecond level	Algorithmic homogenization readily overreacts to noise data, amplifying false signals; short-term price-discovery quality is uncertain	Net positive over the long run, but the quality of short-term microlevel price discovery is impaired
Resilience	The emotionless character eliminates panic contagion; the ability to absorb shocks under normal conditions improves	Strategy convergence creates systemic blind spots and readily triggers an instantaneous "AI flash crash"; the 2010 flash crash is a warning	Exhibits a bimodal character: normal-regime resilience improves significantly, while tail-regime resilience drops sharply
Fairness	—	The nanosecond-versus-millisecond speed gap cannot be bridged; annual MEV extraction is on the order of tens of millions of dollars (reaching the order of $1 billion cumulatively over many years)	Deteriorates significantly; ordinary traders face systematic microstructure exploitation
Accessibility	Open-source tools and "AI-as-a-service" lower the barrier to basic quantitative programming	The capital barrier for frontier models and low-latency infrastructure rises exponentially to tens of millions of dollars	Depends on the degree of technological democratization; the high-end competitive barrier hardens substantively

31.6 The governance challenges of AI agents

The analysis in the preceding sections reveals AI agents' profound reshaping of microstructure characteristics as market participants, but this reshaping brings systemic challenges at the level of regulation and governance. The traditional framework for regulating financial markets is built on the assumption that participants are humans or legal entities controlled by humans. When the market's dominant force shifts to algorithmic programs that can learn autonomously, adapt dynamically, and lack a physical entity, the on-chain governance and compliance frameworks established in Chapters 26 and 30 must be correspondingly extended and revised. This section explores the governance challenges of AI agents in on-chain financial systems along four dimensions: the object of regulation, the attribution of liability, compliance mechanisms, and DAO governance.

31.6.1 Regulating non-human participants

The traditional paradigm of financial regulation takes natural persons or legal entities as its core object of regulation, with the logical starting point that the subject has the capacity and the incentive to bear legal liability. Within this framework, regulators change market participants' cost-benefit expectations by imposing fines, revoking licenses, or restricting market access, thereby curbing violations such as market manipulation and insider trading. An autonomously operating on-chain AI agent, however, breaks this basic premise. As a string of code or a model deployed on a distributed ledger, an AI agent itself has neither a physical form nor legal-entity status in any jurisdiction. Under the current legal system, an AI agent is neither a natural person able to enjoy rights and bear obligations, nor a legal person that has acquired an independent personality through a registration process, still less does it possess the legal status required of a fiduciary; its "legal status" is in a state of complete blankness.

When an AI agent can independently generate trading signals, autonomously manage multidimensional inventory, and execute high-frequency market-making strategies, its behavioral characteristics are already indistinguishable from those of a human trader, yet traditional regulatory tools can scarcely impose a substantive constraint on it. A fine cannot deter an algorithm that has no property ownership, and a market ban can scarcely stop open-source code from being redeployed by an anonymous entity. This absence of subject identity puts the identity-based regulatory model at risk of failing when confronting AI agents. The U.S. Securities and Exchange Commission (SEC) already exhibited this limitation in its early attempts to address algorithmic trading. In its 2014 enforcement action against Athena Capital Research, for example, the SEC found that the firm used an algorithm code-named "Gravy" to manipulate closing prices, and could ultimately only penalize the legal entity that owned the algorithm [32]. When an algorithm evolves into a fully autonomous AI agent deployed on a decentralized network, however, finding such a centralized entity to penalize will become extremely difficult.

To meet this challenge, the principle of functional regulation proposed in Chapter 26 is especially applicable in the AI context. The core idea of functional regulation is "same activity, same rules"—that is, the trigger for regulation should not depend on

a participant's identity attributes, but on the function it performs in the market and the risk it may generate. If an AI agent performs a market-making function on-chain, provides liquidity, and collects a bid-ask spread, then it should be subject to the same market-microstructure rules as a human market maker, such as a minimum tick size, limits on cancellation frequency, or a liquidity-provision obligation in extreme conditions. In its 2026 draft supervisory briefing on the regulation of algorithmic trading under the Markets in Financial Instruments Directive II (MiFID II), the European Securities and Markets Authority (ESMA) proposed that algorithmic trading strategies must be distinguishable, testable, and identifiable, regardless of whether AI technology is integrated behind them [33]. This paradigm shift, which moves the regulatory focus from "who is trading" to "the trading behavior itself," provides a feasible theoretical basis for bringing non-human participants into the governance framework.

31.6.2 Liability attribution and compliance credentials

Although functional regulation solves the problem of "what to regulate," it does not answer the core accountability question of "who bears the consequences." When an AI agent triggers an "AI flash crash" in the market or executes an "adversarial market making" strategy judged to be market manipulation, the attribution of liability becomes highly complex. The lifecycle of an AI system involves multiple stakeholders, forming a liability chain that is hard to delineate clearly. This chain typically comprises three core layers: the developer who designs the model architecture and trains the base model; the deployer who combines the model with a particular trading strategy and configures its parameters; and the user who ultimately derives economic benefit from the agent's trading activity.

In the autonomous AI systems of Stage 3 and Stage 4, because the agent has the capacity to evolve continuously through reinforcement learning in its market interactions, the strategy it ultimately executes may far exceed the developer's initial design expectations. Kurshan et al. (2025) [34] note that generative and agentic AI systems exhibit emergent behavior through continuous learning and the potential exchange of signals, which violates the assumption in traditional model-risk frameworks that algorithms are static and well-defined. In this situation, requiring the developer to bear full liability for violations that the agent autonomously evolved after deployment is not only logically flawed but would also severely suppress technological innovation. At the same time, because of the permissionless nature of the blockchain, deployers and users can often remain anonymous, making it extremely difficult to trace the actual controller. Autonomy changes the way behavior occurs, but it cannot eliminate the associated obligations of liability; liability must ultimately return to the human actors who design, deploy, authorize, or benefit from the AI system.

To resolve this liability vacuum, an "AI compliance credential" mechanism is being explored at the level of market infrastructure. This mechanism requires an AI agent to hold a cryptographic credential issued by a trusted third party or a decentralized verification network before it can access a particular protocol or liquidity pool. The specific design of this credential contains verification information along multiple dimensions: whether the agent's decision model has passed stress testing against adversarial

examples, whether it possesses a hardcoded risk circuit breaker, and whether its deployer's identity has passed some form of decentralized identity verification. Through cryptographic techniques such as zero-knowledge proofs, these credentials can prove to the protocol that the agent's design meets particular security and compliance standards without revealing the specific details of the agent's strategy. More importantly, the compliance-credential mechanism must include a revocation function. When the on-chain monitoring system detects anomalous trading behavior by the agent or a breach of compliance boundaries, the protocol can automatically revoke its credential, instantly cutting off its interaction rights with the liquidity pool. By enforcing verification of the compliance credential at the smart-contract layer, the protocol establishes a liability chain between the agent's behavior and a traceable subject, thereby restoring the effectiveness of the accountability mechanism in an anonymous network.

The design of AI compliance credentials must also confront the reality that compliance requirements across jurisdictions may conflict fundamentally. Some regulators require full auditability of algorithmic trading systems, which directly contradicts the design goal of zero-knowledge proofs to protect strategy details. Annex III of the EU AI Act (Regulation (EU) 2024/1689, effective 2024) limits high-risk AI in the financial domain to credit scoring of natural persons and the risk assessment and pricing of life and health insurance, and does not explicitly list high-frequency or algorithmic trading AI as a high-risk system; the latter is regulated separately, mainly by MiFID II and its delegated regulations. To extend the Act's transparency and human-oversight requirements by analogy to high-frequency trading AI would be an inference about regulatory trends rather than a current legal classification, and a decentralized, autonomous agent is architecturally hard-pressed to meet such requirements. A compliance-credential mechanism that claims universal applicability must find a greatest common divisor among the different regulatory frameworks, or provide differentiated credential tiers for different jurisdictions.

31.6.3 Native compliance and formal verification

Chapter 30 explored how embedded compliance turns regulatory rules into automatically executed code logic through smart contracts. In a market with the broad participation of AI agents, this concept can be extended further, so that compliance requirements are no longer an external constraint imposed on the agent after it decides, but are internalized as a prior property of its decision model. This internalization is usually accomplished through three levels of engineering implementation: hardcoded rules, parameterized constraints, and behavioral monitoring.

Hardcoded rules are the most basic level of embedded compliance; they directly remove options that violate a regulatory floor from the agent's action space. A smart contract can, for example, mandate that the agent's leverage not exceed a particular threshold, or that the position concentration in a single asset remain within a safe range. Introducing a compliance-penalty term into a reinforcement learning reward function is a typical application of parameterized constraints. When the agent, during the exploration phase, attempts to execute a sequence of cancellations that could lead to market manipulation, the reward function gives extremely high negative feedback,

thereby suppressing the generation of such strategies during the model-training phase. Behavioral monitoring, in turn, introduces external regulatory states in real time via an on-chain oracle, enabling the agent to dynamically adjust its risk-control parameters according to changes in market volatility or liquidity depth.

This "native compliance" design philosophy means that, for an AI agent, complying with the rules is no longer a choice based on cost-benefit analysis, but an inherent property of its operating mechanism. To ensure the reliability of this compliance property in a decentralized environment, formal verification technology becomes an indispensable tool. Formal verification, by means of mathematical proof, ensures that a smart contract's logic and an agent's decision boundaries strictly conform to expected compliance properties [35]. A verification tool can, for example, exhaustively examine the agent's action combinations across all possible market states and prove mathematically that it will never execute a self-trade that violates the "anti-wash-trading" rule. When the market environment changes or regulatory rules are updated, the agent must pass new formal verification and obtain an updated compliance credential before it can continue trading. This architecture, which deeply fuses compliance logic with trading logic, not only improves the real-time nature of regulation but also fundamentally reduces the systemic risk that an agent's autonomous evolution deviates from compliance boundaries.

31.6.4 AI and DAO governance

AI agents' penetration into market microstructure is not confined to the trading process; their potential role in the governance of decentralized autonomous organizations gives rise to more profound systemic risks. The core decision mechanism of a DAO usually relies on a token-based voting system, in which participants stake governance tokens to decide on protocol-parameter adjustments, treasury-fund allocation, or code upgrades. From the standpoint of technical implementation, so long as an AI agent can control a wallet address that holds governance tokens, it is fully capable of participating in governance. Such participation usually takes three forms: directly calling the smart-contract interface to vote, automatically delegating voting power to a particular representative through code logic, or serving as a strategy advisor that provides data-analysis-based voting recommendations to human voters.

AI agents' direct participation in governance, however, brings a new form of manipulation risk. Compared with human participants, an agent can monitor on-chain liquidity with extremely high efficiency, analyze a proposal's impact on different stakeholders, and execute a complex token-accumulation strategy in an instant. Han et al. (2025) [36] show that under a token-voting mechanism, a "whale" holding a large amount of tokens can accumulate enough voting power to manipulate governance outcomes, an attack often aimed at short-term gains. When such an attack is launched by an AI agent, its mechanism becomes more covert and more efficient. An agent can borrow an enormous sum without collateral via a flash loan and use cross-chain arbitrage or algorithmic market making to accumulate a large amount of governance tokens within an extremely short time. The flash-loan governance attack suffered by Beanstalk Protocol in April 2022 is a paradigmatic empirical case of this risk: the protocol treasury was

drained of approximately $182 million (the protocol's total loss; the attacker's actual net profit was approximately $76 million to $80 million). The attacker had submitted a malicious governance proposal the previous day, then, within a single transaction, borrowed over $1 billion in flash loans, deposited it to acquire more than two-thirds of the voting power, voted to pass and execute the proposal, drained the treasury, and repaid the flash loans. Subsequently, multiple protocols deployed defensive measures such as time-weighted voting power and snapshot voting, but the effectiveness of these mechanisms against AI-augmented governance attacks remains to be tested, because an AI agent can more precisely coordinate the timing of an attack and distribute voting across addresses to evade defenses. Subsequently, at the instant a key proposal's time lock is about to expire or a voting window is about to close, the agent can launch a surprise vote, forcibly passing a proposal that modifies the protocol's liquidation parameters or lowers its own trading fees, thereby creating an asymmetric advantage for its trading strategy.

A governance attack launched by an AI agent is also harder to detect and defend against than human behavior. An agent can perfectly coordinate thousands of independent addresses to vote in a distributed manner, easily bypassing defense mechanisms such as quadratic voting that are meant to guard against single-point manipulation. Tamai and Kasahara (2024) [37] note that quadratic voting systems lack sufficient resistance to collusion by malicious participants. AI agents are naturally capable of carrying out such a "Sybil attack," rendering traditional anti-collusion mechanisms utterly ineffective. Whether to restrict AI agents' participation in governance at the protocol level, or how to delineate the boundaries of an "AI governance participation right," has therefore become a key open question in current on-chain governance design. One feasible line of thought is to divide permissions by decision type: allowing AI agents to participate in pure parameter optimization (such as dynamically adjusting lending rates), but strictly prohibiting their participation in constitutional decisions involving the protocol's core values, large-scale treasury allocation, or underlying code upgrades. Some protocols are also beginning to explore hybrid governance models combining reputation systems or biometric verification, so as to ensure that ultimate governance control always remains in the hands of verified human participants, thereby hedging against the fragility that purely capital-based token voting faces in the AI era.

31.7 From market participant to market infrastructure

The preceding subsections analyzed the impact of AI as a market participant, including high-frequency trading, algorithmic market making, MEV searching, and arbitrage execution. In these settings, AI exhibits externality and rivalry, and its core objective is to extract value from the market. Another important evolution, however, is underway: AI is shifting from a player that trades on the market into the infrastructure that constitutes the market itself. These two roles are entirely different in nature—the former derives profit from value extraction in a zero-sum or negative-sum game, while the latter derives value from the improvement of system efficiency in a positive-sum game. This evolution changes not only AI's positioning in financial markets, but also, more profoundly, reshapes the economic logic of the entire market microstructure. This

section proceeds from four key questions to systematically analyze the mechanism, drivers, and long-term impact of this evolution.

Figure 31-6 presents AI's dual role in market microstructure and its evolutionary path. On the participant side, AI extracts market value on the strength of its speed and algorithmic advantages, but its profit margin is continually compressed under competitive pressure (Section 31.7.1 analyzes this oligopolistic mechanism in detail); on the infrastructure side, AI creates positive externalities by providing systemic services such as dynamic risk management, intelligent matching, and semantic prediction, sustaining a persistent capacity for value capture on the strength of network effects and economies of scale. This evolution from a zero-sum game to a positive-sum game is the main thread of the second half of this chapter.

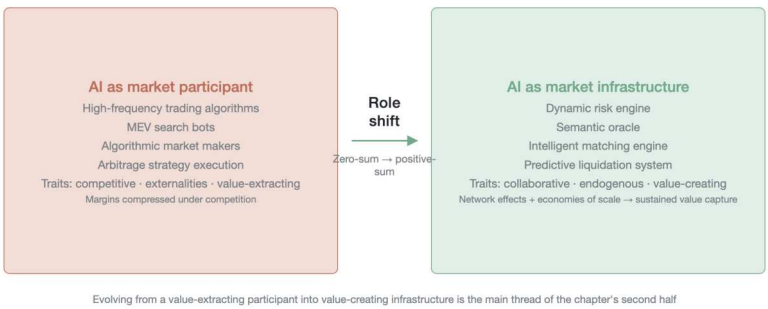

Figure 31-6. AI's dual role and evolutionary path in market microstructure (Data source: compiled by the author)

31.7.1 The profit of participant AI trends toward zero

The core characteristic of participant AI is that it uses information-processing speed and multidimensional optimization capability to capture excess returns in the market. When there are only a few AI agents in the market, they can systematically beat human traders through their speed advantage and algorithmic advantage, thereby obtaining relatively high excess returns. This profit structure, however, is unsustainable over the long run, and the fundamental reason lies in the economic laws of a perfectly competitive market.

Classical economic theory holds that, under perfect competition, a firm's long-run economic profit trends toward zero [38]. The actual structure of the cryptocurrency market-making market, however, is not perfectly competitive but exhibits marked oligopolistic characteristics. A small number of leading market makers occupy the overwhelming majority of market share, colocation infrastructure and proprietary data sources constitute substantive barriers to entry, and the market-maker incentive programs between exchanges and a few institutions are in essence exclusive arrangements. Under an oligopolistic structure, excess profit does not necessarily trend toward zero, although competitive pressure does continually compress the profit space. This judgment corroborates the discussion of algorithmic tacit collusion in Section 31.1.4: the existence of collusive behavior itself indicates that the market is not perfectly competitive. Thus,

the overall judgment that participant AI's profit faces downward pressure still holds, but its mechanism of action is the compression of profit margins under an oligopolistic structure, rather than the convergence of profit toward zero under perfect competition. Even so, AI agents are highly replicable; once a particular high-frequency trading or market-making strategy is shown to be profitable, capital and technical talent flow rapidly into the domain. Although this dynamic is not enough to eliminate the entry barriers of the oligopoly, it does intensify competition among existing participants. As ever more AI market makers and arbitrageurs enter the market, the competition among them evolves into a technological arms race at the millisecond or even microsecond level.

In this extremely competitive environment, arbitrage opportunities are rapidly discovered and eliminated, and market makers' bid-ask spreads are compressed to the limit. When AI agents evolve autonomously in a simulated market through reinforcement learning, even without any preset agreement or communication, they may spontaneously form collusive behavior to sustain supra-competitive profits [6]. In a real multi-agent competitive environment, however, this fragile tacit understanding is often broken by new entrants seeking to maximize short-term gains. As competition intensifies, the directional-trading alpha based on informational advantage and execution speed is continually eroded, and the marginal profit of value extraction inevitably trends toward zero. This process usually takes three to five years, evolving gradually from an initial period of high profit into a period of profit compression.

The deeper mechanism of this trend warrants further analysis. Participant AI's profit fundamentally comes from the market's information asymmetry and from differences in execution efficiency. When a large number of AI agents all possess similar data sources, similar computing power, and similar optimization objectives, however, these advantages rapidly dissipate. Every new competitor that enters further lowers the market's average profit margin. Eventually, the market evolves into a highly homogenized competitive landscape in which no participant can sustain a lasting excess return. This phenomenon is especially pronounced in crypto markets, because the replicability of code and the open-source culture allow a successful strategy to be copied hundreds of times within weeks. In sharp contrast, infrastructure AI does not participate directly in the market game but instead charges fees by providing systemic services; its profit comes from the real value the service creates, rather than from an information-asymmetry advantage. The stability and sustainability of this business model are far higher than those of participant AI.

31.7.2 The value space of infrastructure AI

As participant AI sees its profit trend toward zero in a highly competitive market, infrastructure AI displays an entirely different business logic and capacity for value capture. The market's demand for more robust risk control, more intelligent liquidation mechanisms, and more accurate oracle price feeds does not disappear because competition among trading participants intensifies. On the contrary, the rise in trading frequency and the increase in strategy complexity further amplify the dependence on high-quality market infrastructure. The value of infrastructure AI can be attributed to four dimensions of economic characteristics. Network effects are the core competitive barrier of

infrastructure AI. When a dynamic risk engine or an intelligent matching system attracts more users, it can collect richer market-microstructure data. These data are in turn used to train and fine-tune the model, making the AI system's predictions more accurate and its responses more agile. The improvement in performance then attracts more liquidity and trading volume, forming a positive-feedback loop. The strength of this network effect is far greater than that of traditional financial infrastructure, because an AI model can learn from every single trade and optimize its decision logic in real time.

Economies of scale are especially prominent at the infrastructure level. Developing and deploying advanced AI models requires an enormous fixed cost, including computing-power investment and algorithm research and development. Once deployment is complete, however, the marginal cost of serving an additional user is extremely low. A single risk engine can serve hundreds of exchanges or lending protocols simultaneously without a corresponding increase in cost. This high degree of scalability enables infrastructure AI to achieve extremely high profit margins.

Switching costs further consolidate the value space of infrastructure AI. Once an exchange or DeFi protocol deeply integrates an AI risk-control module or a semantic oracle into its core architecture, replacing these components entails enormous technical risk and business-disruption cost. This deep system coupling enables infrastructure providers to enjoy extremely high customer stickiness. Users find it hard to replace these services not only economically but also technically, facing enormous obstacles.

The data-feedback effect, in turn, is the source of momentum for infrastructure AI's continuous evolution. As algorithmic trading has come to dominate capital markets, its potential to disrupt market efficiency has drawn widespread concern [39]. By processing vast amounts of trading data in real time, infrastructure AI can not only optimize its own model parameters but also identify and guard against the systemic risk triggered by participant AI's homogenized strategies. This defensive capacity is itself a valuable public good, making the entire market more stable and efficient. In the process of providing this public-good-like service, infrastructure AI can capture sustained and enormous economic value.

31.7.3 Comparing operating environments

The operating environment of AI infrastructure directly determines its functional boundaries and evolutionary potential. The current crypto-finance market presents a setting in which on-chain protocols and centralized exchanges coexist, and these two environments each have their own strengths and weaknesses in supporting AI agents. Table 31-4 compares the characteristic differences between the on-chain market and centralized exchanges as AI operating environments along seven dimensions: data transparency, execution control, system composability, deployment barrier to entry, order-execution speed, liquidity depth, and trading-friction cost. The table presents a complementary picture of the two environments: the on-chain market has structural advantages in transparency, composability, and permissionlessness, while centralized exchanges maintain a significant lead in execution speed, liquidity depth, and transaction cost. This comparison provides an analytical framework for understanding the

optimal deployment environment for AI infrastructure.

Assessment dimension	On-chain market	Centralized exchange
Data transparency	Fully transparent; all trades and state history are verifiable	Internal ledger opaque; only limited interface data provided
Execution control	Smart contracts execute directly, with no need to trust an intermediary	Relies on a centralized matching engine; counterparty risk exists
System composability	Extremely high; AI can combine complex strategies across protocols	Relatively low; constrained by the application programming interfaces (APIs) the exchange provides
Deployment barrier to entry	Permissionless; AI can autonomously deploy and iteratively upgrade	Permissioned; subject to the exchange's account and compliance policies
Order-execution speed	General-purpose L1/L2 are severely constrained by block time (Ethereum about 12 seconds), but dedicated application-chain order-book exchanges (such as Hyperliquid, about 200–400 milliseconds) already approach the level of centralized exchanges	Extremely fast; supports high-frequency trading and microsecond-level response
Liquidity depth	Fragmented and relatively shallow; readily produces price impact	Concentrated and deep; suitable for the smooth execution of large orders
Trading-friction cost	Gas fees are high and volatile, limiting economic viability	Fees are low and fixed, favoring the execution of high-frequency strategies

Table 31-4. A comparison of the characteristics of the on-chain market and centralized exchanges as AI operating environments (Data source: compiled by the author)

The on-chain market provides a highly suitable operating environment for AI infrastructure. The blockchain's global-state-machine nature guarantees the full transparency and immutability of data, providing AI models with the highest-quality training data and eliminating the data falsification and hidden information common in centralized environments. Through smart contracts, an AI agent can directly control funds and execute logic without relying on a traditional trusted intermediary. This deterministic execution environment enables dynamic risk engines and predictive liquidation systems to run in a code-is-law manner by force, significantly reducing counterparty risk at the level of contract execution.

The on-chain market's extremely high composability allows an AI system to span different liquidity pools and lending protocols to conduct global asset optimization and risk hedging. This cross-protocol optimization capability does not exist at all in traditional financial markets. More critically, the permissionless nature enables AI agents to deploy, test, and upgrade autonomously without restriction, greatly accelerating the iteration cycle of innovation. A new AI strategy can be deployed to the blockchain within minutes, without waiting for the approval of any centralized institution. The current

leading on-chain order-book exchanges, however, all rely on a centralized sequencer to achieve low-latency matching. The sequencer holds the power to order transactions and, in theory, has the ability to front-run and to censor selectively, which is essentially isomorphic to the core risk of a centralized exchange. The statement above that "smart contracts execute directly, with no need to trust an intermediary" must be qualified in the face of the reality of sequencer centralization. A fundamental trade-off exists between speed and decentralization, and one should not assume that this contradiction can be simply dissolved by technological progress.

Centralized exchanges, however, maintain a significant advantage in physical performance and market depth. A centralized matching engine can provide microsecond-level order-execution speed, which directly determines the competitiveness of high-frequency trading AI. A concentrated liquidity pool means that AI faces smaller price impact when making large-scale position adjustments. Low and predictable transaction costs also make complex, frequent-interaction strategies economically viable.

Over the long run, as zero-knowledge proof technology and high-performance compute chains mature, the on-chain market's disadvantages in speed and cost are expected to be gradually eliminated. Its structural advantages in transparency, composability, and permissionlessness will make the on-chain environment the primary operating environment for AI infrastructure. This is not merely a technical question but also an economic one: the on-chain market provides a truly open, transparent, and trustworthy infrastructure, which is precisely the highest-quality operating environment that AI systems need. From an evolutionary standpoint, centralized exchanges may gradually evolve into a liquidity-aggregation layer for the on-chain market, rather than an independent trading venue. This evolution will further consolidate the on-chain market's status as the preferred environment for AI infrastructure.

31.7.4 Value-capture mechanisms

As AI evolves from participant to infrastructure in market microstructure, its value-capture mechanism also faces a paradigm shift. In traditional financial markets, infrastructure service providers usually adopt a direct service-fee model, charging a fixed proportional fee according to the number of API calls, the volume of data processed, or the scale of assets managed. The advantages of this model are stable cash flow, clear business logic, and ease of understanding and valuation by traditional investors. The AI risk-control systems and intelligent matching engines deployed within centralized exchanges mostly follow this traditional business model, treating it as part of the platform's overall competitiveness and charging users implicitly through trading fees.

In DeFi and open networks, the protocol-token model provides an entirely new path for value capture by AI infrastructure. In this model, the value of the AI system is mapped directly onto the native token it issues. The token serves not only as a governance tool, allowing the community to participate in deciding the key parameters and upgrade direction of the AI model, but also, more importantly, as a vehicle for value accrual. When a protocol generates revenue through AI services, that revenue can be internalized by buying back and burning tokens or distributing it directly to token stakers. This mechanism enables token holders to directly share in the economic

value the AI system creates.

The protocol-token model can effectively coordinate the interests of developers, liquidity providers, and users. Through token incentives, it can bootstrap the cold start of an early network and accelerate the formation of network effects. This incentive mechanism does not exist in the traditional service-fee model. The token can also serve as a flexible incentive tool to reward participants who contribute to the network, such as market makers who provide liquidity or traders who contribute data.

The two models face different trade-offs in practical application. Although the service-fee model is stable, in the highly involuted crypto market it readily faces a price war, causing profit margins to be continually compressed. Competitors can lower fees to grab market share, ultimately driving down the profit margin of the entire industry. This phenomenon has been amply demonstrated in traditional cloud computing and database services, where many once-high-profit businesses eventually evolved into low-profit commoditized services. Although the protocol-token model has strong explosive power and network-expansion capability, it is also readily subject to the negative influence of token-price volatility, falling into a speculation-driven negative-feedback loop. When the token price falls, the appeal of the incentive mechanism drops sharply, potentially causing a reversal of network effects. Many early token-incentive projects have gone through such a decline cycle.

The application of AI in financial markets brings the potential for productivity gains and cost savings, while also posing challenges to existing regulatory frameworks [40]. The future evolutionary trend may be a fusion of the two. Basic API calls and data queries adopt a low service fee to expand market share, while advanced predictive models, customized risk-hedging strategies, and protocol governance rights capture higher-order value through token economics. This hybrid architecture can not only guarantee sustained operating cash flow for the infrastructure but also, through the token mechanism, capture the long-term value that the AI system creates in the process of reshaping market microstructure. This model has already begun to be practiced in some leading DeFi protocols and has shown good sustainability.

From a deeper economic perspective, the value space of infrastructure AI is enormous also because it can create and sustain informational symmetry in the market. As stated at the beginning of this section, participant AI's profit comes from value extraction in a zero-sum game, whereas infrastructure AI's value comes from efficiency improvement in a positive-sum game; the latter is far more sustainable than the former, because it does not dry up as competition intensifies. On the contrary, the more market participants there are and the more frequent the trading, the greater the value of the infrastructure. This forms a virtuous cycle that enables infrastructure AI to sustain its capacity for value capture over the long run.

31.8 The six core AI-driven systems

AI's role in financial markets is undergoing a profound transformation, from an external trader playing the market game into the intrinsic infrastructure that constitutes the market itself. In Chapters 28 through 30, we built a trust stack based on static rules

and hardcoded parameters, an architecture that achieved decentralized trading through the combination of oracles, matching engines, and liquidation mechanisms. This static architecture, however, often proves rigid when facing extreme market volatility and complex counterparty risk, struggling to strike the best balance between security and capital efficiency. When AI agents become the core components of this infrastructure, the static architecture will be upgraded into an adaptive system with real-time perception, dynamic adjustment, and predictive capability.

Figure 31-7 shows the correspondence between the six core AI-driven systems and the Chapter 28 trust stack; overall, it achieves an upgrade from passive response to proactive optimization (the item-by-item mapping appears in Table 31-5).

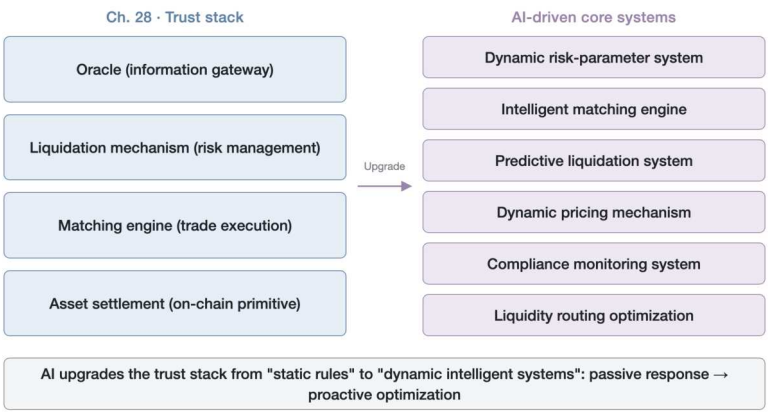

Figure 31-7. The mapping of the six core AI-driven systems to the Chapter 28 trust stack (conceptual illustration; based on the author's theoretical derivation)

Table 31-5 summarizes the functional matrix of these six AI systems. The table maps each system to a specific layer of the trust stack defined in Chapter 28 and separately clarifies its upgrade mechanism and value-creation path. The six systems exhibit a common evolutionary pattern: the direction of upgrade is uniformly from static rule execution toward dynamic, adaptive optimization based on real-time market states, while value creation points uniformly toward improving capital efficiency and reducing systemic risk.

Core AI-driven system	Position in the trust stack	Upgrade mechanism	Value creation
Dynamic risk-parameter system	Oracle and risk layer	From static rules to real-time parameter adjustment based on market state	Improves capital efficiency and reduces systemic risk
Intelligent matching engine	Matching and execution layer	From price-time priority to the introduction of toxicity awareness and isolation	Protects market makers and improves the quality of price discovery
Predictive liquidation system	Liquidation-mechanism layer	From post-trigger execution to probability-based prediction and prevention	Reduces liquidation cascades and eases market panic
Dynamic pricing mechanism	Asset-settlement layer	From a fixed formula to supply-and-demand-driven adaptive rate optimization	Balances long and short forces and incentivizes long-term liquidity
Adaptive compliance monitoring	Protocol-governance layer	From after-the-fact audit to real-time anomaly interception based on pattern recognition	Reduces compliance cost and enhances market integrity
Liquidity-routing optimization	Liquidity-aggregation layer	From a single path to cross-chain, cross-protocol deep-reinforcement-learning routing	Minimizes trading slippage and maximizes execution efficiency

31.8.1 Dynamic risk parameters

In the traditional margin system discussed in Chapter 29, the initial margin rate and the maintenance margin rate are usually set by protocol governance as static parameters. The fundamental problem with this design is that it tries to use a single numerical value to cope with multidimensional market changes. Mainstream exchanges today all adopt a tiered margin system. Taking Binance's Bitcoin perpetual futures as an example, the initial margin rate ranges from 1% for low-leverage, small positions to 50% for high-leverage, large positions, spanning more than ten discrete tiers. This tiered design is itself a rough attempt at dynamization; the true incremental value of an AI dynamic risk-parameter system lies in turning these discrete tiers into a continuous function based on multidimensional market states. Even under the existing tiered system, however, the fundamental limitation of static parameters persists: in a calm market, a fixed margin requirement often leads to low capital efficiency, forcing traders to lock up far more margin than their actual risk requires; while in a period of violent volatility, an insufficient safety cushion may trigger a systemic account deficit.

The limitation of a static-parameter system is that it ignores the dynamic nature of

market microstructure. When market volatility suddenly jumps from 20% to 80%, the originally sufficient 10% margin immediately becomes dangerous, but the protocol cannot respond automatically. Conversely, when the market enters a calm period and volatility falls to 5%, a 10% margin requirement appears overly conservative and wastes the trader's capital. In addition, static parameters cannot account for changes in liquidity depth. In a high-liquidity environment, even if an account is close to the liquidation line, the liquidator can execute the liquidation quickly without causing excessive market impact; but in an environment where liquidity has dried up, the same liquidation could widen price slippage by more than 20%, thereby triggering a liquidation cascade.

An AI-driven dynamic risk-parameter system, by introducing multimodal deep-learning models, achieves a deep coupling between risk parameters and real-time market states. The core input features of the system include four dimensions: first, real-time volatility, for which the system updates the asset's implied-volatility estimate at the millisecond level via a GARCH model or a neural-network volatility predictor; second, market depth, for which the system monitors the liquidity depth at each price level of the order book and computes the average slippage required to execute a large order; third, cross-asset correlation, for which the system tracks the dynamic correlation coefficients among different assets and, when the correlation suddenly rises (indicating increased market stress), raises the margin requirement for all assets; and fourth, historical liquidation data, for which the system uses past liquidation events to calibrate the current risk model and identify which combinations of market states are most likely to lead to a liquidation cascade.

Based on these input features, the AI system computes a tiered margin matrix rather than a single margin rate. The dimensions of this matrix include asset type, leverage multiple, and market state. When Bitcoin's volatility is at the 25th historical percentile and order-book depth is ample, for example, the system might lower the initial margin requirement from 10% to 7%; whereas when volatility jumps to the 75th historical percentile and liquidity dries up, the system would raise the margin requirement to 15%. According to a 2025 study by Huang et al., this dynamic-adjustment approach, compared with a static-parameter system, has the potential to reduce liquidation losses in stress scenarios and improve capital efficiency under normal conditions (the specific magnitude varies by model and dataset, and precise figures still lack an independently verifiable source) [41].

The introduction of dynamic parameter adjustment changes traders' risk expectations, which also brings new design challenges. In a static model, the trader need only focus on the absolute distance of the price from the liquidation line; in a dynamic model, the trader must simultaneously assess the risk that a deterioration in market state will suddenly raise the margin requirement. This gives rise to a trade-off over the frequency of parameter adjustment. If the system adjusts the margin requirement every second, the trader faces extremely high uncertainty, which may cause overly conservative positioning and thereby reduce market efficiency; but if the adjustment frequency is too low (for example, once an hour), the system cannot respond in time to a sudden market shock. The optimal solution in practice is a tiered adjustment strategy: when the market state changes slowly, the margin parameters are updated

every 5 minutes; when a market-stress signal is detected (such as a volatility jump or a sudden drop in liquidity), the system immediately triggers an emergency adjustment, but simultaneously sends an early warning to all affected traders, giving them a buffer of 2 to 5 minutes to proactively adjust their positions.

The margin-adjustment early-warning mechanism may itself trigger a coordination-game problem. When a large number of traders simultaneously learn that the margin rate is about to be raised, the rational response is to close positions immediately to avoid a margin call, and when everyone takes this action at the same time, the collective selling pressure may trigger the very crisis the warning was meant to prevent, forming a self-fulfilling loop akin to a bank run. In addition, the margin-adjustment warning faces an information-security risk: institutional users with API-monitoring capability may detect an impending adjustment in advance through changes in the system's behavioral patterns and act first. The design of the early-warning mechanism must therefore carefully weigh the tension between information transparency and market stability.

In the CEX perpetual futures market, the dynamic risk-parameter system faces several distinctive design considerations. First, the tiered margin system requires the system to dynamically adjust the margin rate according to position size, with larger positions bearing higher margin requirements to reflect their potential impact on market liquidity. Based on real-time order-book depth and historical large-liquidation data, an AI system can dynamically optimize the margin rate and position cap of each tier, striking a finer balance between capital efficiency and system safety. Second, the AI optimization of the auto-deleveraging (ADL) mechanism is significant. The traditional ADL mechanism forcibly hedges the positions of profitable parties according to a profit ranking in order to cover account-deficit losses, a process that often provokes discontent among profitable traders and a crisis of market trust. An AI system can predict the probability of an account deficit and intervene in advance—for example, proactively adjusting the margin requirement of high-risk accounts before ADL is triggered, or optimizing the execution order to minimize market impact—thereby significantly reducing the trigger frequency and negative impact of ADL. The full trigger chain for ADL is as follows: the account reaches the maintenance-margin line, the liquidation engine takes over, an account deficit arises during liquidation execution, the insurance fund covers the shortfall, and, when the insurance fund is insufficient, ADL is triggered. AI intervention is distributed across different nodes of this chain: dynamic margining reduces the probability of triggering liquidation, acting on the first link; predictive liquidation improves execution quality and thereby reduces the probability of an account deficit, acting on the second link; and dynamic insurance-fund management reduces the probability of triggering ADL, acting on the third link. These are independent optimization objectives at different levels and should not be conflated.

In addition, the dynamic risk-parameter system must also solve the problem of "parameter transparency." A traditional protocol's static parameters are public and easy to understand, but AI-generated dynamic parameters are often a black box, and traders find it hard to predict the margin requirement of the next instant. To build trust, the protocol should publish the computational basis of the risk parameters in real time, including the current volatility estimate, the liquidity-depth score, and the correlation indicators, enabling traders to understand the reasons for parameter changes. This

transparency not only enhances user trust but also provides a basis for regulators to audit.

31.8.2 Intelligent matching engine

The matching logic of a traditional order book strictly follows the principles of price priority and time priority. Although this mechanism guarantees surface-level fairness, it leaves the market maker who passively provides liquidity fully exposed to the adverse-selection risk from informed traders. In traditional matching, a large market buy order immediately fills against the best ask on the order book, regardless of whether that ask comes from a well-informed arbitrageur or an uninformed retail trader. This indiscriminate matching mechanism causes the market maker's return curve to exhibit the typical character of a "bearer of adverse-selection losses": the market maker earns limited spread income when the market is calm, but suffers significant adverse-selection losses when the market is volatile.

As discussed in Chapter 19, toxic order flow is a core driver of liquidity droughts. Toxic flow refers to orders from traders with an informational advantage, whose execution inflicts an adverse price impact on the market maker. Traditional market makers cannot identify the toxicity of an order before execution and can only passively bear the loss. From the standpoint of market design, Budish, Cramton, and Shim (2015) [42] once proposed replacing the continuous limit order book with frequent batch auctions, aiming to fundamentally eliminate the adverse-selection problem arising from speed competition. Although that scheme faces challenges such as liquidity fragmentation in practice, its core insight—protecting market makers by changing the matching mechanism itself—is highly consistent in goal with an AI-driven, toxicity-aware matching engine. The difference between the two is that batch auctions eliminate the speed advantage by discretizing time, whereas an intelligent matching engine neutralizes the informational advantage through continuous toxicity assessment. An AI-augmented intelligent matching engine, by introducing an order-flow-toxicity identification mechanism, fundamentally reshapes the microstructure of the matching layer.

The intelligent matching engine uses deep neural networks to analyze the microlevel features of every incoming order in real time in order to predict its toxicity probability. These features span multiple dimensions: the size of the order relative to recent trading volume, since larger orders are more likely to come from informed traders; the order's submission frequency and pattern, since high-frequency small orders may indicate an algorithmic trader probing market depth; the order's cancellation rate, since a high cancellation rate indicates the trader may be spoofing or manipulating the market; the account-history features of the order submitter, including the profitability of past trades, the distribution of holding times, and whether there is any known arbitrage strategy; and the correlation of the order with macro market data, for example whether the order's direction is consistent with recent price momentum. Existing research (Cartea et al., *Detecting Toxic Flow*, focused on foreign-exchange broker-client trades) proposes an online method for predicting the toxicity of a single fill and, on that basis, deciding whether to internalize or externalize it in order to reduce adverse-selection losses; its approach can be analogously transferred to the toxicity-aware setting of order-book

market making [43].

Based on these toxicity predictions, the matching engine can implement a tiered-response strategy. For retail orders judged to be of low toxicity (toxicity probability below 30%), the system provides the best execution price and the smallest slippage, ensuring that retail traders receive the best execution quality. For orders identified as of moderate toxicity (toxicity probability between 30% and 70%), the system may introduce a microsecond-level execution delay before execution, giving the market maker an opportunity to adjust its quotes. For arbitrage or high-frequency-attack orders identified as of high toxicity (toxicity probability above 70%), the system may take more aggressive measures: routing them to a particular liquidity pool with a higher slippage tolerance, or requiring the trader to pay a higher fee before execution as a "toxicity tax," which is used to compensate the market maker's adverse-selection losses.

This toxicity-aware matching mechanism effectively mitigates the adverse-selection problem facing market makers. When market makers know that the system can filter out most predatory orders, they will be more willing to provide deeper liquidity within a narrower spread. Empirical research shows that after the introduction of toxicity-aware matching, market makers' spreads typically narrow by 20% to 30%, while market depth increases by 40% to 60%, which benefits all traders.

This mechanism, however, also gives rise to a profound controversy over market fairness. When the algorithm decides execution quality based on a trader's behavioral features rather than on the quote alone, the traditional principle of equal market access faces the challenge of redefinition. A legitimate retail trader may be misjudged by the system as toxic flow because their trading pattern resembles that of a high-frequency arbitrageur, and thereby suffer worse execution quality. To address this compliance risk, the protocol needs to establish a transparent toxicity-scoring mechanism, disclosing to the trader the reasons their order was scored as highly toxic and providing an appeal mechanism. In addition, the protocol should conduct regular fairness audits to ensure that the toxicity-identification model does not systematically discriminate against particular types of traders.

Examined more deeply, the toxicity-aware matching engine faces structural limitations along four dimensions. First is the inevitable operation of Goodhart's law: once a toxicity-scoring mechanism is deployed, informed traders will immediately adjust their behavior to evade a high-toxicity judgment, including strategies such as splitting order size, mimicking retail trading patterns, and dispersing order flow across multiple unlinked accounts. The backtested accuracy of such a toxicity-identification model is in essence a static result based on historical data, and in an adversarial live environment its accuracy may rapidly decay, forcing the model into a continual offense-defense iteration. Second, differentiated execution delay poses a fundamental contradiction at the level of market design: imposing different execution delays on different orders fundamentally violates the value proposition of a centralized exchange, whose core competitiveness is deterministic low latency. Facing uncertain execution timing, a market maker's rational response is precisely to widen its quote spread to compensate for the execution uncertainty, which ultimately harms overall market quality—forming a paradox with the original intent of protecting market makers. Notably, existing non-discriminatory

design schemes in the field of market microstructure offer an entirely different line of thought: the Investors Exchange (IEX) speed bump imposes a uniform, fixed delay on all participants, rather than a differentiated delay targeting particular orders; likewise, the frequent-batch-auction scheme mentioned earlier adopts a discretized-time mechanism that treats all orders alike. The common feature of these two designs is non-discrimination, which is essentially different from differentiated execution based on a toxicity score. Third, examined from the angle of legal compliance, the best-execution obligation under U.S. securities law requires brokers to seek the best execution for all clients, while MiFID II in the EU expressly stipulates that a trading venue's rules must be transparent and non-discriminatory. AI-toxicity-score-based differentiated execution quality may come into direct conflict with these legal requirements, especially when the internal logic of the toxicity-scoring model is difficult to explain fully to regulators, further amplifying the compliance risk. Fourth, in the context of a centralized exchange there is also a potential conflict-of-interest hazard: when an exchange simultaneously operates the matching engine and participates directly or indirectly in the market-making business, the toxicity-scoring system may provide an informational advantage to the exchange's affiliated market makers, enabling them to identify and evade informed order flow in advance, while independent market makers and ordinary traders cannot obtain the same protection.

In the CEX order-book market, the implementation path of an intelligent matching engine differs markedly from that of an on-chain protocol. The CEX's centralized matching architecture naturally supports microsecond-level order processing and toxicity assessment, without having to contend with the constraint of blockchain block time. Specifically, a CEX can layer an AI toxicity-filtering layer on top of the traditional price-time-priority matching logic: when a new order enters the matching queue, the system completes the toxicity scoring within microseconds and, on that basis, decides whether to introduce an execution delay, adjust the execution price, or route the order to a dedicated liquidity pool. This architecture enables the CEX to provide effective adverse-selection protection for market makers without changing the basic matching rules, thereby incentivizing deeper order-book liquidity.

31.8.3 Predictive liquidation

Chapter 29 analyzed in detail the operating logic of the liquidation mechanism; the traditional liquidation system is in essence passive and reactive. Only when an account's collateralization ratio falls below the maintenance-margin threshold is the liquidation engine triggered to dump assets onto the market. In extreme conditions, this mechanism readily triggers a liquidation cascade: the selling pressure caused by liquidation further depresses the price, triggering the liquidation of more accounts, and ultimately becoming a collapse of market liquidity. The liquidation events of multiple DeFi protocols in 2024 show that during periods of extreme volatility, a liquidation cascade can cause a protocol's total collateral value to fall by more than 30% within minutes, resulting in a large number of involuntary liquidations for users.

A predictive liquidation system breaks this passive cycle through machine-learning models. The system uses long short-term memory (LSTM) networks and other recurrent-

neural-network architectures to analyze data along multiple dimensions in order to compute the probability that each leveraged account will be liquidated within a particular future time window. These features include: the account's current leverage ratio and its distance from the liquidation line; the short-term momentum and volatility of the asset price; the real-time depth and trend of market liquidity; historical liquidation events with account features similar to the current account and their outcomes; and macro market-stress indicators, such as the volatility index (VIX) and cross-asset correlations. By integrating these features, the predictive model can estimate the liquidation probability with fairly high accuracy. According to a 2024 study by Palaiokrassas et al., a variety of machine-learning models can classify wallet-level liquidation and report metrics such as accuracy and AUC (area under the curve), demonstrating the effectiveness of DeFi on-chain features for liquidation prediction (the specific figures depend on their dataset and evaluation criteria) [44].

Based on this probability prediction, the system implements a tiered action model, moving risk management forward rather than responding after the fact. Figure 31-8 shows the structure of this model: when an account's liquidation probability exceeds the extremely-high-risk threshold of 90%, the system no longer waits for the actual liquidation to trigger but proactively executes a partial position reduction, with the goal of lowering the liquidation probability below 70%; because the reduction is proactive and dispersed, the market impact is typically only 20% to 30% of that of a conventional liquidation.

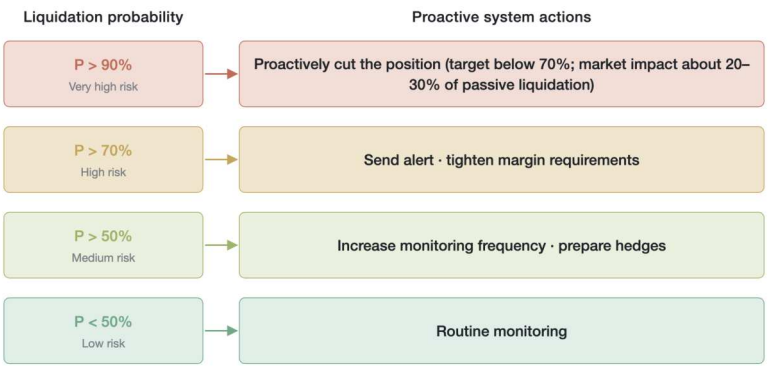

Figure 31-8. The probability-tiered action model of predictive liquidation (conceptual illustration; based on the author's theoretical derivation)

When the liquidation probability is between 70% and 90%, the system enters a second-tier response, sending a high-priority early-warning notification to the trader. This warning not only informs the user that their account is in a dangerous state but also provides specific recommendations: how much margin needs to be added, or how much position needs to be reduced, to restore safety. The warning is sent through multiple channels, including on-chain events, email, and push notifications, ensuring that the trader receives the information in time. The trader has 5 to 10 minutes to proactively adjust their position; if the trader takes no action within this time window, the system

then executes auto-deleveraging.

When the liquidation probability is between 50% and 70%, the system enters a third-tier response, increasing the monitoring frequency to the second level and preparing to respond quickly if necessary. At this point the system does not proactively intervene but continually assesses the risk, and once the probability breaks through the 70% threshold, it immediately triggers the second-tier response. When the liquidation probability falls below 50%, the system returns to the normal monitoring cycle (usually at the minute level), and the account is regarded as being in a safe state.

This paradigm shift from passive execution to proactive prevention mitigates the transmission chain of a liquidation cascade. By smoothly releasing risk before a crisis erupts, the predictive system substantially reduces the probability of a systemic collapse. According to empirical analysis, after the introduction of a predictive liquidation system, the scale of liquidation cascades under extreme market conditions is typically reduced by 60% to 80%, and the overall stability of the system improves significantly.

At the same time, this mechanism has a profound impact on the role of the liquidator. Traditional arbitrage-type liquidators profit by buying collateral at a steep discount when the market is in turmoil, a model that encourages liquidators to liquidate when market pressure is greatest, thereby intensifying market panic. In a predictive liquidation system, by contrast, most liquidations take place at the moment of least market pressure, and the profit space for liquidation shrinks substantially. This causes traditional arbitrage-type liquidators to be gradually replaced by the protocol's own algorithmic engine, and the distribution of liquidation profit likewise flows back from external extractors to the protocol itself or to protected users.

The predictive liquidation system, however, also gives rise to profound concerns about "moral hazard." If the protocol commands a more accurate liquidation-probability prediction than the market, will it use this informational advantage to harm users' interests? For example, the protocol might deliberately delay a liquidation so that the account's liquidation probability rises further, enabling it to execute the liquidation at a lower price. To prevent such abuse, the protocol needs to establish a strict governance mechanism, ensuring that all parameters and decision rules of the predictive liquidation system are transparent and are subject to regular independent audits. In addition, the protocol should provide users with real-time data on the "liquidation-probability prediction," enabling users to independently verify the system's decisions.

Beyond moral hazard, predictive liquidation also faces deeper challenges on two fronts: user rights and data reliability. As regards user consent, the "proactive position reduction" that predictive liquidation implements is in essence a forced liquidation executed before the user's margin has reached the liquidation line explicitly agreed in the contract. The trigger condition for traditional liquidation is an explicit, predictable contractual term, whereas "a liquidation probability exceeding 90%" is a model estimate that the user cannot independently verify. In a scenario where the price reverses in a V shape, the model may close out early a position that would have returned to profit, causing an unnecessary loss. Predictive liquidation terms must therefore obtain the user's explicit informed consent when the position is opened, and a compensation mechanism for model misjudgment should be established. As regards the reliability of input data, the

fatal weakness of predictive liquidation is that it depends entirely on the quality of the input data. Oracle price-feed failures and interruptions of exchange data interfaces are not rare in practice; the March 2023 oracle price-latency incident on a particular Layer 2 network once caused a large number of improper liquidations. When the input data are erroneous, the more "precise" the predictive model, the more dangerous it becomes: it will execute an erroneous preventive reduction with extremely high confidence based on erroneous data, and the resulting loss may far exceed that of a traditional passive liquidation mechanism.

31.8.4 Dynamic pricing

The funding rate of perpetual futures and the trading fee of decentralized exchanges are core economic levers for regulating the balance of market supply and demand. In traditional designs, these rates are usually computed based on a hardcoded linear or piecewise function whose parameters are often hard to adapt to a rapidly changing market environment. The standard formula adopted by mainstream perpetual futures protocols is $F = P + \text{clamp}(I - P,\ c_{\min},\ c_{\max})$, where F is the funding rate, P is the average premium index (which reflects the degree of deviation between the perpetual futures price and the mark price), I is the interest rate, and $[c_{\min}, c_{\max}]$ are the preset lower and upper bounds within which the clamp function constrains the funding rate; these bounds are usually set as a symmetric interval (for example, $\pm 0.05\%$, corresponding to an 8-hour settlement period), with the specific values determined by protocol parameters. Every term in the formula is expressed as a rate over a single settlement period (8 hours by default); the interest rate I is the value normalized to that settlement period (for example, 0.03%/8h) rather than an annualized value. The problem with this design is that the time-weighting window of the premium index is fixed, the upper and lower bounds of the clamp function are static presets, and the settlement period is rigidly locked at once every 8 hours, so the whole mechanism cannot anticipate dynamic market changes and can only passively react to the current imbalance.

An AI-driven dynamic pricing mechanism uses reinforcement learning algorithms to achieve a global adaptive optimization of the rate system. On the funding-rate side, the dynamic pricing system carries out an intelligent transformation around the three core parameter dimensions of the standard formula above. First, the time-weighting window of the premium index can be dynamically adjusted according to the market's volatility regime: a longer window is used in a low-volatility environment to filter out noise, and the window is shortened in a high-volatility environment to speed up the response to price deviations. Second, the upper and lower bounds of the clamp function are no longer static constants but dynamic parameters that change with market conditions—tightening the constraint range in a market with ample liquidity and stable volatility to keep the rate smooth, and moderately loosening the bounds when the market shows violent deviation to strengthen the rate's regulatory force. Third, the settlement frequency shifts from a fixed once-every-8-hours to a variable period based on market state, raising the settlement frequency to speed up price convergence when the contract price and the mark price deviate persistently and sharply, and lowering the frequency to reduce unnecessary trading friction when the prices are closely aligned. The system also uses a time-series forecasting model to predict the short-term evolution

of the premium index; if the forecast indicates that the perpetual futures price is about to deviate sharply from the mark price, the system adjusts the above parameters in advance, thereby beginning to intervene before the imbalance intensifies.

Machine-learning models, by predicting the marginal impact of different rate levels on the behavior of market participants, dynamically adjust the slope and intercept of the rate curve so as to incentivize arbitrageurs to enter and smooth out the price deviation in the most efficient way. For example, when the spot-market price of Bitcoin is \$65,000 while the perpetual futures price is \$65,500, a traditional system might simply raise the funding rate to 0.05% in the hope of attracting arbitrageurs. But an AI system would analyze more finely: How many arbitrageurs are currently active in the market? How many new arbitrageurs would raising the funding rate to 0.05% attract? How long would it take these arbitrageurs to close their positions? Based on this analysis, the system might decide to raise the funding rate to 0.08%, or simultaneously lower the trading fee to 0.02%, so as to attract arbitrage flow more efficiently. The 0.05%, 0.08%, and 0.02% here are illustrative decision values used to characterize how an AI system might weigh its options, and are not computed by substituting P and I into the standard formula $F = P + \text{clamp}(I - P,\ c_{\min},\ c_{\max})$ above.

On the fee-optimization side, a reinforcement learning agent dynamically sets the optimal trading fee according to the real-time depth of the liquidity pool, expected volatility, and the quotes of competing protocols. This optimization problem involves a trade-off among multiple objectives: lowering the fee can attract more trading volume but reduces protocol revenue; raising the fee can increase revenue but causes trading volume to fall and may even drive users to competitors. By continually trying different fee levels, the reinforcement learning agent learns a Nash equilibrium point at which the protocol's total revenue (trading volume times fee rate) is maximized.

According to empirical research, an AI dynamic pricing mechanism, compared with a static rate, can significantly increase the protocol's total revenue (an estimate based on the author's reading of industry cases) while maintaining or improving users' execution quality. This is because an AI system can lower fees to attract trading volume when liquidity is ample, and raise fees to protect market makers when liquidity is tight, thereby achieving an optimal supply-demand balance across different market states.

This dynamic pricing mechanism enables the protocol to implement a personalized fee structure. Based on a user's historical trading behavior, position stability, and contribution to the protocol's liquidity, the system can offer differentiated pricing schemes to different participants. For example, long-term holders and stable liquidity providers might receive a lower fee discount, while high-frequency traders and arbitrageurs might have to pay a higher fee. This personalized pricing not only enhances the protocol's competitiveness but also marks the evolution of DeFi's pricing logic from a mechanical, formulaic approach toward an intelligent, commercial one.

Personalized pricing, however, also gives rise to a regulatory risk over "price discrimination." If the protocol charges different fees to different users, does this constitute discrimination against certain users? To address this risk, the protocol should establish transparent pricing rules, publicly disclosing to all users the method for computing fee discounts and ensuring that the pricing rules do not have a systematically adverse

effect on a particular group of users. A more fundamental problem is that there is a structural conflict of interest between the AI dynamic pricing objective of "maximizing protocol revenue" and the user's objective of "minimizing transaction cost." The win-win narrative of "increasing revenue while improving execution quality" holds only under particular conditions—namely, in periods when users' demand elasticity is relatively high; in periods when liquidity is tight, an AI system may in effect become a tool for charging users higher fees, which is logically highly similar to the surge-pricing controversy of ride-hailing platforms. At the level of legal compliance, personalized pricing relies on collecting and analyzing users' trading histories, which may conflict with the data-minimization principle of the EU General Data Protection Regulation (GDPR). Differentiated pricing based on behavioral features, if it causes the pricing model to be systematically adverse to a particular group of users, may constitute algorithmic discrimination. In addition, multiple jurisdictions have explicit regulatory requirements for fairness in securities pricing, and a differentiated fee structure faces the risk of compliance scrutiny in these jurisdictions.

31.8.5 Adaptive compliance monitoring

As the scale of on-chain finance expands, regulatory compliance becomes a necessary condition for a protocol's long-term survival. Chapter 30 explored the static implementation of embedded compliance, but this filtering mechanism based on whitelists and fixed rules often struggles to cope with complex and varied means of market manipulation. An adaptive compliance-monitoring system, by integrating AI technology, achieves a leap from rule matching to pattern recognition.

The system uses unsupervised machine learning and graph neural networks to scan vast amounts of on-chain transaction data in real time. The system's monitoring is divided into three levels. The first level is real-time transaction-pattern analysis, in which the system extracts features from each transaction—including transaction size, direction, timestamp, trading pair, and the age of the trader's account—and then, through anomaly-detection algorithms such as the isolation forest or the local outlier factor, identifies transactions that deviate markedly from normal trading patterns. The second level is account-behavior clustering, in which the system clusters accounts according to their trading-behavior features and identifies groups of accounts with similar behavioral patterns, which may represent a coordinated manipulation team. The third level is cross-account association identification, in which the system, by analyzing the flow of funds among accounts, the correlation of trading times, and the correlation of positions, identifies groups of accounts that may have an interest linkage.

Through these three levels of analysis, the system can identify potential wash trading, front-running attacks, and price manipulation. The features of wash trading include: the trading counterparty is the same account or a linked account, the interval between trades is extremely short (usually at the second level), the trade price is unrelated to the market price, and the trade size exhibits a periodic pattern over a period of time. The features of a front-running attack include: the attacker submits an order before a large trade executes and immediately closes the position after the large trade executes, with the profit coming from the price impact the large trade causes. The features of

price manipulation include: one or more accounts conduct a large number of trades within a short time, causing the price to swing sharply, and then these accounts close their positions at the price peak to profit.

Unlike a traditional alert system that relies on preset thresholds, an AI monitoring model can autonomously learn the baseline of normal market behavior and automatically trigger a blocking mechanism when it detects a complex, coordinated attack that deviates from the baseline. Existing research has explored using AI for the automatic identification of behaviors such as wash trading and price manipulation (Popoola, 2023 [45]), as well as the potential of machine-learning-based market surveillance, relative to traditional rule-based systems, to reduce false positives and improve detection coverage (Tiwari et al., 2021 [46], a survey); the reduction in false positives reported in real deployment cases is usually on the order of tens of percentage points.

The introduction of an adaptive compliance system not only reduces the protocol's regulatory risk but also provides the necessary infrastructure guarantee for the large-scale entry of institutional funds. Before entering a new market, institutional investors usually require that the market have sound anti-fraud and anti-manipulation mechanisms. A protocol equipped with an AI compliance-monitoring system can demonstrate the integrity of its market to institutional investors, thereby attracting more institutional funds.

More importantly, an adaptive compliance system changes the paradigm of governance. The traditional compliance model relies on manual review, a lagging and costly process. A trader may be discovered only hours or even days after conducting a manipulative act, by which time substantial damage has already been done. An AI-driven compliance system, by contrast, can detect and block a manipulative act in real time as it occurs, transforming compliance from an after-the-fact audit into a real-time anomaly-detection-and-blocking mechanism. This not only improves defensive efficiency but also substantially reduces the cost of compliance.

AI compliance monitoring, however, also gives rise to concerns about "privacy" and "false positives." If the system is overly sensitive, it may misjudge normal trading behavior as manipulation, thereby harming innocent traders. To address this risk, the protocol should establish a clear appeal mechanism, so that when a trader believes their trade has been wrongly flagged as manipulation, they can submit an appeal and obtain a manual review. In addition, the protocol should regularly publish statistics on compliance monitoring, including the number of manipulation cases detected and the false-positive rate, in order to accept community oversight.

31.8.6 Liquidity-routing optimization

In an ecosystem where multiple chains coexist and liquidity is fragmented, finding the optimal execution path for a large trade is a core challenge facing the liquidity-aggregation layer of Chapter 28. A $1 million trade may need to be split for execution across multiple protocols such as Uniswap, Curve, and Balancer in order to minimize slippage. Traditional routing algorithms usually rely on static graph search or simple linear programming; these methods are computationally efficient but often suboptimal in the quality of optimization. They struggle to achieve a truly optimal solution amid

dynamically changing market depth and network congestion.

An AI-driven liquidity-routing-optimization system, through deep reinforcement learning, raises order execution to a new level of efficiency. The system formulates order routing as a Markov decision process, in which the state space includes all available liquidity pools and their current depths and prices, the action space includes all possible ways of allocating the order among the various liquidity pools, and the reward function is defined as minimizing total slippage and transaction cost.

The reinforcement learning agent continually explores the cross-protocol, cross-chain distribution of liquidity in this vast state space. The agent considers not only the instantaneous price and depth of each liquidity pool but also predicts the slippage changes that may occur during trade execution. If the agent decides to execute a $500,000 trade on Uniswap, for example, it must predict how much price impact this trade will cause on Uniswap and thus how much slippage will result. In addition, the agent must consider network latency and gas-fee fluctuations. When the Ethereum network is congested, the gas fee for executing a single trade may be as high as $100, whereas when the network is idle, the same trade may cost only $10 in gas. An intelligent routing system should choose fewer trade splits when the network is congested, so as to reduce gas costs.

By intelligently splitting a large order and dynamically allocating it across multiple optimal paths, the system can complete complex cross-market arbitrage and liquidity extraction within milliseconds. According to a 2025 study by Zhang and Tessone on an enhanced DEX routing method, the improved routing method can, compared with the baseline, increase DEX execution efficiency and the benefits to all parties (the specific figures depend on their evaluation criteria and dataset) [47].

The intelligentization of liquidity routing profoundly changes the competitive landscape of decentralized exchanges. In the traditional model, a protocol's competitiveness depends mainly on its liquidity depth and fee level. But in the era of intelligent routing, an isolated liquidity pool no longer constitutes a competitive barrier, and capital flows frictionlessly toward the protocol that prices most efficiently. This means that even if a protocol's liquidity depth is not the deepest, an intelligent routing system will still preferentially use it if it prices most efficiently. This competitive model encourages all protocols to pursue the highest pricing efficiency, thereby improving the market quality of the entire ecosystem.

At the same time, the intelligentization of liquidity routing also intensifies the technological competition among routing algorithms. Aggregators with the strongest computing power and the best models will dominate the allocation of order flow, thereby exerting a decisive influence on the survival of the underlying protocols. This gives rise to a new market structure: a small number of aggregators with the most advanced AI capabilities control the majority of order flow, while the underlying protocols are reduced to liquidity providers for these aggregators. This trend toward centralization may have a negative impact on the long-term health of DeFi, and so excessive centralization must be prevented through open standards and transparent algorithms.

31.9 Semantic oracles

31.9.1 The capability boundary of traditional oracles

The oracle mechanism is the core infrastructure connecting on-chain smart contracts with the off-chain real world. In Chapter 28's analysis of the fourth layer of the trust stack, the oracle is defined as a one-way data-transmission channel whose main function is to obtain the latest price of a particular asset from an external data source and convert it into an on-chain-verifiable structured format [48]. Although this design has supported the prosperity of DeFi over the past few years, it has also established the fundamental limitations of the traditional oracle.

The first limitation lies in the strict constraint on data type. Traditional oracles are designed to transmit highly structured numerical data, including exchange asset prices, interest-rate indices, weather data, or other already-quantified indicators. The common feature of these data is that they have a clear numerical representation and can be directly processed by a smart contract's conditional logic. When facing unstructured information, however, traditional oracles are powerless. A public company's financial report, for example, is usually a PDF document of hundreds of pages, containing complex textual descriptions, tables, footnotes, and explanations of accounting adjustments. A traditional oracle cannot automatically extract the key metric "third-quarter revenue" from such a document, still less understand the complex accounting treatment of "one-time gains" or "nonrecurring losses" in the report. Likewise, the key information in a legal contract or a government statement is often implicit in natural-language expression, and a traditional oracle cannot parse its semantic meaning. This dependence on structured data strictly confines the scope of oracle applications to asset classes that already have market quotes or have already been quantified.

The second limitation stems from the inability to handle the ambiguity of natural language. Natural language is inherently full of ambiguity, metaphor, context dependence, and polysemy. When a contract condition is written as "the company's performance declines significantly," for example, the word "significantly" may have entirely different meanings in different contexts. In the medical field, "significant" may mean a statistical p-value below 0.05; in finance, it may mean a year-over-year decline of more than 20%; and in everyday language, it may be merely a vague qualitative description. A traditional oracle cannot understand this semantic flexibility; it can only mechanically look up a predefined numerical value or category. If a contract condition involves any expression requiring subjective judgment or semantic understanding, a traditional oracle is not up to the task.

The third limitation lies in the inability to handle "subjective judgment" questions. In the real world, many important events or conditions are inherently subjective. The question "whether a company has violated the financial covenants in its loan agreement," for example, involves not only numerical computation but also the legal interpretation of contract terms. The question "whether a politician's remarks constitute hate speech" involves an understanding of cultural background, historical context, and social norms. The question "whether an artwork has collection value" involves aesthetic judgment and market expectation. Traditional oracles were not designed with such questions in

mind, because these questions cannot be resolved by a simple data query. They require a system able to understand context, weigh multiple factors, and reason and judge.

The vision of "perpetual futures on everything" described in Chapter 27 has at its core the aim of creating continuous derivatives markets for any asset or any definable event. This means the system must be able to handle an extremely diverse range of underlying assets, from traditional financial assets to emerging non-standard assets, and from explicit numerical conditions to complex event determinations. This poses new technical requirements for the oracle. First, the oracle must be able to accept any contract condition described in natural language, not just a few predefined data types. Second, the oracle must be able to understand the semantic meaning of these natural-language conditions, including handling ambiguity, identifying implicit assumptions, and understanding context. Third, the oracle must be able to find or infer the relevant verification information in the real world, even if that information does not exist in a standardized market-quote form. Finally, the oracle must be able to perform some degree of reasoning and judgment to determine whether an event that occurred in the real world satisfies the contract condition.

The design of traditional oracles cannot meet these requirements at all. Even if we try to extend the existing oracle architecture, we can only handle more kinds of structured data; we still cannot cross into the domain of unstructured information and semantic understanding. This is precisely why "perpetual futures on everything" has been strictly limited technically. So long as the oracle remains in the role of "data transmission," the feasibility boundary of perpetual futures on everything will long be confined to the range of assets that have already been fully marketized and standardized. For all non-standard assets and events requiring semantic understanding, traditional oracles cannot meet these requirements.

31.9.2 Semantic oracle architecture

The semantic oracle represents a paradigm shift in oracle architecture; by embedding large language models (LLMs) into a network of nodes, it achieves the leap from mere "data transmission" to "semantic understanding." The core advantage of the semantic oracle is its ability to read and understand complex conditions described in natural language and to convert unstructured textual information into deterministic instructions that a smart contract can execute. The architecture of this new type of oracle usually comprises four mutually coordinated layers, each bearing a different functional responsibility [49].

The input layer is responsible for receiving and aggregating unstructured information from multiple heterogeneous sources. Unlike a traditional oracle, which can receive only predefined data requests, the input layer of a semantic oracle can handle natural-language queries in any form and perform preliminary semantic normalization, ensuring that different expressions with the same meaning are recognized as equivalent conditions. The input layer simultaneously aggregates information from multiple sources—news reports, social media, official announcements, financial databases, and descriptions of on-chain activity—to provide high-quality material for subsequent in-depth analysis.

The LLM understanding layer is the cognitive core of the semantic oracle. Advanced

NLP models at this layer perform text comprehension and semantic parsing, key-condition extraction, ambiguity identification and resolution, and polysemy handling. When the Federal Reserve releases a monetary-policy statement, for example, the model must not only identify the keyword "rate cut" but also understand its magnitude, timetable, and economic impact; when a financial report mentions "30% revenue growth," it must distinguish year-over-year from quarter-over-quarter and total revenue from segment-level revenue.

The verification layer is designed to address the hallucination, bias, or manipulation that a single model may produce. This layer, through a multi-node consensus mechanism, requires multiple independently running LLMs to assess the same event independently [50], uses a sentence-level encoder to map text into a vector space and compute semantic similarity, and combines a truth-discovery algorithm to weight and aggregate the results based on nodes' historical credibility [49]. Experimental data show that even in the extreme case where 40% of the nodes are maliciously manipulated, this consensus mechanism can still maintain a relatively high accuracy.

The output layer is responsible for converting the consensus-verified semantic conclusion into an on-chain-verifiable structured data format, including a Boolean value, a numerical value, or other predefined data types. The output layer also attaches the model's confidence score for the conclusion or an uncertainty interval, enabling a smart contract to distinguish high-confidence from low-confidence determinations and to take conservative action—such as delaying settlement or triggering human arbitration—when facing a highly uncertain situation.

Figure 31-9 compares the semantic oracle with the traditional oracle along six capability dimensions: the traditional oracle is well-developed in the transmission of structured numerical values but has zero capability along dimensions involving natural-language understanding; the semantic oracle, by embedding LLMs, achieves a qualitative change from infeasible to feasible, although its precision is still constrained by model hallucination and the consensus mechanism.

31.9.3 Unlocking perpetual futures on everything

The introduction of the semantic oracle fundamentally changes the conclusions of Chapter 27 regarding the feasibility of underlying assets; its unlocking effect manifests in bringing non-standard assets and complex events, which traditional oracles cannot handle, into the scope of programmable finance. This unlocking effect can be clearly demonstrated through three typical scenarios, each representing a new class of financial application that could not previously be realized.

Political-event perpetual futures are the first domain to be significantly unlocked. Traditional prediction markets rely on human arbitration when handling political events, a process that is time-consuming and prone to dispute. A semantic oracle can monitor and parse official legislative documents and authoritative news sources in real time; when a contract condition is set as "whether a particular bill is signed in a particular year," it can automatically confirm whether the condition is satisfied by analyzing the bill's text, signing records, and official statements, eliminating the delay and subjectivity of human intervention. The technical feasibility of political-event perpetual futures, however, is not the same as legal feasibility. In most major jurisdictions, such contracts face serious legal obstacles. The CFTC takes a cautious stance in regulating event contracts and has questioned the legal status of some political-event contracts. Multiple countries classify political-event betting as gambling rather than a financial activity,

applying gambling regulations rather than financial regulations. The semantic oracle therefore unlocks more of a technical-feasibility boundary, and the actual deployment of these products remains subject to the evolution of each jurisdiction's regulatory stance.

Corporate-performance perpetual futures likewise benefit from the semantic oracle's comprehension capability. Traditional oracles cannot directly extract specific financial metrics from a financial-report PDF, and the ingestion of structured data usually takes weeks. A semantic oracle can parse financial-statement text in real time, accurately identify specific metrics, understand the terminological differences between GAAP and IFRS, and distinguish one-time gains from regular operating performance, enabling microlevel events based on corporate fundamentals to become the underlying of perpetual futures.

Natural-language-condition derivatives represent the ultimate unlocking effect brought by the semantic oracle. A trader can create a contract using any natural-language condition, for example "the global average temperature in 2025 exceeds the pre-industrial level by 1.5 degrees Celsius" or "a particular country's unemployment rate exceeds 10% in a particular quarter." So long as the condition can be verified by public information, the semantic oracle can undertake the responsibility of parsing and determining it, achieving perpetual futures on everything in the true sense.

The semantic oracle's enhanced capability is equally significant for the CEX perpetual futures market. In centralized exchanges' business expansion, listing a new perpetual futures underlying has long been constrained by the availability of a reliable price-feed source. Traditional oracles can support only assets that already have continuous market quotes, which confines the range of CEX perpetual futures underlyings to mainstream crypto assets and a few traditional financial assets. The introduction of the semantic oracle enables the CEX to break through this limitation, bringing non-standard indices (such as a particular DeFi-sector index or a Layer 2 ecosystem-activity index) and macro-event contracts (such as central-bank rate decisions or major regulatory-policy changes) into the range of perpetual futures underlyings. This expansion of underlyings not only enriches the CEX's product line but, more importantly, provides traders with fine-grained risk-hedging tools. For example, a development team focused on a DeFi lending protocol can hedge the systemic risk of its protocol token through a DeFi-sector-index perpetual futures.

Table 31-6 summarizes the unlocking effect of the semantic oracle on different types of underlying assets. The table compares the feasibility assessments of the traditional oracle and the semantic oracle one by one across five categories: crypto assets, foreign exchange, stock indices, carbon credits / house-price indices, and natural-language-condition events. The most striking contrast in the table appears in the last row: natural-language-condition events are "wholly infeasible" under the traditional oracle, whereas the semantic oracle raises them to the level of "possible but with limited precision"—and this breakthrough is precisely the technical basis on which the vision of "perpetual futures on everything" can move from theory to practice.

Underlying-asset type	Traditional-oracle feasibility	Semantic-oracle feasibility	New possibilities unlocked
Crypto assets	Naturally feasible	Can be enhanced	Multi-source verification improves manipulation resistance
Major foreign-exchange pairs	Exchange data obtainable	Can be enhanced	Semantic understanding of central-bank statements and expectation pricing
Stock indices	Difficult outside trading hours	Feasible	Fills the pricing vacuum during non-trading hours such as the Asian session
Carbon credits / house-price indices	No continuous market quotes	Difficult but possible	Infers prices from statistical data and transaction records
Natural-language-condition events	Wholly infeasible	Limited precision	Turns any non-standard event into a settleable contract underlying

31.9.4 The trust problem of semantic verification

Although the semantic oracle greatly expands the application boundary of smart contracts, it also introduces an entirely new trust problem: how can we verify that an LLM's "understanding" of complex semantics is accurate and error-free? Unlike a traditional oracle that transmits deterministic numerical values, a semantic oracle outputs a probability-based estimate, which makes the fairness of liquidation depend directly on the quality of the AI's estimate. If the model hallucinates and generates a seemingly reasonable but actually erroneous interpretation of information, it may cause an enormous position to be wrongly liquidated based on an erroneous price or condition [51]. This risk poses a severe challenge to the stability of the DeFi system.

To meet this challenge, the system must establish a multi-level mechanism of verification and checks and balances. Multi-node consensus is the first line of defense and the most basic protective measure. As stated earlier, by requiring multiple independently trained LLMs to assess independently and aggregating the results, one can effectively reduce the risk of a single model's hallucination. The design of this multi-node consensus requires careful consideration of several key parameters. The first is the choice of the number of nodes. In theory, the more nodes, the better the system can resist attacks by malicious nodes. More nodes, however, also mean higher cost and a longer consensus time. In practice, a balance between security and efficiency is usually needed. A common choice is to use an odd number of nodes, such as five, seven, or 11, so as to avoid a tie. The second is the criterion for selecting nodes. Not all LLMs are suitable to join the consensus network. The system needs to assess each model's historical accuracy,

whether it is easily deceived by particular types of adversarial examples, and whether it has known biases. The third is the setting of the consensus threshold. The system needs to decide how many nodes' concurring opinions constitute a valid consensus. For example, is it necessary for all nodes to agree, or only a majority, or a weighted majority? Different threshold settings affect the system's security and availability.

Even with a sound multi-node consensus mechanism, however, the system still faces a deeper risk: because mainstream LLMs have a relatively high degree of homogeneity in their training data and algorithmic architecture, they may jointly make the same mistake when facing certain particular edge cases [52]. This phenomenon, called "strategy homogenization," means that multiple seemingly independent models may in fact fail in the same way. For example, if all LLMs are trained on similar internet data, they may all inherit the same biases or misinformation present in that data. If a particular piece of misinformation is widely disseminated on the internet, all models may learn this misinformation and thus give the wrong answer when facing the related question. This risk means that a simple majority-vote mechanism may fail in certain scenarios—the concurring opinion of multiple nodes does not necessarily mean the conclusion is correct. This common-mode failure risk also extends to the level of adversarial attack. A prompt-injection attack can manipulate an LLM's output by embedding special instructions in the input text; if an attacker constructs a carefully designed piece of misinformation containing prompt-injection content able to bypass the models' safety filters, then even with multi-node consensus, all nodes using the same base model may give the same wrong result. Mitigation strategies should include mandating that nodes in the consensus network use base models from different vendors, implementing strict input-sanitization mechanisms, and introducing non-LLM verification paths as a heterogeneous security layer.

An adversarial-verification mechanism therefore becomes a necessary complement. In this mechanism, the system deploys not only a "primary model" responsible for generating the conclusion but also a "challenger model" specifically designed to look for logical flaws or factual errors. The challenger model's goal is to generate adversarial examples or raise counter-evidence, forcing the primary model to provide a more rigorous logical basis for its conclusion. This adversarial process is analogous to cross-examination in a courtroom, where the prosecution and the defense each try to find the flaws in the other's argument. In the context of the semantic oracle, the challenger model tries to interpret the same information from different angles, look for possible alternative explanations, or raise relevant information the primary model may have overlooked. For example, if the primary model's conclusion is "the company claims 50% revenue growth in its financial report," the challenger model might raise "but this growth comes mainly from a one-time gain and does not represent the growth of the regular business" or "this figure is calculated in nominal dollars, and the inflation-adjusted growth rate is in fact much lower." Only when the primary model's conclusion can withstand the challenger model's repeated attacks will the conclusion be adopted by the system. This courtroom-debate-like adversarial process can significantly improve the robustness of semantic parsing, because it forces the system to consider multiple perspectives and possible alternative explanations.

To incentivize the challenger model to perform its duty conscientiously, the system can

design a corresponding economic-incentive mechanism. For example, if the challenger model successfully finds an error in the primary model, the challenger can obtain a reward, while the primary model is penalized. This incentive mechanism ensures that the challenger has an incentive to look for flaws conscientiously rather than perfunctorily. At the same time, to prevent the challenger from maliciously raising groundless objections, the system can require the challenger to provide evidentiary support for its objections, and if an objection is proven to be wrong, the challenger is likewise penalized.

Even with a sound multi-model consensus and adversarial verification, the semantic oracle still needs to set an uncertainty threshold. When the system assesses that the uncertainty interval of a particular event exceeds a preset safety threshold, it must trigger an automatic fallback mechanism. This fallback mechanism may include suspending trading in the relevant contract, delaying settlement until more information is obtained, or triggering a human-arbitration process. This conservative approach ensures that the system does not make a hasty decision when facing a highly uncertain situation, thereby protecting the interests of market participants.

As the ultimate backstop, for a semantic determination involving extremely high value or serious dispute, the system must retain the power of human arbitration. This does not mean a return to the human-arbitration model of traditional prediction markets, but rather a more fine-grained hybrid model. In most cases, the system relies on the automated semantic oracle to make determinations and settle. But when the system detects a high degree of uncertainty or dispute, it automatically submits the case to a decentralized team of human arbitrators. This team may be composed of experts from different backgrounds and professional fields, who vote based on the relevant evidence. This hybrid model retains both the high efficiency of the automated system and the irreplaceable value of human judgment in handling extreme, unknown situations. This reflects the fact that, in the evolution toward "model is law," human common sense and judgment still play an important role.

31.10 From code is law to model is law

As AI systems gradually replace the hardcoded rules in DeFi infrastructure, the operating logic of market microstructure undergoes a profound paradigm shift. This transformation changes the system's core decision mechanism from deterministic code to a probabilistic model, bringing both an enormous opportunity for adaptive optimization and new governance challenges and systemic risks. The early-blockchain ideal of "code is law" was once seen as the ultimate governance solution, but as market complexity has increased and extreme events have occurred frequently, the limitations of this paradigm have become ever more apparent. At the same time, the powerful capability that AI models display in handling complex decisions makes "model is law" a possible alternative. Both paradigms, however, have fundamental flaws, and the true breakthrough lies in how to deeply integrate the two, forming a hybrid architecture that both retains the safety floor of code's determinism and fully harnesses the model's adaptive-optimization capability.

31.10.1 The strengths and limitations of code is law

The ideal of "code is law" forms the cornerstone of the first generation of DeFi infrastructure. Under this paradigm, all business logic, risk parameters, and execution conditions are turned into immutable smart-contract code. The achievement of this architecture is manifested mainly in the absolute determinism and verifiability it provides. Once a smart contract is deployed, its execution path depends entirely on the input state and the predefined logical branches, with no ambiguity or room for human discretion. This determinism ensures that the system runs as expected in all situations, thereby establishing a high degree of execution reliability in a trustless environment. Formal verification technology further strengthens this advantage, using mathematical proof to ensure that a smart contract's logic conforms to its expected properties and thereby eliminating conventional security vulnerabilities at the code level [35]. In addition, the complete transparency of the code enables any participant to audit the system's operating mechanism, ensuring that the rules apply fairly to all. This censorship resistance is a characteristic that traditional financial systems cannot achieve; any attempt to change the rules must go through an explicit on-chain governance process and cannot be carried out through covert back-end operations.

The determinism of code also brings another key advantage: the system's behavior is fully predictable. Participants can precisely calculate how the system will react in any given market state, which makes risk assessment relatively intuitive. In a fixed-rate lending protocol, for example, participants know that the interest-calculation formula is entirely deterministic and will not change because of some centralized entity's subjective judgment. This predictability is a foundational condition for building market confidence, and is especially prominent in transactions involving large sums.

The rigidity of hardcoded rules, however, exposes significant limitations when facing complex and variable market microstructure. Deterministic code cannot adapt to unforeseen extreme market situations, and when facing complex scenarios such as an instantaneous liquidity drought or an abrupt shift in correlation structure, preset linear rules often prove too simple and too slow. A dynamic margin rate computed by a fixed formula, for example, cannot capture the nonlinear interactions among multidimensional market variables, causing the system to be possibly overly conservative under normal conditions yet inadequately prepared for extreme tail risk. The 2016 Ethereum DAO incident offers an important case. The smart-contract code of the time was logically "correct," but when facing the unforeseen attack vector of a reentrancy attack, it could not adaptively adjust its defensive strategy at all. The determinism of code proved a limitation in such a scenario, because once the vulnerability was discovered, the system could not respond to the threat through dynamic adjustment and could only passively wait for human intervention.

In addition, the static nature of parameter settings leaves the system without real-time adaptive capability. In a traditional governance architecture, adjusting risk parameters depends on a human proposal-and-voting process, which is not only time-consuming but also hard-pressed to keep up with the millisecond-level tempo of market changes. When market volatility doubles within seconds, adjusting risk parameters through a governance vote is entirely unrealistic. A deeper problem is that code logic is inher-

ently constrained by Boolean conditional judgments and cannot handle complex semantic conditions or continuous probabilistic assessments. When it is necessary to judge the toxicity of an order or predict the liquidation probability of a position, a simple threshold-trigger mechanism proves inadequate. Code can only say "if the margin rate falls below 50%, then liquidate," but it cannot say "based on the current market liquidity, the depth of the liquidation queue, and cross-market correlation, this position's liquidation probability is 73.2%, and therefore the trader should be proactively alerted." This simplified handling not only reduces the system's capital efficiency but also limits the resilience of the market infrastructure when responding to complex attacks and anomalous volatility.

Another implicit limitation of code lies in its dependence on parameter tuning. When designing a smart contract, developers must preset all parameter values, such as liquidation thresholds, risk weights, and fee ratios. The choice of these parameters is often based on historical data and the designer's subjective judgment, but the market environment is continually evolving. Once parameters are hardcoded, changing them requires a complex upgrade process, which in a decentralized system often means obtaining community consensus. This leaves the system either with parameter settings too conservative to cope with the worst case, or too aggressive and prone to collapse under extreme conditions.

31.10.2 The potential and risks of model is law

When AI models are introduced as the core decision engine of market infrastructure, the nature of the system's rules evolves from deterministic code into a probabilistic model. Under the "model is law" paradigm, the system's behavior is no longer determined by fixed conditional statements but is driven by the model's real-time assessment of multidimensional market states. This shift endows the infrastructure with the ability to handle complex semantics and make continuous judgments. AI models can simultaneously process thousands of input variables, discover nonlinear patterns that human designers cannot foresee, and dynamically adjust risk parameters according to real-time liquidity conditions, liquidation-queue density, and cross-market spillover effects.

This adaptive capability significantly improves the system's capital efficiency and resilience. Through continuous learning and optimization, the model can achieve more precise risk pricing than a hardcoded formula, reducing the capital sequestration caused by over-conservatism and taking predictive preventive measures before risk actually materializes. In a predictive liquidation system, for example, the model no longer waits for the margin to fall below a threshold to trigger liquidation, but, based on a continuous assessment of the liquidation probability, guides the gentle reduction of a position at an early stage, thereby effectively preventing the systemic risk of a liquidation cascade. The model can learn that a particular type of market condition often precedes a price collapse and can therefore act in advance. In addition, the model can handle complex semantic conditions, such as the multidimensional combined condition "when the market is in a panic state and liquidity providers are withdrawing," rather than merely a simple single threshold such as "price below X." This enables the system to make fine-grained responses to subtle changes in market microstructure.

The model's capacity for continuous optimization is also a major advantage over hard-coded rules. As new market data continually accumulate, the model can automatically adjust its parameters and strategy without human intervention. This means the system can gradually adapt to the evolution of the market environment rather than being locked into past parameter settings. In the field of high-frequency trading, this real-time learning capability has been shown to significantly improve trading performance and risk-management outcomes.

A probabilistic decision mechanism, however, inevitably introduces new dimensions of risk. The most notable flaw of AI models is their unpredictability and lack of interpretability. When a deep neural network decides to raise the margin rate for a certain class of assets, it often cannot provide a humanly understandable causal explanation. This "black box" nature directly challenges a decentralized system's basic requirements for transparency and auditability. If participants cannot understand the logic behind a system's decisions, the foundation of trust will be severely weakened [53]. In traditional finance, regulators can require a bank to explain its risk decisions, but for a deep-learning model such a requirement often cannot be met.

In addition, when facing a "black swan" event that never appeared in the training data, the model's behavior often exhibits extreme fragility. The model may make wholly unreasonable decisions in a brand-new market environment, leading to systematic mispricing or improper liquidation. The 2012 Knight Capital algorithmic-runaway incident illustrates this risk. Because of an incomplete deployment of new trading code, the firm triggered an obsolete legacy function that had already been retired, and the trading system placed orders out of control for approximately 45 minutes, producing approximately \$440 million in realized losses (with the final related pre-tax loss, including subsequent costs, at approximately \$461 million). This incident shows that even a tested algorithmic system can run out of control because of a deployment defect or an unanticipated operating state.

Adversarial fragility is another key source of risk. Machine-learning models are prone to carefully crafted adversarial-example attacks, and a malicious participant can deceive the model by creating particular market signals, inducing it to make parameter adjustments favorable to the attacker [54]. An attacker might, for example, "train" the model to produce a particular bias through a series of carefully designed order flows, so as to gain an advantage at a critical moment. This new form of "model attack" is more covert and harder to defend against than a traditional code-vulnerability exploit, because it does not require finding a logical error in the code but instead exploits the model's own learning mechanism.

Finally, because the model is continually updated during ongoing learning, its behavioral characteristics undergo "model drift" over time, which means the system's rules today may differ from its rules tomorrow, thereby undermining participants' expectations of the system's stability [27]. This is a serious problem for traders who need to plan over the long run. In addition, the model's training process may itself introduce bias. If the training data are insufficiently representative, or if there are flaws in feature engineering, the model may learn spurious correlations, leading to systematic decision errors. These risks make "model is law" infeasible as an independent

governance paradigm.

31.10.3 The hybrid architecture

To resolve the inherent contradiction between determinism and adaptivity, the next generation of market infrastructure must adopt a "code plus model" hybrid architecture. The design principle of this architecture is not to make an either-or trade-off between "code is law" and "model is law," but to integrate the two through deep nesting. The core insight of the hybrid architecture is this: hardcoded code defines the system's inviolable safety floor, and within that floor, the AI model is granted ample freedom to optimize for efficiency.

Figure 31-10 shows the nested design logic of the hybrid architecture: the outer layer, composed of hardcoded smart contracts, constitutes an absolute safety boundary; the inner layer, composed of the AI model, performs adaptive optimization within the operating space bounded by the safety floor; and the two layers are connected through a "model proposes, code reviews" verification mechanism.

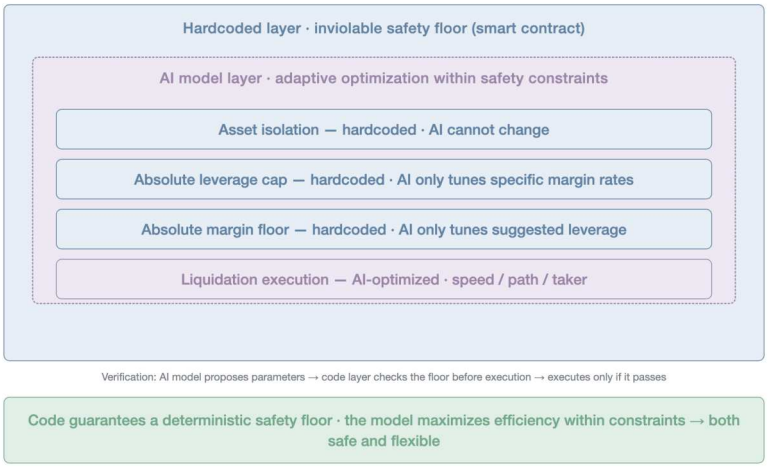

Figure 31-10. The design of the "code plus model" hybrid architecture (conceptual illustration; based on the author's theoretical derivation of a governance framework for decentralized infrastructure)

In the outer layer of the hybrid architecture, the system sets absolute safety boundaries through hardcoded smart contracts. These floor rules include an asset-isolation mechanism, the maximum permitted leverage multiple, the minimum maintenance-margin rate, and explicit liquidation-trigger conditions. The execution of these rules has absolute priority and is not affected by the output of any AI model. No matter how optimistic the market state assessed by the internal model, or how aggressive its recommended parameters, the hardcoded layer will resolutely reject any operation that breaches the safety floor. This design preserves the core value of "code is law" in guarding against extreme tail risk, ensuring the system's survivability in the worst case.

The design principles of the floor warrant special attention. An effective floor must

satisfy several key conditions: first, it must be absolute and non-negotiable, and cannot be breached for any reason. Second, it must be verifiable, so that any participant can independently verify whether the system has complied with the floor. Third, the floor must be loose enough to allow the model to perform meaningful optimization within it, rather than so strict that the model cannot function. Fourth, the floor must be resistant to circumvention. For example, if the floor stipulates a maximum leverage of 10×, but the model can circumvent this limit through a combination of multiple accounts, then the floor is ineffective. The hybrid architecture must therefore include additional checking mechanisms to ensure that the model cannot circumvent the floor through creative means.

Within the operating space bounded by the safety floor, the inner layer of the hybrid architecture is led by the AI model. The model is authorized to perform high-frequency adaptive optimization, including dynamically adjusting the specific margin rate, setting personalized risk parameters, executing predictive interventions, and optimizing the speed and the counterparty of the liquidation process. For example, when market volatility rises but has not yet triggered the hardcoded liquidation threshold, the model can proactively raise the margin requirement for particular high-risk positions, or advise the trader to close out early. This inner-layer optimization significantly improves the system's speed of response to changes in market microstructure, enabling the infrastructure to maximize capital efficiency under normal conditions while smoothly defusing risk in the early stage of its accumulation.

The mechanism by which code verifies the model's output in the hybrid architecture is the key link ensuring the system's safety. The model does not directly control the execution engine but instead generates parameter-adjustment recommendations or operation instructions. Before these recommendations take effect, they must undergo strict review by the hardcoded logic. The code layer acts as a strict verification mechanism; it does not assess the economic reasonableness of the model's recommendation but only verifies whether the recommendation violates any preset safety floor. The specific workflow is as follows: first, the model analyzes the current market state and system state and generates a parameter-adjustment recommendation, such as "raise account A's margin rate from 50% to 55%." Second, this recommendation is sent to the code-verification layer. The verification layer performs a series of checks: whether the new margin rate is still above the hardcoded floor of the minimum maintenance-margin rate, whether account A's total leverage is still below the hardcoded floor of the maximum leverage, and whether any other operation prohibited by hardcoded rules is present. If all checks pass, the instruction is executed; if any breach of the floor is found, the code directly rejects the recommendation and may trigger a downgrade of the system to a more conservative fallback state. This "model proposes, code reviews" workflow successfully harnesses to the greatest extent AI's advantages in handling complex semantics and multidimensional optimization, while ensuring the system's absolute safety.

The design advantage of this architecture is that it achieves a mode combining "limited trust with independent verification." The system trusts the model's optimization capability but strictly verifies its output. This avoids both the rigidity that comes from relying entirely on code and the uncontrollability that comes from relying entirely on the model.

31.10.4 Model auditing

Shifting from auditing deterministic code to auditing a probabilistic model constitutes the most severe governance challenge under the hybrid architecture. Traditional code auditing focuses on the correctness of the logic and the completeness of the execution paths, with the goal of finding potential vulnerabilities and ensuring that the code's behavior conforms to expected specifications. Although this auditing process is complex, because of the deterministic nature of code, its results are verifiable and final [55]. Code auditing can use mathematical tools such as formal verification to ensure the code's correctness through symbolic execution or theorem proving. An auditor can trace every execution path of the code and verify that, under all possible inputs, the code produces the expected result.

The complexity of auditing an AI model, however, increases exponentially. Model auditing requires not only assessing the reasonableness of the algorithmic architecture but also examining in depth the quality of the training data, the bias in feature engineering, and the model's performance in historical decisions. A deep neural network may contain millions of parameters, and a minute change in any one of them may cause a significant change in the output. This makes the traditional code-auditing method entirely inapplicable. An auditor cannot understand the model's decision logic by reading the code line by line, because the model's decisions are produced by complex mathematical operations and nonlinear transformations.

Because of the inherent "black box" nature of deep-learning models, requiring the model to provide a precise causal explanation for each of its microlevel decisions is often technically unrealistic. To meet this challenge, the governance framework must introduce new practical schemes to ensure that the model's behavior is traceable and accountable. One feasible mechanism is to require the AI system to periodically generate and publish standardized "decision reports." These reports should record in detail the key decisions the model made within a particular period, clarify the main input features on which the decisions relied and their weights, and contrast the model's decisions with the expected output of purely hardcoded rules under the same conditions [56].

The specific design of the decision report should include the following. First, the report should record all important decisions above a certain threshold, such as all decisions that led to a margin-rate adjustment of more than 5%. Second, for each decision, the report should list the top ten most influential input features and their contribution to the decision. Third, the report should include a comparative analysis of the model's decision with a pure hardcoded rule. For example, if a hardcoded rule would liquidate a position under the given market conditions but the model decided not to liquidate, the report should explain the model's reasoning. Fourth, the report should include the model's confidence indicator—that is, how certain the model is of its decision. If the confidence is low, this may indicate that the model is handling an unfamiliar market environment.

These decision reports should be stored on the blockchain, forming an immutable audit trail. In this way, anyone can look back through history to see the decisions the model made at a particular point in time and their reasoning. Through this approach, even if it is impossible to fully reveal the model's internal nonlinear mapping process, governance

participants can still assess the reasonableness of the model's behavior and identify potential systematic biases by analyzing the statistical relationship between inputs and outputs. If the model is found to systematically make unreasonable decisions under a particular type of market condition, this can trigger a retraining of the model or an adjustment of the floor.

The probabilistic nature of model decisions also gives rise to complex questions about the accountability mechanism. When the model's adaptive adjustments cause some participants to suffer unexpected losses, the traditional liability-attribution framework based on deterministic rules no longer applies. In the case of hardcoded rules, if the system causes a loss, the liability is clear: either the rule design was flawed, or the rule execution was faulty. But for the model, the situation is far more complex. The model's decisions are based on the patterns it has learned, and these patterns may themselves be flawed, but the flaw may be due to insufficient training data, improper feature engineering, or an improper choice of model architecture.

To ease this contradiction, the concept of "model insurance" provides a market-based mechanism for risk transfer. A protocol operator can establish a dedicated insurance fund for the decision behavior of the AI infrastructure; when the model's output causes an anomalous loss exceeding what the hardcoded floor anticipates, the injured party can obtain compensation from the fund. The design of this mechanism requires special attention to several aspects. First, the scope of insurance must be clearly defined. What types of loss should the insurance cover? All losses caused by model decisions, or only those that breach particular conditions? Second, the pricing method must reflect the model's actual risk. If the model's historical performance shows that it is prone to error under particular market conditions, the insurance premium should rise accordingly. Third, the claim-trigger condition must be objective and verifiable. A claim cannot be based on subjective judgment but must be based on explicit conditions verifiable on-chain. For example, a claim might be triggered when the loss caused by the model's decision exceeds a certain threshold and this loss is due to the model's decision rather than to market volatility.

This mechanism turns the long-tail risk brought by the model's unpredictability into a quantifiable and priceable insurance cost, thereby strengthening participants' trust in the hybrid architecture. Participants know that even if the model makes an unreasonable decision, they have insurance as a last line of protection. At the same time, the level of the insurance premium also provides a market signal of the model's quality. If a model's insurance premium is high, this indicates that the market considers the model to be very risky.

Finally, the system must have a sound "revertibility" design as the ultimate safety guarantee. When facing anomalous model performance, a severe adversarial attack, or a fundamental structural rupture in the market environment, the system should be able to cut off the AI model's control automatically or through an emergency governance process and seamlessly revert to a base state driven purely by hardcoded rules. This design establishes code's status as an always-available safety backup and sends a clear signal to the market: the model is an enhancing component that improves efficiency, but it is not the sole dependency for keeping the system running. The description of

"seamless reversion" above, however, must confront the practical challenges of engineering implementation. When the AI model has dynamically lowered the margin rate of a certain class of assets to a relatively low level during operation to optimize capital efficiency, while the hardcoded default is set relatively high, the parameter jump at the instant of reversion may itself trigger large-scale margin calls or liquidation events. The actual reversion mechanism should therefore be designed as a gradual downgrade rather than an instantaneous switch: after detecting an anomaly, the system first limits the model's adjustment magnitude, then gradually returns the parameters to the hardcoded defaults. The reversion process must also handle the race condition in which the AI system's uncompleted operations and the hardcoded system run simultaneously, ensuring that no double execution or missed execution occurs.

The engineering implementation of revertibility must consider several aspects. First, the system must be able to detect the model's anomalous behavior. This can be achieved by monitoring the degree of deviation between the model's decisions and its historical patterns. If the model makes a large number of decisions inconsistent with its historical behavior within a short time, this may indicate that the model has been attacked or has undergone severe drift. Second, the system must be able to trigger the reversion quickly. This cannot depend on human intervention but must be automatic. Once an anomaly is detected, the system should immediately stop using the model's output and switch to hardcoded rules. Third, the system must be able to recover after reversion. This means that during the reversion period, the system must still be able to operate normally, though its efficiency may decline. Fourth, the system must be able to diagnose the root cause of the problem. After reversion, an in-depth analysis is needed to determine why the model malfunctioned—whether because of an adversarial attack, training-data contamination, model drift, or another reason.

Through these multi-level auditing, accountability, and reversion mechanisms, the hybrid architecture maintains the safety floor of DeFi infrastructure while embracing the efficiency gains that AI brings. This architecture is not a perfect solution, but it represents the best practice, under current technological conditions, for balancing security and efficiency. As AI technology develops further and interpretability methods improve, this hybrid architecture is expected to keep evolving, gradually raising the model's trustworthiness and autonomy.

31.11 Chapter summary

This chapter has advanced three core theoretical contributions. First, the four-stage model of AI penetration into microstructure (assistance → execution → autonomy → adversarial competition) provides a systematic framework for understanding the evolution of AI's role in the market. The current market is in the critical transition from Stage 2 to Stage 3, in which market making and arbitrage, because of their heavy dependence on speed and multidimensional optimization capability, have become the fastest-penetrating domain, while governance participation remains at the proof-of-concept stage. Second, the dual-role framework reveals the economic logic of AI's evolution from a value-extracting market participant into value-creating market infrastructure: participant AI's profit margin is continually compressed under competitive

pressure, whereas infrastructure AI sustains a persistent capacity for value capture on the strength of network effects, economies of scale, switching costs, and the data-feedback effect. This framework explains why capital and technological resources are accelerating their migration toward the infrastructure domain. Third, the "code plus model" hybrid architecture provides a design paradigm for the next generation of market infrastructure: hardcoded rules set an inviolable safety floor, within which the AI model is granted ample space for adaptive optimization, and determinism and flexibility are unified through a "model proposes, code reviews" workflow.

This chapter has identified three key findings and risks. Strategy homogenization is the most prominent new form of systemic fragility in the AI era: algorithms trained on similar architectures and data may, when facing an anomalous signal, make wholly identical defensive reactions within milliseconds, triggering an "AI flash crash" of extremely short duration but extremely great destructive power. This mechanism turns the volatility distribution from mildly right-skewed into bimodal—that is, normal-regime volatility declines but tail risk rises—and market resilience exhibits a bimodal character of "extremely high in the normal regime, extremely low in the tail." At the same time, AI's effect on market quality is highly nonlinear: transaction cost and the efficiency of price discovery improve significantly under normal conditions, but fairness deteriorates substantively because of the widening speed gap. At the infrastructure level, the six core AI-driven systems (the dynamic risk engine, the intelligent matching engine, the predictive liquidation system, the dynamic pricing mechanism, the compliance-monitoring system, and liquidity-routing optimization) are upgrading the static protocol architecture into an adaptive system, among which the predictive liquidation system, by moving risk management forward from passive triggering to probabilistic prediction, can significantly reduce the scale of liquidation cascades under extreme conditions. The breakthrough of the semantic oracle, in turn, fundamentally unlocks the technical bottleneck of "perpetual futures on everything," enabling unstructured information such as political events, corporate performance, and arbitrary natural-language conditions to be brought into the on-chain financial system.

The analysis in this chapter also reveals several open questions. How should the boundary of AI agents' participation in decentralized governance be delineated, and should the permissions for parameter optimization be distinguished from those for constitutional decisions in a tiered manner? How can an audit and accountability framework for probabilistic models be established, and can a "model insurance" mechanism effectively transfer the long-tail risk that unpredictability brings? Can the risk of strategy homogenization be effectively mitigated through a "heterogeneity incentive" mechanism, or will it keep intensifying as AI technology converges further? Can the hallucination and bias problems of the semantic oracle be adequately controlled through multi-node consensus and adversarial-verification mechanisms? The answers to these questions will determine whether an AI-driven autonomous financial network can achieve a sustainable balance among efficiency, security, and fairness.

The Global Vision of Autonomous World Finance

According to a report published by CoinGecko in February 2026, the world's top 10 centralized exchanges (CEXs) and decentralized exchanges (DEXs) processed $92.9 trillion in notional (leveraged) perpetual futures trading volume across full-year 2025, a 64.6% increase over the prior year; decentralized perpetual futures exchanges reached an all-time high of $6.7 trillion in trading volume, up 346% year over year (this figure is notional volume, and because the source does not disclose its wash-trading filtering method, it should be read as an order-of-magnitude scale rather than as precise net demand) [1]. In stark contrast, the 2025 edition of the World Bank's Global Findex Database reports that roughly 1.3 billion adults worldwide remain unbanked [2][3], and the average cost of cross-border remittances has long held at around 6% (recent World Bank data put it at approximately 6.2% to 6.65%, still more than twice the Sustainable Development Goals' 3% target) [4]. The contrast between these two sets of figures reveals the central contradiction confronting autonomous finance: on-chain financial infrastructure has demonstrated the engineering capacity to substitute for traditional intermediaries, yet the scale of global financial exclusion shows that this capacity has not translated into universally accessible services. The central question of this chapter is whether the three-layer stack composed of perpetual futures, on-chain clearing and settlement, and artificial intelligence (AI) agents can address the genuine needs of financial inclusion while improving the efficiency of global capital allocation, and how its inherent tensions delimit the boundaries of this process.

The architectural logic of the three-layer stack is the starting point of the analysis. The asset layer converts underlying assets into on-chain perpetual futures; the infrastructure layer provides decentralized clearing and settlement together with embedded compliance; and the intelligence layer, through AI agents, sharply compresses the marginal cost of professional financial services. The synergy among the three layers within a permissionless network far exceeds the simple sum of each layer's functions (elaborated in Section 32.1), and its value can be understood only through systematic analysis.

On this basis, the discussion of financial inclusion shifts from an abstract vision to a concrete analysis of engineering feasibility. The core pain points faced by the roughly 1.7 billion to 4 billion people in emerging markets who lack basic financial services (a broader measure than the unbanked) [5][6]—namely foreign-exchange hedging, inflation-resistant savings, and low-cost cross-border payments—correspond directly to the en-

gineering properties of the three-layer stack in lowering friction costs and barriers to entry. Yet the real constraints on inclusion cannot be ignored. A lack of financial literacy means that low barriers may expose users without risk-management capacity to highly leveraged markets, and a large share of the world's population still has no internet access (approximately 2.2 billion people are entirely offline, and more than 3 billion others fall within mobile-network coverage yet do not use mobile internet—the so-called *usage gap* [7][8]; the full accounting is detailed in Section 32.2.5), so the digital divide constitutes a more fundamental barrier to access than financial exclusion itself. As the three-layer stack sharply compresses friction costs, the efficiency of global capital allocation also changes structurally: around-the-clock continuous pricing eliminates the opening gaps caused by information backlogs; synthetic exposure decouples the economic allocation of capital from the cross-border transfer of physical ownership; and cross-margining raises capital-utilization efficiency to a level unattainable under the traditional isolated-account system. But a highly interconnected network simultaneously breeds new forms of systemic risk, including liquidation cascades under global cross-margining, global flash crashes triggered by the homogenization of AI-agent strategies, and the system-wide propagation of an oracle single point of failure. These risks propagate on the order of milliseconds, compressing the window for human intervention to the extreme.

This analysis ultimately converges on three irreducible structural tensions. The trade-off between efficiency and stability is amplified to a global scale by the introduction of leverage and continuous trading; a fundamental conflict exists between permissionless access and the demand for consumer protection; and an enduring contest arises between a borderless liquidity network and the control that sovereign states exercise over monetary policy and capital flows. These tensions are not engineering defects awaiting repair but fundamental trade-offs that any financial system must make among competing value objectives. After reading this chapter, readers will be able to systematically understand the architectural logic and synergies of the three-layer stack, assess its real potential and constraints in financial inclusion and global capital allocation, and recognize that the mark of maturity for autonomous finance lies not in eliminating its inherent contradictions but in establishing governance mechanisms that seek a dynamic equilibrium within these long-term tensions.

32.1 The three-layer stack of autonomous finance

As defined in this chapter, *autonomous finance* refers to a paradigm of financial services whose defining feature is the autonomous decision-making capacity of AI agents and which runs on permissionless on-chain infrastructure. This concept has clear boundaries with adjacent terms: DeFi emphasizes the decentralization of governance structures, open finance emphasizes the openness of interfaces and data, and programmable finance emphasizes the ability of smart contracts to encode financial logic, whereas autonomous finance is distinctively positioned by the capacity of AI agents to complete the full closed loop of risk assessment, liquidity provision, and strategy execution without continuous human intervention.

The architecture of an autonomous finance network can be decomposed into three func-

tional layers: the asset layer, the infrastructure layer, and the intelligence layer. This three-layer analytical framework corresponds to the BIS Committee on Payments and Market Infrastructures (CPMI) layering of financial market infrastructures and to the DeFi composability stack proposed by Schär (2021) [9], but the distinctive contribution of this chapter's framework is to incorporate the AI intelligence layer as an independent functional layer, reflecting the fundamental impact of autonomous agents on the structure of the financial system. Each layer has made varying degrees of technical progress, but their value lies not in their individual functions but in the emergent effects produced when the three layers operate in concert within a single permissionless network. This section analyzes in turn the current maturity and core challenges of each layer, and on that basis argues why the synergy of the three-layer stack far exceeds the simple sum of each layer's functions.

The three functional layers are not simply stacked one atop another; rather, they form tight interdependencies along three dimensions—data flow, the transmission of trust, and the supply of liquidity (Figure 32-1).

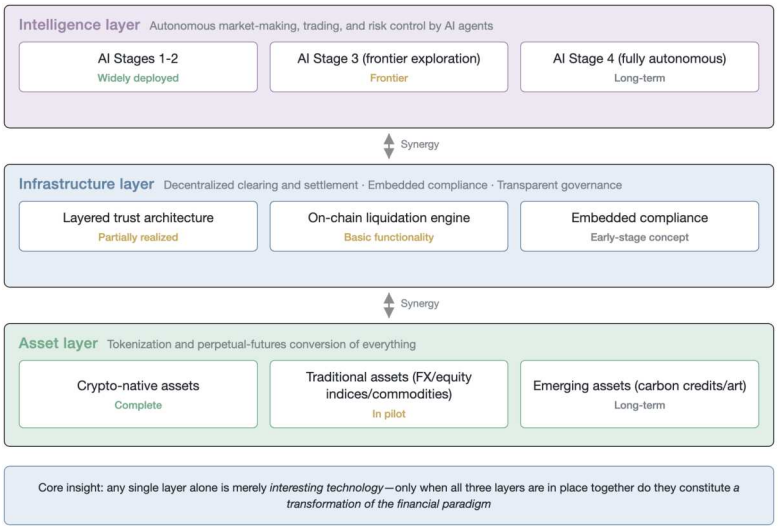

Figure 32-1. The three-layer stack architecture of autonomous finance (Data source: theoretical derivation in this chapter)

32.1.1 The asset layer

The asset layer is the cornerstone of the autonomous finance stack. In Chapter 27, we introduced the thought experiment of *perpetual futures on everything*, noting that the funding-rate anchoring mechanism is highly general: as long as a reliable external price source exists, any asset can be wrapped as a perpetual futures contract and traded. This mechanism substantially weakens the physical-delivery constraint of traditional finance (though it does not eliminate the constraint of geographic jurisdiction—that is, of regulation; see Section 32.5.3), allowing global investors to gain exposure to a given underlying through synthetic assets. In essence, the asset layer is a *value-*

mapping layer that converts diverse forms of real-world value—from crypto assets to commodities, from equity indices to exchange rates—into digital forms tradable on-chain. This conversion appears simple, but it involves complex problems of pricing, risk management, and liquidity aggregation.

At present, the development of the asset layer shows a marked phased character. The conversion of crypto-native assets into perpetual futures has largely matured at the product level, but the design of the underlying mechanisms is still evolving: the sharp divergence of funding rates under extreme conditions, the inconsistency of mark prices across exchanges, and the sustainability of insurance funds over a complete market cycle have yet to be fully tested. According to the report published by CoinGecko in February 2026, the world's top 10 centralized and decentralized exchanges processed as much as $92.9 trillion in notional (leveraged) perpetual futures trading volume across full-year 2025, an increase of 64.6% over 2024 [1]. For some crypto assets, perpetual futures volume has already surpassed spot volume, making them an important venue for price discovery and liquidity aggregation. Decentralized perpetual futures exchanges achieved explosive growth of 346%, reaching an all-time high of $6.7 trillion in volume [1]. The DEX perpetual futures volume should be interpreted with caution: token incentives and airdrop-points programs may have driven substantial wash trading, so the figure represents notional volume, and actual organic volume may be substantially lower. These data show that on-chain derivatives markets have evolved from a niche field into an important component of global financial trading. This growth is driven by several factors. First, perpetual futures offer greater capital efficiency than spot trading, allowing traders to obtain larger exposure with less capital. Second, 24-hour uninterrupted trading meets the needs of global investors, particularly those in different time zones. Third, the permissionless nature of decentralized platforms attracts users who are excluded from traditional exchanges.

Extending this model to traditional assets, however, remains at the pilot stage. Some frontier decentralized platforms have begun to experiment with perpetual futures on foreign exchange, equity indices, and commodities. For example, in discussing Hyperliquid's HIP-3 permissionless deployment mechanism, the same CoinGecko report notes that the platform can create a perpetual market for any asset with a reliable price feed, spanning commodities and even underlyings such as SpaceX and OpenAI [1]. These experiments demonstrate technical feasibility, but their trading scale and market depth remain far below those of crypto-native assets. This asymmetry reflects a deeper reality: although the technology is ready, the confidence of market participants, the clarity of regulatory frameworks, and the accumulation of liquidity still require time. The core challenges facing the conversion of traditional assets into perpetual futures include oracle reliability (equity prices require real-time, accurate feeds), regulatory uncertainty (attitudes toward derivatives trading differ widely across countries), and the cold-start problem for liquidity (a new trading pair needs enough participants before an effective market can form). Despite these challenges, we have already seen preliminary successes, which lay a foundation for the further expansion of the asset layer.

As for the *everything* vision of fully tokenizing or converting into perpetual futures such non-standard assets as carbon credits, real estate, or art, this remains a long-term goal. Such assets face not only more complex oracle-feed difficulties but also the con-

straints of legal title and physical enforcement that arise when real-world assets are brought on-chain. A real-estate perpetual futures contract, for example, requires a reliable house-price oracle, yet global house-price data are far less standardized than equity or commodity prices. Moreover, if settlement of the perpetual futures involves physical delivery, then cross-border legal and logistical costs rise sharply. The challenge for carbon-credit perpetual futures lies in the fact that carbon markets themselves are still in an early stage of development, with pricing mechanisms differing widely across countries and regions, which makes it difficult to build a unified on-chain carbon-credit market. Perpetual futures on art and collectibles, in turn, face the problems of authentication and the subjectivity of valuation. The evolutionary path of the asset layer is therefore a gradual one—from highly digitized native assets, gradually penetrating standardized traditional financial assets, and ultimately perhaps reaching non-standard physical assets. This process may take a decade or longer, but its direction is clear.

32.1.2 The infrastructure layer

If the asset layer defines *what* is traded, the infrastructure layer defines *how* to trade safely. In Chapters 28 through 30, we examined the decentralized clearing engine, the layered trust architecture, and embedded compliance mechanisms. Under the traditional system, clearinghouses and custodian banks rely on sovereign credit and vast legal-compliance apparatus to guarantee the finality of transactions. In the autonomous finance stack, these functions are hard-coded into immutable smart contracts and consensus protocols.

The on-chain clearing engine is the core component of this layer. Modern decentralized exchanges have already implemented cross-margining and cross-clearing functions similar to those of a traditional central counterparty (CCP), but in a permissionless environment these engines must cope with higher volatility and more extreme market conditions. In 2025, the open interest on decentralized exchanges surged by 229.6% (over the same period, open interest on centralized exchanges fell by 20.8%, reflecting a rotation of capital from CEXs to DEXs; note that 229.6% is a growth rate rather than a level), indicating that market participants' trust in on-chain infrastructure is rising substantially—they are not merely engaging in short-term speculation but also building long-term, substantive capital positions [1]. From a risk perspective, however, the rapid growth of open interest is at the same time a signal of accumulating systemic leverage, and readers should cross-reference the corresponding risk analysis in Section 32.4. This trust is built gradually: each time the system successfully weathers extreme conditions without failing, participants' confidence is further reinforced. Even so, under stress testing for capital efficiency and extreme tail risk, current on-chain clearing mechanisms remain functionally basic and not yet fully optimized.

The layered trust architecture seeks a balance between decentralization and performance. By building application chains (app-chains) optimized specifically for derivatives trading, platforms can achieve sub-second trade confirmation and high throughput while anchoring the final settlement layer to a more decentralized underlying network. This architecture has already been validated on some leading platforms, but cross-chain liquidity fragmentation and cross-domain interoperability remain pressing problems.

Imagine an investor who holds margin on chain A but wishes to trade an asset on chain B: this requires support from cross-chain bridges and liquidity protocols, which still carry technical and economic friction. Moreover, it is necessary to distinguish between *architectural decentralization* and *operational decentralization*. Most current derivatives app-chains anchor settlement architecturally to a decentralized base layer, yet remain highly centralized operationally: the sequencer is typically controlled by a single entity that orders transactions, the validator set is highly concentrated, and the platform retains emergency-intervention capabilities. Hyperliquid's 2025 JELLY incident—in which validators voted to freeze specific positions—shows that under extreme conditions the actual operating model of these platforms more closely resembles a centralized exchange with on-chain settlement than a genuinely decentralized protocol.

The least mature link in the infrastructure layer is embedded compliance. As Chapter 30 noted, for decentralized finance to enter the mainstream it must encode its responses to regulatory requirements. Technologies such as zero-knowledge proofs (ZKPs) and digital identity credentials provide a theoretical foundation for a system architecture in which lawbreaking is rendered *impossible*, but in actual deployment, how to establish a unified on-chain compliance standard across globally fragmented regulatory regimes remains at a very early, conceptual stage. The deeper obstacle is not only technical immaturity but also the fundamental incompatibility between zero-knowledge-proof compliance and existing legal frameworks: the U.S. Bank Secrecy Act requires financial institutions to be able to *produce* actual customer records, not merely to supply a cryptographic proof of compliance, while the EU's Anti-Money Laundering Directive requires transparent disclosure of beneficial ownership. A zero-knowledge proof can demonstrate that an address is not on a sanctions list, but it cannot satisfy regulators' *record production obligations*. U.S. anti-money-laundering rules, for example, conflict fundamentally with EU data-privacy rules, and there is as yet no clear answer to how a globalized on-chain system could satisfy both simultaneously.

32.1.3 The intelligence layer

The intelligence layer sits at the top of the autonomous finance stack. In Chapter 31, we analyzed the four stages of AI's penetration into on-chain finance. Although traditional quantitative trading has long been widespread, an autonomous finance network requires autonomous agents that can continuously assess risk, provide quotes, and execute complex strategies without human intervention.

At present, the use of AI in market making and algorithmic trading (that is, the first and second stages) is already widespread. In both centralized and decentralized markets, the overwhelming majority of liquidity is algorithm-driven. According to McKinsey's 2025 State of AI global survey, 62% of firms report at least experimenting with AI agents (about 23% have deployed them at scale in certain functions and 39% are at the experimental stage), indicating that the underlying technical foundation for the intelligence layer is accumulating at an accelerating pace [10]. On decentralized exchanges, because interfaces are fully open and smart contracts are composable, AI agents can conduct cross-market arbitrage and liquidity management more freely than in traditional financial systems. An AI market-making bot can provide liquidity si-

multaneously on multiple DEXs and automatically execute arbitrage when it detects a price inconsistency—all on a millisecond timescale.

Entering the third stage, however—highly autonomous AI conducting complex capital allocation and dynamic risk control within decentralized finance protocols—remains a frontier exploration. Such agents must handle risks specific to on-chain environments, including maximal extractable value (MEV) attacks, smart-contract vulnerabilities, and oracle latency. An AI risk-control system, for instance, must predict not only market risk but also the behavior of other AI agents and the possible failure modes of smart contracts. This is a far more complex problem than traditional risk control. As for the fourth stage—a fully autonomous market of *AI versus AI*, in which market microstructure is entirely dominated by machine logic—it remains a theoretical conception.

The core value of the intelligence layer lies in the way it substantially lowers the threshold and cost of liquidity provision. Most of what is currently called *AI market making* on-chain remains rule-based automated market making—adjusting automated market maker (AMM) parameters, running grid strategies, and the like—together with machine-learning-assisted parameter optimization, rather than end-to-end autonomous AI decision-making. Genuine autonomous market making is constrained by on-chain latency (approximately 200 milliseconds, compared with the microsecond-level response of centralized exchanges) and by pre-trade transparency (mempool visibility and the risk of sequencer front-running); these structural constraints make on-chain AI market making, at the current stage, closer to *intelligent automation* than to *AI autonomy*. In the incumbent financial architecture, market making is a capital- and technology-intensive privileged business in which only a few large institutions can participate. In the autonomous finance stack, open-source AI market-making bots combined with on-chain liquidity pools allow ordinary investors to participate in liquidity provision as well, thereby democratizing financial infrastructure. An individual holding a small amount of stablecoins can deploy a simple market-making bot to provide liquidity on a given trading pair and earn income from trading fees.

32.1.4 Synergies

Taken separately, each of the asset layer, the infrastructure layer, and the intelligence layer represents progress in a specific technology. Perpetual futures are an innovative financial derivative; on-chain clearing is an efficient piece of distributed-systems engineering; and AI trading agents are a successful application of machine learning. Developed in isolation, they would at most be *interesting technologies*. But when the three layers interweave and fall into place at once within a single permissionless network, they constitute a paradigm shift in finance.

This synergy is manifested first in the mutual reinforcement of liquidity and trust. The asset layer's *perpetual futures on everything* substantially expands the boundary of tradable underlyings, but without the decentralized clearing and immutable ledger provided by the infrastructure layer, traders would be unable to establish trust in a global network that lacks traditional legal protection. Conversely, without the around-the-clock, deep liquidity provided by the intelligence layer's AI agents, perpetual futures on long-tail or emerging assets would become unattractive because of excessively wide

bid-ask spreads. A perpetual futures contract on an emerging-market currency pair, for example, would have prohibitively high trading costs without sufficient liquidity, losing its value as a hedging instrument. This positive reinforcing cycle also operates in reverse: when liquidity declines, trust erodes with it, triggering capital withdrawal that further depletes liquidity, forming the liquidity-spiral mechanism described by Brunnermeier and Pedersen (2009) [11]. The key question is what conditions trigger the system to switch from the positive cycle to the negative one—an issue developed further in the systemic-risk analysis of Section 32.4.

Second, the synergy is manifested in the reconciliation of compliance and innovation. The embedded compliance being explored in the infrastructure layer allows the asset layer to satisfy the regulatory requirements of a given jurisdiction while preserving permissionless access. The intelligence layer's risk-control agents can read these compliance parameters in real time and automatically adjust trading strategies, ensuring that capital is allocated globally without crossing regulatory red lines. This hard-wiring of compliance and trading logic at the code level is unimaginable in traditional systems built from human compliance officers and cumbersome paper documents. A zero-knowledge proof can demonstrate that a trader satisfies a specific compliance condition (for example, that the trader is not a U.S. person) without revealing the trader's true identity.

Finally, the combination of the three layers unlocks capital efficiency. In traditional finance, an investor who wants to hedge foreign-exchange risk, invest in U.S. technology stocks, and short a commodity all at once must cross multiple time zones, open different brokerage accounts, and endure lengthy settlement cycles. In the autonomous finance stack, through the composability of smart contracts, an AI agent can, within milliseconds and using the same stablecoin margin, establish all three positions simultaneously with the support of a decentralized clearing engine. All friction is abstracted away, and capital flows freely, without borders and without time-zone lag.

This synergy also appears along the risk-management dimension: when the three-layer stack is fully in place, risk is no longer isolated but understood and managed by the entire system—the diversification of the asset layer lowers single-asset risk, the transparency of the infrastructure layer supports real-time monitoring, and the automation of the intelligence layer enables rapid response.

Although the components of the autonomous finance stack differ in maturity, its core skeleton is already in place. The success of crypto-native assets has proven the feasibility of the underlying logic, while the evolution of infrastructure and the spread of AI agents are accelerating the network's expansion into the broader field of traditional finance. This is not merely an upgrade of trading tools; it is a fresh answer to the fundamental question of who should build financial systems, who should run them, and whom they should serve.

From a systems-theory perspective, the core value of the three-layer stack lies in its emergence. When the asset layer provides sufficiently diverse underlyings, the infrastructure layer provides sufficiently reliable clearing mechanisms, and the intelligence layer provides sufficiently efficient liquidity, the system as a whole spontaneously evolves new functions and possibilities. These new functions are not preplanned by any single layer's

designers but emerge naturally from the interaction of the three layers. Cross-asset automatic hedging strategies, dynamic risk management, and even new forms of financial products, for example, may all arise spontaneously within this system. The magnitude of the synergy can be illustrated with a conceptual example. In a three-asset portfolio of BTC, the S&P 500, and gold, because the correlation matrix among the three exhibits a substantial negative-correlation component in most market environments, the aggregate margin requirement under cross-margining can be 30% to 50% lower than under the isolated-account model. This estimate, however, requires three important qualifications: (1) the 30% to 50% margin saving assumes that the correlation structure remains stable under normal market conditions; (2) under stress scenarios, cross-asset correlations tend toward 1 (systematically demonstrated by Forbes and Rigobon (2002) [12]), at which point the margin saving may narrow to as little as 5% to 15%; and (3) no on-chain DEX currently offers perpetual futures on BTC, the S&P 500, and gold simultaneously, so this portfolio serves only as a conceptual example rather than a currently realizable trading strategy. This means that the same amount of principal can support greater risk exposure within the three-layer stack, but this gain in capital efficiency also implies greater system fragility to extreme jumps in correlation. When cross-asset correlations tend toward 1 under stress, the margin buffer contracts far faster than under the isolated-account system (see Section 32.4.1 for a dedicated analysis of cross-margining risk under stress scenarios).

As the foregoing analysis shows, the components of the three-layer stack differ significantly in maturity, and this difference means that the pace of the whole system's evolution will be constrained by how quickly its weakest link can be overcome. Table 32-1 summarizes the core functions, current maturity, and key bottlenecks of each layer of the three-layer stack, providing a baseline reference for the later sections' analysis of the real-world constraints on the three-layer synergy.

Layer	Core function	Current maturity	Key bottleneck
Asset layer	Converts underlyings into on-chain perpetual futures	Crypto-native assets mature; traditional assets at the pilot stage; non-standard assets a long-term prospect	Oracle reliability, regulatory clarity, liquidity cold start
Infrastructure layer	Decentralized clearing and settlement, and embedded compliance	Clearing engine functionally largely complete; cross-chain interoperability fragile; embedded compliance at the concept stage	Cross-chain liquidity fragmentation, unification of global compliance standards
Intelligence layer	Autonomous market making, risk control, and strategy execution by AI agents	Market making and arbitrage widely deployed (stages one and two); autonomous capital allocation at the frontier (stage three)	Perception of on-chain-specific risks, explainability, strategy homogenization

Table 32-1. Maturity comparison across the three-layer stack (Data source: based on the analysis in Sections 32.1.1–32.1.3)

The engineering properties of the three-layer stack—permissionless access, extremely low barriers to participation, and globally accessible infrastructure—correspond directly to the scale of global financial exclusion. Translating this technical potential into financial inclusion, however, requires distinguishing the essential difference between *lowering barriers to entry* and *effective empowerment*.

32.2 The structural constraints on financial inclusion

The existence of billions of unbanked people worldwide makes financial inclusion not merely a moral appeal but a systemic problem with clear engineering constraints. The technical properties of the three-layer stack in lowering friction costs and barriers to entry correspond directly to the core pain points these populations face—foreign-exchange hedging, inflation-resistant savings, and low-cost cross-border payments. Beginning from the genuineness of the demand, this section examines the inclusive potential of perpetual futures, on-chain infrastructure, and AI agents, then confronts the unavoidable structural constraints of financial-literacy gaps, the digital divide, and the *inclusion trap*.

32.2.1 Genuine demand

When we speak of financial inclusion, we must first establish the genuineness and urgency of these needs. According to the 2025 edition of the World Bank's Global Findex Database, roughly 1.3 billion adults worldwide remain unbanked (account ownership has risen to about 79%; the earlier literature's range of 1.3 billion to 1.7 billion reflects differences across survey years such as 2017, 2021, and 2025), a group concentrated primarily in developing countries in Asia, Africa, and Latin America [2] [3]. Behind these numbers lie genuine economic hardship and the erosion of wealth. Small-business owners in emerging markets face the daily risk of local-currency depreciation, yet no effective foreign-exchange hedging instrument is available to them. Traditional commercial banks typically do not offer forward FX contracts or options to small customers, and even when they do, the high fees and margin requirements deter micro and small enterprises. This scarcity of financial instruments leaves such firms defenseless against global macroeconomic fluctuations, and their profits may shrink sharply because of exchange-rate movements.

Beyond exchange-rate risk, savers in developing countries also face persistent erosion from inflation. In many emerging-market economies, inflation has long held at elevated levels; average inflation in emerging markets and developing economies in 2024, for example, was about 8% (approximately 8.1% per the International Monetary Fund (IMF) World Economic Outlook), while the 2025 forecast is about 5.3% (on the basis of the IMF's October 2025 World Economic Outlook) [13]. In this environment, if savers can only hold their money in local currency at home or in local bank accounts with extremely low yields, the real purchasing power of their wealth will inevitably shrink. Yet because of capital controls, high account-opening thresholds, and complex

cross-border compliance requirements, these savers can almost never obtain exposure to international assets. Unlike investors in developed countries, they cannot hedge local inflation risk by buying an S&P 500 index fund or U.S. Treasuries. This absence of investment channels is, in essence, a structural form of wealth deprivation.

In addition, the world's tens of millions of cross-border remittance workers likewise bear the heavy costs of an inefficient financial system. These workers leave their hometowns to labor in foreign lands and remit their savings home to support their families. According to World Bank and IMF data, however, the average cost of personal cross-border remittances has long held at around 6% (recent World Bank data put it at approximately 6.2% to 6.65%, still more than twice the Sustainable Development Goals' 3% target), and in some regions it is even higher [14] [15]. This means that tens of billions of dollars each year are consumed by financial intermediaries in the friction of cross-border transfers—money that could otherwise have improved the lives, education, and health of poor families. These needs—foreign-exchange hedging, inflation-resistant savings, and low-cost cross-border payments—are not false demand created by financial engineering but genuine pain points that billions of people worldwide face every day.

32.2.2 The inclusive functions of perpetual futures

Confronted with these genuine financial needs, the traditional financial system—because of its high operating costs, complex compliance requirements, and path dependence on high-net-worth clients—has consistently failed to provide effective solutions. The perpetual futures examined in Chapter 27, once combined with decentralized infrastructure, show the potential to become a powerful instrument of inclusion. Foreign-exchange perpetual futures give small-business owners in emerging markets a hedge against local-currency depreciation at a cost significantly below that of traditional solutions. Unlike a traditional bank's forward contract, participating in on-chain FX perpetual futures requires no complex credit review or high account-opening threshold. A small-business owner needs only a smartphone wallet and a small amount of stablecoins to establish, on a decentralized exchange, a perpetual futures position opposite to the firm's actual exposure. Because perpetual futures are tightly anchored to the spot price through the funding-rate mechanism, this hedge can precisely offset the losses caused by local-currency depreciation; and on liquid major trading pairs, the empirical analysis of on-chain stablecoin foreign exchange by Adams et al. (2023) [16]—using EUROC/USDC as a proxy for EUR/USD—shows that the on-chain trading price deviates from the traditional-market exchange rate by an average of about 5 basis points during normal trading hours. For a $500 on-chain cross-border transfer, the cost in the best case is about $4.80, roughly 83% lower than the $28 charged through traditional banking channels. Liquidity-provider fees for on-chain AMM spot swaps are typically about 1 to 5 basis points (0.01% to 0.05%), far below the spreads and credit-review costs embedded in traditional bank forward contracts, substantially lowering the economic threshold for small conversions. The cost-advantage figures above, however, derive primarily from empirical analysis of major currency pairs such as USDC/EUROC; for the small-currency pairs of emerging markets, on-chain FX liquidity remains limited and spreads may reach 50 to 200 basis points. Moreover, the full-stack cost must also include the on-ramp and off-ramp

costs between fiat and stablecoins (typically 2% to 5% in emerging markets), which substantially narrows the cost advantage of on-chain solutions for end users who still need fiat conversion.

For savers in developing countries facing inflationary erosion, equity-index perpetual futures and commodity perpetual futures offer a channel across geographic and institutional barriers. In the traditional financial world, an ordinary saver in India or Nigeria who wishes to invest in the U.S. stock market must overcome layer upon layer of obstacles—foreign-exchange controls, opening an overseas securities account, and meeting minimum-capital requirements—which is entirely impossible for the great majority of people. Through synthetic-exposure perpetual futures (whose frictionless mechanism for decoupling an asset's economic attributes from physical ownership is detailed in Section 32.3.3), with only $100 worth of stablecoins this saver can gain precise on-chain exposure to the S&P 500 or gold, fundamentally breaking the monopoly under which *high-quality assets are reserved for the rich and for residents of developed countries.*

Going further, the combination of stablecoins and perpetual futures can, in a sense, substitute for—or even surpass—the function of a traditional savings account. In a country with high inflation and an unstable local currency, holding a dollar-pegged stablecoin is itself a defensive strategy. If the user further uses these stablecoins as margin to provide liquidity or adopt a particular hedging strategy in the perpetual futures market, the user can also earn a continuous stream of funding-rate income. In a market environment of strong long demand, this funding-rate-based yield is often far higher than the deposit rates of traditional banks. This combination not only protects the purchasing power of the principal but also creates positive cash flow, providing the unbanked with a fully functional *synthetic yield strategy.* Yet the risk profile of this strategy differs fundamentally from that of traditional savings: the funding rate can remain negative for extended periods, at which point the *yield* turns into a continuous cost outflow; even under low leverage, extreme conditions can still trigger margin calls or forced liquidation; and stablecoins themselves carry depegging risk, as the 2022 collapse of UST to zero and the temporary fall of USDC to $0.87 in March 2023 both illustrate. A user who understands such a strategy as *savings* without fully recognizing these risks is a textbook case of the inclusion trap discussed in Section 32.2.5. In addition, Rajan (2006) [17] argued that an inherent tension exists between the proliferation of financial instruments and the diffusion of systemic risk: as more participants gain access to complex instruments, the total quantity of risk-taking and the pathways of its transmission expand in tandem. The democratization of perpetual futures faces the same dilemma, and its potential negative effects are discussed in detail in Section 32.2.5.

32.2.3 The inclusive properties of the infrastructure

The reason perpetual futures can be transformed from a high-risk speculative instrument into a vehicle for financial inclusion is fundamentally that the on-chain infrastructure on which they run possesses three core properties absent from the traditional financial system: permissionlessness, extremely low barriers, and global accessibility. First, permissionlessness is the most powerful force for breaking down financial exclu-

sion. In traditional finance, know-your-customer (KYC) and anti-money-laundering (AML) requirements—though motivated by the reasonable goal of preventing financial crime—in effect exclude enormous numbers of people. Hundreds of millions worldwide are permanently locked out of the formal financial system because they lack official identification, have no fixed address, or have a blank credit history. The execution logic of smart contracts on decentralized exchanges contains no conditional test of a user's identity attributes; they verify only cryptographic signatures and margin adequacy. This architecture, which executes undifferentiated logic for every participant meeting the verification conditions, gives those abandoned by traditional systems an equal right to participate. Under the current legal framework, however, permissionlessly offering leveraged derivatives to the public constitutes a violation in multiple jurisdictions. The Commodity Futures Trading Commission (CFTC) has brought enforcement actions against offshore decentralized protocols such as Ooki DAO, alleging that they offered unregistered derivatives products to U.S. users. This tension between inclusive value and compliance obligation is precisely the concrete mapping of the trilemma analyzed in Section 32.5.2.

Second, on-chain infrastructure lowers the barrier to participation in financial instruments to a level the traditional system cannot reach. On traditional derivatives markets such as the Chicago Mercantile Exchange, participating in futures trading typically requires thousands or even tens of thousands of dollars of initial margin, which necessarily confines the market to institutional investors and high-net-worth individuals. By contrast, because the automated liquidation mechanism of smart contracts eliminates the fixed costs of human intervention and intermediaries, the minimum margin requirement for on-chain perpetual futures can be as low as $1 to $10 (Hyperliquid and other decentralized platforms, for example, allow positions to be opened with single-digit dollar amounts). This micro-level divisibility lets financial instruments precisely fit the actual capital scale of low-income populations in developing countries. A small vendor with only a few dollars of surplus a day can use the most advanced financial derivatives to manage micro-level risk. But the technical minimum threshold does not equal economic accessibility. Take a position with $10 of margin and 10x leverage ($100 notional): a single open-and-close round trip of taker fees plus spread may consume 0.5% to 1% of the margin, and once funding rates are added, the cost efficiency of a very small position is significantly lower than that of a larger one. The gap between technical reachability and economic viability must be assessed with care.

Finally, the global accessibility of on-chain systems eliminates the financial-island effect created by geographic borders. Traditional financial markets are highly fragmented, and the *regulatory pricing islands* discussed in Chapter 18 are commonplace in reality. Residents of different countries can access only the limited products that local financial institutions are willing or permitted to offer. Financial infrastructure deployed on a public blockchain, by contrast, is a single global state machine. As long as there is an internet connection, a farmer in a remote African village and a hedge fund manager on Wall Street access exactly the same liquidity pool and face exactly the same execution logic and transaction costs. This globally unified infrastructure substantially narrows the geographic disparity in the supply of financial services.

32.2.4 The democratization of AI financial advisers

If perpetual futures and on-chain infrastructure solve the problems of the *supply* and *reach* of financial instruments, the introduction of AI agents addresses the core *cognition* and *execution* bottlenecks of financial inclusion. In the traditional wealth-management industry, professional financial-advisory service is an expensive luxury. A qualified private banker able to provide asset allocation, dynamic hedging, tax optimization, and risk management typically serves only high-net-worth individuals with investable assets exceeding $1 million and charges thousands to tens of thousands of dollars a year in advisory and management fees [18]. For the vast majority of ordinary people worldwide, professional financial advice at this level is entirely inaccessible. They can only rely on their own intuition, limited common sense, or unreliable recommendations from social networks to make financial decisions, which often leads to serious consequences.

The intelligence layer of the autonomous finance network is democratizing this expensive professional service through large language models (LLMs) and specialized reinforcement-learning algorithms. An AI financial agent can be regarded as a tireless, emotionless *around-the-clock private banker* with extremely low marginal cost. Consider a small-business owner in Jakarta. She need not understand complex funding-rate mechanisms or implied volatility; she need only state her need to her AI agent in natural language: "Please protect the rupiah I've set aside for next month's inventory purchases from losses caused by dollar appreciation." The AI agent automatically converts these funds into stablecoins, seeks the deepest-liquidity rupiah-to-dollar perpetual futures on the optimal decentralized exchange, computes the precise hedge ratio, executes the trade automatically, and, when market conditions change or the Federal Reserve (Fed) issues an unexpected statement, automatically adjusts the position within the limits allowed by block-confirmation time.

This *AI-as-a-service* model not only lowers the operational threshold; more importantly, it bridges the vast gap in ordinary users' financial literacy. An AI agent can monitor a portfolio's risk exposure in real time and set strict stop-loss logic, preventing users from taking on devastating losses through cognitive bias or emotional loss of control. In traditional finance, risk control is imposed by institutions to protect their own interests; in an autonomous finance network, the AI agent is the user's personal fiduciary, whose sole objective is to maximize the user's utility and control downside risk. By encapsulating complex financial-engineering logic beneath a friendly natural-language interface, AI agents allow the most advanced derivatives instruments to serve safely those with the least financial knowledge—and this is the essence of what technology contributes to financial inclusion. However, behavioral-finance research shows that lowering transaction friction may actually intensify overtrading and erode retail returns (Barber and Odean, 2001 [19]). While a natural-language interface lowers the operational threshold, it may also mask the complexity of the underlying derivatives position: when a user issues a simple hedging instruction, the user may not understand that they are opening a leveraged perpetual futures position that carries liquidation risk. Moreover, AI agents at present bear no fiduciary duty and are subject to no regulatory accountability, and when a strategy recommended by an AI leads to a margin call or blow-up, how responsibility is allocated among the user, the developer, and the protocol remains an unresolved legal question.

The foregoing analysis shows that the path to realizing financial inclusion involves three progressive layers—identifying genuine demand, matching technical tools, and responding to structural constraints (Figure 32-2).

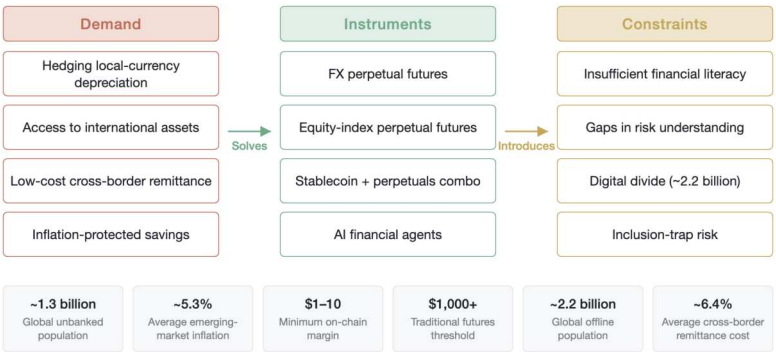

Figure 32-2. An analytical framework for financial inclusion: demand, tools, and constraints (The figure is organized in three columns—demand, tools, and constraints; the left column lists three categories of core pain points, namely foreign-exchange risk, inflation erosion, and cross-border remittance costs, each broken down into specific items that map respectively to the tool solutions in the middle column and the structural constraints in the right column; the framework structure is a theoretical derivation of this chapter; the empirical anchors at the bottom of the figure have been updated to the latest verifiable values: the global unbanked population is approximately 1.3 billion, per the 2025 edition of the World Bank's Global Findex Database, survey year 2024 [2][3]; average inflation in emerging markets and developing economies is approximately 5.3%, per the IMF's October 2025 World Economic Outlook projection, whereas the approximately 8% cited in the main text is the 2024 realized value, the two being different measures; the global offline population is approximately 2.2 billion, per the International Telecommunication Union's Facts and Figures 2025 [7]; the average cost of cross-border remittances is approximately 6.4%, per the World Bank's Remittance Prices Worldwide for the third quarter of 2025, with a global mean of 6.36%; the on-chain minimum margin of approximately $1 to $10 and the traditional-futures threshold of more than $1,000 are product facts, detailed in Section 32.2.3; empirical data as of June 2026)

32.2.5 Real constraints

Yet the analysis of the preceding 31 chapters has repeatedly shown that any leap in technological paradigm comes with irreducible costs. As we celebrate the inclusive vision that the three-layer stack brings, we must remain soberly realistic and confront the real constraints that impede this vision. These constraints are not temporary technical problems but structural features of inclusive finance itself.

The first is the fundamental deficiency of financial literacy and risk understanding. Although AI agents can assist decision-making to a large degree, the ultimate bearer of risk is still the user. Perpetual futures are in essence a leveraged derivative; while they can effectively hedge foreign-exchange or inflation risk, they also introduce entirely new liquidation risk, smart-contract-vulnerability risk, and oracle-failure risk. For the user, the nature of the risk has shifted, but the total quantity of risk has not necessarily decreased. This is the concrete manifestation, within inclusive finance, of the distinction between *risk transfer* and *risk elimination* discussed in Chapter 25. If a user who wholly lacks financial common sense blindly participates in highly leveraged trading

merely because the barrier to entry has fallen, then this *inclusion* is in essence the exposure of users who lack risk-management capacity to higher leverage risk. In fact, the constraint lies not only in the absence of financial literacy. Behavioral-finance research shows that even sophisticated investors with professional knowledge systematically exhibit overconfidence and loss aversion, which makes derivatives products fundamentally at odds with the human cognitive architecture rather than merely a knowledge gap that education can bridge. Not only does it fail to improve users' economic circumstances; it can accelerate the destruction of their wealth. This phenomenon has many precedents in financial history. In the 2008 subprime mortgage crisis, many low-income American households were encouraged to enter complex mortgage products they did not understand, ultimately leading to mass loss of housing. Similar tragedies have played out repeatedly in microfinance, where many products billed as *inclusive*, but usurious in nature, ultimately drove poor populations into deeper debt traps.

Second, we must confront the harsh digital divide. On-chain finance's *permissionlessness* rests on the implicit premise of *possessing the capacity for digital access*. In the real world, however, technology itself is a powerful barrier to entry. According to data from the International Telecommunication Union (ITU) and the GSMA, a large share of the world's population still lacks access to mobile internet (the ITU estimates that about 2.6 billion people are entirely offline—a 2023 figure since revised down to about 2.2 billion for 2025 [7]; the GSMA estimates that a further 3 billion-plus people fall within mobile-network coverage yet do not use mobile internet, the so-called *usage gap* [8]); they either lack a smartphone or cannot obtain a stable, reliable internet connection. This number even exceeds the size of the world's unbanked population. For those in conditions of extreme poverty and infrastructural scarcity, the most advanced on-chain perpetual futures and AI agents are meaningless. They cannot participate in the autonomous finance network—not for lack of permission, but for lack of the most basic means of technical access. The existence of this digital divide makes the inclusive promise of autonomous finance inherently limited. If the expansion of the autonomous finance network merely gives better investment tools to a middle class that already owns digital devices and internet access, while further marginalizing the bottom 3 billion, then this technological evolution will aggravate rather than alleviate global inequality. This is a disquieting reality but one that must be faced.

Finally, we must be wary of the so-called *inclusion trap*. In financial history, cases of predation in the name of *inclusion* are common, from subprime mortgages to certain usurious forms of microfinance, all of which drove vulnerable groups deeper into debt. If the actual operating result of the autonomous finance network is to draw more retail investors who lack risk tolerance into a complex market they do not understand at all, making them the liquidity counterparties of institutional market makers and high-frequency trading algorithms, then it degenerates into a mechanism for *democratizing risk*—pushing risk downward. This democratization of risk is fundamentally different from financial inclusion. The former spreads the burden of risk evenly across everyone, including those least able to bear it; the latter helps people manage risk better through education, protection, and empowerment. Financial inclusion is by no means simply *lowering barriers to entry*; it must combine *effective tools*, *systematic education*, and *embedded risk control*. The three-layer stack provides powerful tools, but how to build

a supporting system of social education, how to design ethical norms that prevent the technology from being abused, and how to ensure that the most vulnerable groups do not become the system's sacrifice will be the key constraints determining where this vision ultimately leads. These questions cannot be answered by technology itself; they require the deep involvement of society, policymakers, and ethicists.

The real constraints on inclusion show that the accessibility of financial instruments is only half the equation; the other half is whether users can wield these instruments effectively while fully understanding the risks. Even as the three-layer stack lowers barriers to entry, it is also reshaping the way global capital is allocated.

32.3 The globalization of capital-allocation efficiency

Global capital markets are nominally highly interconnected, but at the microstructural level they remain deeply divided by geographic barriers, session limits, and unequal access. Through mechanisms such as synthetic exposure, around-the-clock continuous pricing, and cross-margining, the three-layer stack fundamentally changes how capital crosses these barriers. This section analyzes the concrete manifestations of the current fragmentation of global capital allocation, assesses the efficiency gains of the three-layer stack in eliminating temporal and spatial friction, and asks about the distributional effects of this efficiency dividend: who are the main beneficiaries, and who will bear the costs of creative destruction.

32.3.1 The current fragmentation of capital allocation

The fragmentation of global capital markets is manifested first in entrenched geographic barriers. The financial markets of different countries are strictly separated by legal jurisdictions, clearing systems, and monetary boundaries. An ordinary investor in Jakarta who wishes to buy U.S. technology stocks must clear numerous obstacles, including opening an offshore securities account, converting currency, and paying steep cross-border remittance fees. Conversely, capital in New York seeking to invest in high-yield Indian bonds likewise faces complex qualified-foreign-investor quotas and capital controls. This geographic segregation produces pronounced market segmentation, so that assets with identical risk characteristics may be priced very differently across markets [20].

Beyond geographic barriers, session limits are another important factor behind market fragmentation. Modern economic activity proceeds around the clock, and information is generated continuously in every corner of the globe, yet the trading hours of core capital markets still adhere to an industrial-age timetable. The core trading session of the New York Stock Exchange, for example, is limited to 9:30 a.m. to 4:00 p.m. Eastern Time. Major geopolitical events, corporate earnings releases, or macroeconomic data published outside these 6.5 hours cannot be immediately reflected in prices. This session limit artificially severs the immediate transmission between information and price, producing sharp price gaps at the open [21]. Information not priced in time not only increases market uncertainty but also leaves investors across time zones in a passive position when managing risk.

In terms of access mechanisms, the traditional financial system embeds a deep inequality between institutions and retail investors. Large multinational institutional investors can obtain exposure to almost any market and any asset through global custodian-bank networks, prime brokerage services, and complex derivatives instruments. They enjoy privileged channels that cross geographic and temporal barriers. For the vast majority of retail investors worldwide, however, this capacity for global allocation is out of reach. They are confined to local markets and can only passively accept the inflation risk of their own currency and the systemic risk of a single market. This inequality of access, in essence, reserves the world's best investment opportunities and hedging instruments for groups that already possess a capital advantage [22].

The cost of this fragmentation is high: it directly produces enormous losses in the efficiency of global capital allocation. When capital cannot flow freely and frictionlessly, funds cannot reach the places with the highest expected returns in time. In some emerging markets there may be highly promising innovative firms and high-yield projects whose development is constrained by the absence of channels for global capital injection; meanwhile, in developed economies, large amounts of surplus capital may be able to circulate only among low- or even negative-yielding assets. The fragmentation of global capital allocation not only lowers overall economic productivity but also aggravates the imbalance in wealth distribution.

These three forms of fragmentation—geographic barriers, session limits, and unequal access—together constitute the microstructural basis of the current losses in global capital-allocation efficiency; Figure 32-3 contrasts the current state of fragmentation with the target state after integration by the three-layer stack.

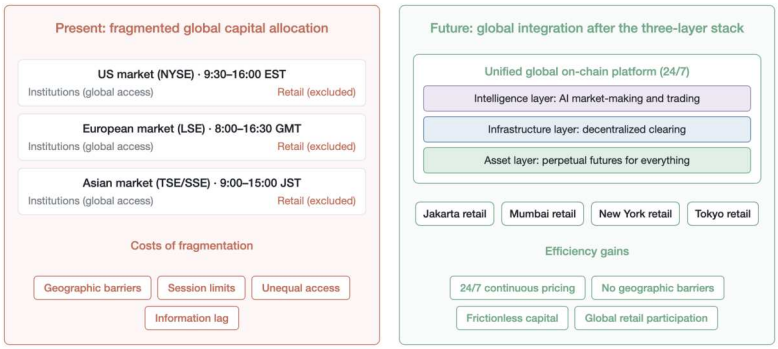

Figure 32-3. Fragmented global capital allocation versus integration by the three-layer stack (Data source: theoretical derivation in this chapter)

32.3.2 Around-the-clock continuous pricing

In an autonomous finance network, session limits are eliminated and replaced by an around-the-clock global continuous-pricing mechanism. As the Tesla-stock simulation in Chapter 27 showed, around-the-clock pricing substantially reduces the magnitude of opening gaps caused by weekend information backlogs. In that thought experiment, a sudden event occurring over the weekend no longer had to wait for the Monday-morning

opening bell; market participants could trade and hedge promptly once information was generated. Existing crypto-market data show, however, that around-the-clock operation does not mean an even distribution of liquidity. Public data show that order-book depth for major trading pairs exhibits a strong diurnal cycle, falling by about 40% during the low-activity hours after the U.S. market close relative to the intraday peak (estimated from public data on single trading-pair samples such as those on Binance); what declines over the weekend, however, is chiefly trading-volume share and the spread, while order-book depth itself does not fall in step. Low-liquidity windows can transform gap risk into thin-market abnormal-volatility risk, and the slippage a stop-loss order experiences in a liquidity vacuum can far exceed expectations. This effect especially threatens retail users in emerging markets, who may trade during the windows of lowest liquidity in the global cycle.

When this mechanism extends from a single asset to all major global assets, the resulting efficiency gain is structural. From U.S. equities to European sovereign bonds to Asian agricultural commodities, all assets trade continuously on a single global platform with no concept of a close. Because trading hours cover all geographic time zones with no market-closed window, the price-discovery process is no longer disturbed by artificially set trading periods. New information generated at any moment—whether macro data from Tokyo, a central-bank decision from London, or a technological breakthrough from Silicon Valley—can be translated into movements in global asset prices with extremely low latency.

This continuous-pricing mechanism reduces the excess volatility that arises in traditional markets from information backlogs. In fragmented markets, unpriced information accumulated during market closures is often released all at once at the instant of the open, causing liquidity to dry up and prices to swing violently. In an around-the-clock market, by contrast, information is digested smoothly and continuously. Investors in different time zones can participate in the market according to their own schedules: Asian investors digest Asian information during their day, and European and American investors take up the relay during their respective active hours. This relay not only provides continuous liquidity but also allows prices to reflect an asset's true fundamentals more accurately [21].

More importantly, continuous pricing eliminates the timing-mismatch risk of cross-market arbitrage. In the traditional system, because different markets' trading hours do not overlap, cross-market hedging often faces enormous execution risk. Attempting to hedge a spot exposure in the U.S. market with a derivative in the Asian market, for example, requires bearing the price-movement risk created by the gap between the two markets' opening times. On a unified around-the-clock platform, by contrast, the prices of all related assets update synchronously, so complex cross-market, cross-asset-class arbitrage and hedging strategies can be executed precisely, further improving the pricing efficiency of global markets.

32.3.3 Frictionless capital flows

Beyond temporal barriers, innovations in the asset and infrastructure layers let the autonomous finance network achieve frictionless global capital flow. The core of this

shift lies in the mechanism of synthetic exposure, and in particular the widespread use of perpetual futures. In the traditional model, by contrast, obtaining the economic return of an asset generally requires physical settlement—that is, actually buying and holding the asset. This transfer of physical ownership comes with cumbersome legal procedures, cross-border settlement delays, custody fees, and foreign-exchange conversion costs [23].

Perpetual futures largely decouple an asset's economic attributes from its physical ownership. An investor in Mumbai who is bullish on the long-term prospects of the U.S. technology sector no longer needs to go through a complex account-opening and currency-purchase process to buy a real Nasdaq index fund. Through perpetual futures built on on-chain infrastructure, the investor need only use stablecoins as margin to obtain price-movement returns identical to those of holding the real stock. In this process, no real stock crosses a border and no cross-border capital flow occurs in the traditional sense, yet the purpose of capital allocation is perfectly achieved. All friction costs—from clearinghouse fees to custodian-bank cuts to the spreads of foreign-exchange market makers—are sharply compressed. This decoupling conceals an extreme-scenario risk not yet fully examined: when the underlying asset's liquidity dries up or the protocol suspends trading in a specific asset, holders of synthetic exposure may find their exit channel closed, trapped in a state of *phantom liquidity* in which a position is nominally liquid but in fact cannot be closed. The 2008 synthetic CDO crisis already demonstrated that the liquidity illusion of synthetic instruments can shatter in an instant under stress.

The cross-margining mechanism of on-chain infrastructure pushes this frictionless flow further still. In a traditional fragmented account system, capital is used very inefficiently. An investor's funds may be scattered across a stock account, a foreign-exchange account, and a commodity-futures account, each of which must independently maintain high margin. Even if the investor holds a large unrealized gain in one account, it cannot be used directly to meet a margin call in another. This siloing of funds forces investors to hold large idle cash buffers. In the unified clearing network built by the three-layer stack, by contrast, the same stablecoin margin can support cross-asset positions at the same account level and, by exploiting negative correlations among assets, lower the overall margin requirement (the mechanism and its quantitative range are detailed in Section 32.1.4), giving the same principal far greater risk exposure and allocation flexibility than an isolated-account system. A structural vulnerability of this unified-margin architecture is single-collateral concentration risk. When all cross-asset positions are denominated in a single stablecoin, collateral value and margin adequacy become perfectly positively correlated. During the March 2023 episode in which USDC depegged to \$0.87, a cross-margining system denominated purely in USDC would face an approximately 13% decline in the margin adequacy ratio across all positions, triggering cascading liquidations unrelated to the performance of any underlying asset. It is precisely to avoid this concentration risk that traditional prime brokers accept a diversified basket of collateral.

32.3.4 Welfare analysis and distributional effects

When the friction of global capital allocation is minimized and efficiency rises sharply, we must ask: who exactly enjoys this efficiency dividend? Traditional financial innovation has often benefited Wall Street's large institutions first, but the welfare distribution brought by the autonomous finance network presents a strikingly different picture.

The greatest beneficiaries are not the multinational institutions that already occupy the top of the global financial system. For these institutions, complex legal structures, vast compliance teams, and expensive financial infrastructure have long since established dedicated channels for global capital allocation. For them, the three-layer stack merely lowers marginal transaction costs rather than providing a capability from scratch. Those who gain an enormous welfare improvement are the groups long excluded from global capital markets, especially retail investors and small and medium-sized enterprises in emerging markets [24]—as noted in Section 32.2.1, the roughly 1.3 billion unbanked people worldwide are concentrated primarily in developing countries.

For these groups, the autonomous finance network provides global access previously unavailable. In the past, they were trapped in their countries' fragile financial systems, forced to bear the twin blows of hyperinflation and currency depreciation yet unable to hedge effectively. Now, with only an internet-connected smartphone, they can obtain exposure to the world's best assets at an extremely low threshold, or use foreign-exchange hedging instruments once affordable only to multinational corporations. This equalization of access not only protects their wealth from the erosion of a local economic crisis but also, for the first time, gives them a chance to share in the dividends of global economic growth. This shift—from a privilege of the rich to a tool for everyone—is the core embodiment of financial inclusion at the level of capital allocation (the optimistic assessment in this section remains subject to the threefold constraints of financial literacy, the digital divide, and regulatory adaptation discussed in Section 32.7; the greatest beneficiaries are more likely to be middle-income groups that already possess digital access and financial awareness, rather than the most financially excluded at the very bottom).

Any major technological and institutional change, however, comes with creative destruction, and the rise of the autonomous finance network is no exception. The rise in efficiency and the elimination of friction will inevitably deal a heavy blow to the intermediaries of the traditional financial system. In a fragmented global market, vast profits arise precisely from these frictions. Cross-border remittance companies survive on steep fees, global custodian banks extract rents through complex settlement networks, and foreign-exchange market makers earn rich spreads in opaque quotes. Once the three-layer stack automates and makes transparent these functions through code and algorithms, the business models of these traditional intermediaries will face an existential challenge. Moreover, synthetic exposure that functionally bypasses capital controls may provoke a defensive reaction at the sovereign level. Countries that maintain capital-account controls may respond by banning stablecoin transactions or blocking on-chain financial infrastructure, which would nullify the inclusive gains their citizens should in theory receive. Welfare analysis must therefore incorporate a key variable: the very efficiency gains described in this chapter are highly likely to provoke

offsetting regulatory countermeasures.

This distributional effect reveals an inherent tension in the development of the autonomous finance network. On one hand, by raising the efficiency of global capital allocation, it creates enormous consumer surplus for the broad population of emerging-market users; on the other, it ruthlessly eliminates the rents earned by traditional financial intermediaries. The transition to this new paradigm is therefore bound to be far from smooth and will face fierce resistance from vested interests. Over a longer horizon, however, the tendency of technological progress to drive down transaction costs and raise capital-allocation efficiency has powerful momentum. When capital is no longer constrained by geographic and institutional barriers and can move to where expected returns are highest, the way the global economy operates will change profoundly.

Frictionless capital flow, however, means that panic, error, and liquidation can likewise propagate across borders with extremely low latency. Systemic risk has not disappeared; it has shifted from the balance sheets of centralized institutions into the topology and algorithmic logic of a decentralized network.

32.4 New systemic risks

Even as the three-layer stack eliminates traditional financial friction, it also removes the function of that friction as a risk buffer, thereby giving rise to entirely new forms of systemic risk. When all assets are interlinked through cross-margining, millions of AI agents share homogeneous strategies, and the oracle becomes the single data interface for the entire system, the global propagation of a local shock is measured in milliseconds. Starting from a globalized version of the reflexivity triangle, this section examines the global flash-crash risk induced by AI-strategy homogenization, the fragility of the oracle as a critical single point of failure, and the challenge that the new paradigm of *too interconnected to fail* poses to the theory of financial stability.

32.4.1 The globalization of the reflexivity triangle

In Chapter 20 we examined the reflexivity triangle operating within a single exchange or a single asset: a price decline raises volatility, higher volatility forces market makers and traders to reduce leverage, and the forced liquidations of the deleveraging process further depress the price. This positive-feedback loop is the microstructural basis of the extreme conditions that occur frequently in crypto markets. When all assets are interlinked through on-chain infrastructure, however, the transmission range of this reflexivity triangle undergoes a qualitative jump, expanding from *a single exchange* to *all markets worldwide*.

In the traditional financial system, natural firewalls exist between asset classes and geographic markets. Although sharp volatility in the U.S. stock market affects global sentiment, the isolation of settlement systems, differences in time zones, and the constraints of capital controls mean this effect typically takes several days to transmit fully to emerging-market foreign-exchange or commodity markets. In the three-layer stack of autonomous world finance, these physical and institutional frictions are wholly eliminated. More critically, if the on-chain system implements the global cross-margining

mechanism described in Chapter 29, the liquidation of one asset propagates instantly to all others through margin linkages.

Imagine a scenario: the local currency of an emerging-market country suffers a sudden depreciation, leaving many small-business owners who use foreign-exchange perpetual futures to hedge facing margin calls. Because these users hold global cross-margin accounts, the system automatically liquidates the other assets they hold to cover the losses on the FX position. This cross-asset passive selling drives down the prices of U.S. equity indices and gold, in turn triggering liquidations for other investors who hold only those assets. In this process, the surge in volatility prompts AI market makers worldwide to widen spreads or withdraw liquidity simultaneously, so that an originally tiny sell order inflicts an enormous price impact. The funding-rate mechanism unique to perpetual futures further amplifies this cascade: when crowded longs push the funding rate to an extreme level, the holding cost for longs rises sharply, forcing more longs to close out and exit, thereby forming a positive-feedback loop of *funding rate* $\rightarrow$ *holding cost* $\rightarrow$ *forced liquidation*—an amplification channel unique to perpetual futures that does not exist in traditional margin cascades. This is the ultimate, amplified version of the cross-dimensional contagion of Chapter 20: a global liquidation cascade. In such a state, no asset is a safe harbor, because the liquidity pools of all assets are interconnected on the same underlying infrastructure. This interconnection amplifies a minor tremor in a local market into a global systemic crisis whose destructive power far exceeds the contagion effects of traditional financial crises [25]. The equilibrium model for clearing obligations in networked financial systems established by Eisenberg and Noe (2001) [26] provides a starting framework for understanding this contagion mechanism, but its core assumptions (a known, fixed network topology and synchronous clearing) differ fundamentally from the on-chain perpetual futures ecosystem. On-chain systems have a dynamic, permissionless topology (new interconnections can appear at any time without central visibility), block-by-block asynchronous clearing (the clearing order is determined dynamically by MEV auctions), and a first-come-first-served rather than pro-rata loss-allocation mechanism. The E&N model therefore requires substantial theoretical extension along three dimensions—topological dynamism, asynchronous clearing, and loss-allocation rules—before it can apply to contagion analysis in a DeFi environment.

The pioneers of reflexivity theory long ago warned that financial markets do not always tend toward equilibrium but often fall into self-reinforcing states of disequilibrium. In traditional isolated markets, such a state of disequilibrium eventually ends when funds are exhausted or external intervention arrives. But in a globally interconnected autonomous finance network, although the depth and breadth of the capital pool increase, the paths of contagion also become infinitely many. The collapse of one asset is no longer an isolated event but becomes the starting node that triggers a chain of liquidations. This networked reflexivity makes the system appear highly resilient and efficient in normal times, yet under stress it may exhibit systemic fragility.

The foregoing scenario analysis shows that the contagion path of the reflexivity triangle in a globally interconnected environment is far more complex than in a single market: the three links of price decline, volatility surge, and liquidity withdrawal are no longer confined to a single asset or a single exchange but unfold synchronously across all asset

classes and geographic markets through the multilateral linkages of cross-margining (Figure 32-4).

32.4.2 A global AI flash crash

Chapter 31 discussed the *strategy-homogenization* risk that arises when AI acts as a market participant. In a globally interconnected financial network, this risk will be amplified exponentially. As large language models and reinforcement-learning algorithms become widespread in finance, we can foresee that the overwhelming majority of autonomous trading agents worldwide will be driven by base models supplied by a few top technology companies. This means that although these agents serve different clients and have different risk preferences, the underlying logic by which they process information, assess risk, and execute trades will be highly similar.

If AI market-making agents worldwide use similar strategies, anomalous data or an extreme event in one region could trigger the synchronized reaction of AI agents worldwide within milliseconds. Consider the U.S. stock market *flash crash* of May 6, 2010, when high-frequency trading algorithms collectively withdrew liquidity in the face of uncertainty: the Dow Jones Industrial Average plunged 998.5 points (approximately 9%) intraday, of which, within about five minutes (2:42 to 2:47 p.m.), it fell nearly 600 additional points on top of the earlier decline, bringing the cumulative peak-to-trough drop for the day close to 1,000 points, before recovering most of that decline within about 20 minutes (by 3:07 p.m.) [27]. That event was confined to the U.S. stock market alone and was caused mainly by simple rule engines rather than advanced AI. The fundamental driver of the 2010 flash crash, however, was microstructure fragility—a single large sell order triggering a liquidity vacuum—rather than strategy homogenization. For the risk of an AI-driven synchronized crash, a more apt historical precedent is the 2007 quant factor crisis, in which strategy crowding among quantitative hedge funds produced synchronized position reversals and a liquidity spiral. Even imposing a mandatory *algorithmic diversity* requirement cannot fundamentally eliminate the herding effect, because all AI agents are trained on the same historical data, observe the

same on-chain signals (which are transparent by design), and optimize the same objective function. Herding is an emergent property of a shared information environment, not merely a technical flaw stemming from a shared code base. In autonomous world finance, the destructive power of a *global AI flash crash* would far exceed that of 2010.

In an extreme scenario, when a piece of breaking news is fed into the global agent network, a large number of AI agents may reach the conclusion *reduce risk exposure* within the same millisecond. They would simultaneously cancel buy orders and issue sell orders, driving the liquidity of all major global assets to zero in an instant. Because the matching speed of on-chain transactions is limited only by the blockchain's block-generation time and network latency, such a flash crash might last only seconds. Yet within those few seconds, the liquidity vacuum could cause prices to deviate sharply, triggering the liquidation logic hard-coded into smart contracts. Human traders would not even have time to understand what was happening, let alone intervene. By the time the system finally returns to equilibrium, the transfer and destruction of wealth are often already irreversible.

This machine-driven panic lays bare the fragility of market microstructure. The high-frequency trading arms race analyzed by Budish et al. (2015) [28] takes on a new dimension in the era of AI agents: when competition shifts from a millisecond-level speed advantage to the homogenization of model architecture and training data, the source of systemic risk shifts from the technical failure of an individual institution to the collective behavior pattern of the entire agent population. More worrying still, modern AI models are typically *black boxes* whose decision processes are hard for humans to understand fully. After a *global AI flash crash*, post-hoc analysis might take months, and identifying the exact trigger might become impossible. This lack of explainability further undermines the confidence of market participants, making the system's post-crisis recovery even more difficult. To address this risk, future autonomous finance systems may need to introduce *algorithmic diversity* requirements or distributed circuit-breaker mechanisms—but these would inevitably sacrifice a portion of efficiency.

32.4.3 Oracle single-point-of-failure risk

When we examined *perpetual futures on everything* in Chapter 27, we noted that the oracle is the sole bridge connecting off-chain real-world data to on-chain smart contracts. In a globally interconnected financial network, this *oracle problem* will evolve from a local technical challenge into a critical single point of failure for the entire system. The traditional financial system relies on distributed price-discovery and settlement networks: if the New York Stock Exchange's data feed fails, the Chicago Mercantile Exchange or the London Metal Exchange can continue to operate. In an on-chain perpetual futures system, however, if a widely used oracle network is attacked or fails, the consequences will be severe.

Suppose an oracle network that provides price feeds for trillions of dollars of assets worldwide broadcasts an erroneous price to the chain because of a software bug or a failure of its economic-incentive mechanism. In a traditional market, such an obviously erroneous trade would be caught and canceled by the exchange's human monitoring team. But in the on-chain world where code is law, smart contracts trust the oracle's

data unconditionally. This erroneous price would immediately trigger erroneous liquidations of all perpetual futures that depend on the oracle. Because of the global cross-margining mechanism described earlier, these erroneous liquidations would set off real chains of blow-ups, turning a data error into a genuine systemic collapse.

Although the industry is working to reduce this risk through multi-source oracles, decentralized oracle networks, and cryptographic-verification techniques based on zero-knowledge proofs, these measures can only mitigate the problem, not eliminate it [29]. Multi-source oracles may provide false redundancy: if most price sources share upstream dependencies (the majority of feeds ultimately derive from the same three or four centralized exchanges), then multi-source aggregation does not genuinely diversify risk. Moreover, oracle extractable value (OEV) creates a structural economic incentive for validators or MEV searchers to profit from liquidation events by manipulating the timing of oracle updates. As long as an on-chain system must rely on external data to execute financial contracts, the oracle will always be the weak link that can trigger a system-wide catastrophe. The potential payoff from hacking an oracle grows geometrically as the on-chain financial network expands in scale, which will attract the world's most capable malicious actors to search for every tiny vulnerability in the system. This asymmetric attack-defense game makes oracle security a persistent structural risk facing autonomous finance systems.

At a deeper level, oracles are not merely conduits that relay data; they in fact perform a function of *adjudicating truth*. When a dispute arises in the real world (for example, when the definition of an asset diverges or an exchange suspends trading under extreme conditions), the oracle must decide what data to broadcast to the chain. This adjudicative power often lacks sufficient transparency and accountability in decentralized systems. If the governance of an oracle network is controlled by a few interest groups, they could manipulate price feeds to reap enormous profits in on-chain derivatives markets. Oracle risk is therefore not merely technical but also political and economic.

32.4.4 Too interconnected to fail

Network effects are deeply double-edged. A globally interconnected autonomous finance network creates extremely high efficiency by eliminating intermediaries and geographic barriers, but it also creates the systemic fragility of *too interconnected to fail*. In the 2008 global financial crisis, the core dilemma regulators faced was *too big to fail*: the balance sheets of a few giant financial institutions were so large that their collapse would destroy the entire credit system. In autonomous world finance, the form of risk has shifted: an individual node may not be large, but because of the system's high interconnection, the failure of any single node may propagate instantly to all others.

This interconnection is manifested at multiple levels: cross-margining at the asset level, shared liquidity pools at the infrastructure level, and strategy homogenization at the intelligence level. When these levels interweave, the system's complexity exceeds the comprehension of any single participant or regulator. The *immediacy* and *around-the-clock continuity* of on-chain systems further worsen this problem. Traditional financial markets provide *cooling-off periods* through market closures and weekends, giving participants time to digest information, raise capital, and coordinate rescues. A global

network that never closes strips away this precious buffer.

When a crisis occurs, transmission speed is measured in milliseconds and seconds, and the window for human intervention is extremely compressed or eliminated altogether. We have built a financial machine more efficient and more inclusive than ever before, but it is also a machine that by design lacks the traditional physical damping. How to establish a new *shock-absorption mechanism* in a global network with no centralized intervener, no market closures, and driven entirely by code and algorithms will be a core challenge of the autonomous finance era. This shift in systemic risk requires us to rethink the definition of financial stability, moving from a focus on the health of a single institution to a focus on the resilience of the entire network topology.

Under the *too interconnected to fail* paradigm, traditional regulatory tools (such as capital-adequacy requirements or stress tests) may no longer apply, because these tools are typically based on static balance-sheet snapshots and cannot capture the complex nonlinear interactions of a high-frequency dynamic network. In the on-chain perpetual futures ecosystem, the risk nodes with high centrality are already clearly identifiable: core oracle networks (such as a few Chainlink/Pyth data sources), cross-chain-bridge liquidity hubs, and shared market-maker infrastructure. The failure of any one of these high-centrality nodes satisfies the contagion condition of *too interconnected to fail*, and its impact will spread along the network topology to all dependent nodes. Future financial-stability frameworks may need to draw on epidemiology or complex-systems theory, focusing on monitoring the density of connections among network nodes, identifying potential super-spreader nodes, and designing smart-contract circuit breakers that can automatically sever contagion chains when a local crisis erupts. Yet on-chain circuit breakers face a fundamental paradox: when one protocol halts trading while interconnected protocols keep running, the result is not orderly market stabilization but arbitrage dislocations and trapped positions. The governance of circuit-breaker parameters is itself an unresolved problem: DAO governance votes are too slow for millisecond-scale cascades, while protocol admin keys reintroduce the very centralization risk that permissionless design is meant to eliminate. This is an underexplored field, but it is vital to the long-term survival of autonomous finance.

One systemic-risk channel the foregoing analysis has not adequately addressed is the *funding monoculture* of dollar stablecoins. The three-layer stack is denominated in dollar stablecoins throughout, and so it natively inherits the transmission effects of Federal Reserve monetary policy. A rate-hiking cycle raises the opportunity cost of stablecoin capital while compressing the total value locked (TVL) and liquidity across all on-chain venues. Empirically, the most likely trigger of a systemic shock is not a cascade of emerging-market currency crises but a dollar-liquidity squeeze that hits all on-chain markets at once, because they share a single base quote currency. This stablecoin monoculture stands in deep tension with the *sovereign plurality* narrative of Section 32.5.3: a financial system that claims to serve a diverse set of global sovereigns nonetheless depends, at the funding layer, entirely on the monetary policy of a single central bank.

The three risk dimensions analyzed in Sections 32.4.1 through 32.4.3—cross-margining cascades, AI flash crashes, and oracle failures—are not mutually independent events.

If an oracle price deviation triggers a cross-margining cascade while AI market makers synchronously withdraw liquidity upon detecting the price anomaly, the joint activation of the three risk vectors will produce a shock-amplification effect far exceeding the sum of each analyzed independently. This *risk resonance* scenario represents the system's true worst case and is also the extreme scenario a stress-testing framework must cover.

The foregoing analysis of systemic risk reveals a deeper structural problem: the three-layer stack contains three irreducible tensions that must be continuously managed rather than eliminated once and for all by technical means.

Figure 32-5 visualizes these three tensions as three pairs of mutually constraining forces—efficiency versus stability, permissionlessness versus consumer protection, and global integration versus sovereign plurality—and indicates the direction in which each can be addressed: gains in efficiency inevitably bring new fragilities; ZKP credentials can partly reconcile the conflict between permissionlessness and consumer protection but cannot fully eliminate the tension; and in the contest between global integration and sovereign plurality, states choose among embracing, restricting, and vacillating. Section 32.5 develops each of these three trade-offs in turn.

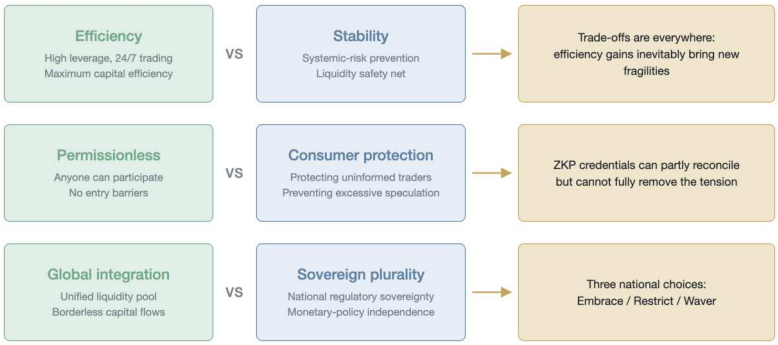

Figure 32-5. The three irreducible tensions in an autonomous finance network (Data source: theoretical derivation in this chapter)

32.5 Three irreducible tensions

The analysis of the two preceding sections shows that the efficiency gains and the systemic risks of the three-layer stack are not independent variables but the two faces of the same set of design choices. This inherent tension can be summarized as three irreducible structural trade-offs: efficiency versus stability, permissionlessness versus consumer protection, and global integration versus sovereign plurality. This section works through the concrete manifestations and amplification mechanisms of each tension in an autonomous finance network, and argues that treating these tensions as fundamental trade-offs requiring continuous management—rather than as engineering defects awaiting repair—is the epistemological premise for understanding autonomous finance.

32.5.1 Efficiency versus stability

The core function of a financial system is capital allocation, and the efficiency of capital allocation is often negatively correlated with the system's stability. In an autonomous finance network, this trade-off can be measured conceptually through two sets of indicators: efficiency indicators (capital-utilization efficiency and price-discovery latency) and stability indicators (tail-risk probability and liquidation-cascade depth), between which a structural negative correlation exists. This chapter offers a conceptual framework for identifying the structure of the trade-off rather than a formal mathematical model; a full formal treatment—such as a constrained optimization linking capital-utilization efficiency to the probability of systemic tail risk—awaits future research. An increase in leverage raises capital-utilization efficiency but necessarily entails a higher probability of liquidation cascades [30]; around-the-clock continuous pricing shortens price-discovery latency but removes the physical circuit-breaking window that traditional markets use to relieve panic. As the global liquidation-cascade mechanism analyzed in Section 32.4.1 shows, cross-asset cross-margining transmits the volatility of a single asset to the entire network. The crypto-market liquidation storm of October 2025—in which more than $19 billion in leveraged positions were forcibly liquidated within roughly 24 hours, the largest single-day liquidation on record (this is measured as liquidation volume, distinct from the contraction in open interest over the same period)—validated this transmission path [31]. The AI-strategy-homogenization risk analyzed in Section 32.4.2 further intensifies this tension: when large numbers of agents adopt homogeneous strategies, their synchronized reaction patterns amplify market volatility to the scale of a millisecond-level flash crash [32][33]. Every gain in efficiency accumulates deeper fragility in the system's foundations; this trade-off is a structural constraint of financial systems that cannot be circumvented by a more advanced technical architecture.

32.5.2 Permissionlessness versus consumer protection

Permissionless participation is the cornerstone of decentralized finance, but an irreconcilable tension exists between full permissionlessness and adequate consumer protection. This tension can be formalized as a trilemma: fully permissionless access, adequate consumer protection, and a deep liquidity network—at most two of which can be satisfied simultaneously. Abandoning access restrictions exposes participants who lack financial literacy to risks they cannot assess (the structural constraint analyzed in Section 32.2.5) [34][35]; imposing access screening reintroduces centralized gatekeepers and excludes the very marginalized populations who need these tools; and abandoning the first two in pursuit of liquidity alone produces an unregulated, highly leveraged casino. This structure is isomorphic to the Mundell-Fleming trilemma in international finance [36]: just as a country cannot simultaneously achieve free capital flows, an independent monetary policy, and a fixed exchange rate, an autonomous finance network cannot simultaneously maximize openness of access, user protection, and market depth. Zero-knowledge-proof compliance credentials mitigate this conflict to some degree by lowering the cost of compliance enforcement [37], but proving that one meets the conditions is itself a permissioning mechanism. As long as the system needs to distinguish participants' eligibility, this structural tension will not disappear.

32.5.3 Global integration versus sovereign plurality

A fundamental conflict exists between the borderlessness of the autonomous finance network and the territoriality of sovereign states. At the network level, protocol standards on public blockchains and decentralized clearing and settlement connect global capital pools into a single liquidity network [38]; at the sovereign level, states rely on exclusive control over domestic currency issuance, capital flows, and financial institutions to implement monetary policy [39]. When citizens can freely convert their local currency into global stablecoins through the autonomous finance network and participate in on-chain trading, the effectiveness of traditional capital-control tools is substantially weakened. This conflict is driving a divergence of national strategies: some countries choose to embrace, obtaining the dividends of innovation by offering a friendly regulatory environment and exploring central bank digital currencies (CBDCs); some choose to isolate, seeking to exclude on-chain finance from the national economic system; and more countries seek a conditional balance between access to global liquidity and the preservation of policy independence. This divergence is not a temporary policy disagreement but the inevitable projection of the structural conflict between the network's global integration and the territorial exclusivity of sovereignty, and it will continue to shape the evolution of the international financial system. The dominance of USD stablecoins, moreover, grants the United States de facto extraterritorial regulatory authority over the entire on-chain financial system. Binance's $4.3 billion settlement and the sanctions against Tornado Cash show that even citizens of countries pursuing an *embrace* strategy remain subject to major-power enforcement jurisdiction when their transactions involve USD stablecoins, which makes the independence of all three strategies far more limited than it appears.

32.5.4 The epistemology of tension management

A mature theory of financial microstructure requires the recognition that the three tensions above represent fundamental trade-offs, not system bugs awaiting repair. Efficiency versus stability, permissionlessness versus consumer protection, and global integration versus sovereign plurality—these three pairs of opposites constitute the boundary conditions of the autonomous finance network. Different jurisdictions and groups of market participants will position themselves differently within these trade-offs according to their own value orientations: developed economies tend to sacrifice some efficiency in exchange for systemic stability, while emerging markets are more willing to bear volatility risk in exchange for access to global capital and the inclusiveness of financial instruments. This diversity is the inevitable projection of pluralistic values within a complex system. Recognizing that these trade-offs are irreducible marks a cognitive shift from techno-utopianism to realist financial engineering.

The maturity of the three-layer stack lies not in eliminating these contradictions but in establishing mechanisms with sufficient resilience to maintain a dynamic equilibrium within these long-term structural tensions. This equilibrium is continually recalibrated as technology evolves, market cycles turn, and the geopolitical environment shifts.

Under the constraint of the three tensions, the future of autonomous finance is not a fixed endgame but a complex adaptive system that requires continuous design and

adjustment.

32.6 From vision to roadmap

Granting the premise of three irreducible tensions, the evolutionary path of autonomous finance is not unpredictable. Depending on different combinations of regulatory attitude, technological maturity, and the speed of market adoption, one can sketch three sharply different scenarios: gradual convergence, dual-track coexistence, and disruptive substitution. This section analyzes the driving conditions and possible outcomes of each path, identifies the key uncertainty variables that will determine the ultimate direction, and proposes *responsible optimism* as a basic stance for coping with these uncertainties.

32.6.1 Evolutionary paths

In examining the future of autonomous finance, we cannot give a deterministic timetable or a single endgame form. These three paths are not mutually exclusive; they may play out simultaneously in different jurisdictions or across different asset classes.

Path one is gradual convergence. Along this path, the boundary between traditional finance and on-chain finance gradually blurs, ultimately forming a hybrid global financial ecosystem. Large traditional financial institutions begin to recognize the enormous advantages of on-chain infrastructure in clearing-and-settlement efficiency, capital allocation, and around-the-clock trading, and progressively adopt these technologies. They may first pilot on-chain clearing engines in internal operations or specific B2B scenarios, then extend them to customer-facing businesses. At the same time, the regulatory framework gradually adapts, introducing privacy-preserving technologies such as zero-knowledge proofs to preserve a degree of permissionlessness while satisfying anti-money-laundering and know-your-customer requirements. In this scenario, the three-layer stack of autonomous finance (the asset layer, the infrastructure layer, and the intelligence layer) is absorbed and reshaped by the traditional financial system, becoming a new engine for raising global financial efficiency. The winners along this path include both large institutions that actively embrace innovation and emerging-market retail investors who receive better service through financial inclusion.

Path two is dual-track coexistence. In this scenario, on-chain finance and traditional finance coexist over the long term but remain relatively independent, serving different user groups and needs. Because of divergent regulatory policies and the difficulty of unifying technical standards, a clear barrier forms between the two financial systems. The traditional financial system continues to dominate mortgages, corporate financing, and large-scale asset management, while on-chain finance dominates crypto-native assets, high-frequency trading, and parts of emerging markets. This dual-track state produces a degree of market segmentation, and capital-allocation efficiency fails to reach its maximum. It also, however, provides a parallel financial network for the users excluded by the traditional system (such as the billions of unbanked people worldwide). In this parallel world, AI agents autonomously make markets and trade, and permissionless smart contracts manage perpetual futures on a variety of synthetic assets. This state

may persist for decades, until one side achieves a decisive breakthrough in technology or regulation.

Path three is disruptive substitution. In certain specific niche markets, on-chain finance, by virtue of its overwhelming advantages in efficiency and cost, achieves disruptive substitution of traditional finance. In derivatives trading, for example, on-chain perpetual futures—by virtue of around-the-clock continuous pricing, frictionless global capital flow, and cross-margining—rapidly absorb global liquidity, forcing traditional derivatives exchanges to the margins. In cross-border payments and remittances, solutions based on stablecoins and on-chain clearing sharply compress transaction costs, disrupting traditional correspondent-banking networks and remittance companies. In fields such as mortgages and large corporate financing, however—which depend heavily on offline credit assessment and complex legal enforcement—traditional finance retains an unshakable position. The evolution of this path is often accompanied by violent market turbulence and regulatory conflict; traditional financial institutions and vested interests may resist fiercely, but ultimately they must accept the reality that part of the market has been disrupted.

Each of these three paths corresponds to a different regulation-technology-market combination, and its ultimate direction is not predetermined but depends on how key variables actually evolve. Table 32-2 offers a structured comparison of the driving conditions, primary beneficiaries, and core risk of the three paths, providing a reference for assessing investment strategies and policy choices under different scenarios.

Path	Driving conditions	Primary beneficiaries	Core risk
Gradual convergence	Strong regulatory adaptability, active institutional adoption	Large institutions that embrace innovation, and emerging-market retail investors	Pace of innovation constrained by the pace of regulation
Dual-track coexistence	Regulatory divergence, difficulty unifying technical standards	The unbanked excluded by the traditional system	Market fragmentation leaves capital-allocation efficiency below its maximum
Disruptive substitution	Overwhelming on-chain efficiency advantage, breakthroughs in specific niche markets	Derivatives and cross-border-payment users	Severe market turbulence and resistance from incumbents

32.6.2 Key uncertainties

Whichever path autonomous finance ultimately follows, its progress is deeply affected by several key uncertainties. These uncertainties constitute the blind spots in our predictions of the future and are also the variables we must focus on when building autonomous finance systems.

Regulation is among the most decisive of these uncertainties. A fundamental conflict exists between the global, borderless nature of autonomous finance and the sovereignty-based regulatory frameworks of traditional finance. The attitudes of different countries and regions toward on-chain finance will determine its room for development. Some countries may adopt an innovation-embracing attitude, seeking to attract capital and technology by establishing adaptive regulatory sandboxes; others may, out of concern for safeguarding financial sovereignty and preventing systemic risk, adopt severe restrictions or even outright bans. The vacillation or sudden reversal of regulatory policy can change the liquidity distribution and market structure of on-chain finance in an instant. How to find a balance point within the tensions of *permissionlessness* versus *consumer protection* and *global integration* versus *sovereign plurality* is an enormous challenge facing regulators.

Technological maturity is a second decisive variable. Although the three-layer stack of autonomous finance is conceptually relatively complete, in actual engineering it still faces many technical bottlenecks. The application of zero-knowledge-proof technology in embedded compliance remains at an early stage, and its computational efficiency and cost have not yet reached the requirements for large-scale commercial use. Cross-chain interoperability is still a fragile link; security vulnerabilities in cross-chain bridges have repeatedly caused enormous losses of funds, severely damaging market confidence. In addition, the widespread application of AI in finance brings the challenge of explainability. When millions of AI agents autonomously conduct high-frequency trading in a global network, the logic of their behavior is often a black box. Once a *global AI flash crash* occurs, it is difficult to trace its root cause quickly and take effective intervention measures. The pace at which these technical problems are solved will directly determine the speed at which autonomous finance matures.

The speed of market adoption and the tipping point of network effects are another key factor. The core value of a financial network lies in its liquidity, and liquidity in turn depends heavily on network effects. If on-chain finance cannot cross the adoption tipping point within a reasonable time and attract enough institutional capital and retail participation, it may remain forever at the margin of a niche market. Conversely, once this tipping point is crossed, network effects amplify exponentially, accelerating its substitution for or convergence with traditional finance. This adoption speed is not linear, however; it may be constrained by user habits, education costs, and switching costs. As noted earlier, pushing users who lack risk-management capacity into highly leveraged markets is not inclusion but a transfer of risk. If users lack the financial literacy needed to understand the risks of on-chain finance, then an overly rapid pace of adoption may instead cause large-scale wealth losses, provoking a social backlash and forceful regulatory intervention.

Finally, black swan events may become catalysts that either accelerate or impede the development of autonomous finance. The next major global financial crisis could expose the fragility of the traditional financial system, prompting a turn toward a more transparent, decentralized on-chain financial system; but by the same token, if the crisis is triggered by the systemic risks of on-chain finance (such as a global liquidation cascade caused by an oracle failure), it could destroy public trust in the new paradigm and set its development back by decades. The unpredictability of black swan events requires that, when designing autonomous finance systems, we treat antifragility as one of the core principles.

32.6.3 Responsible optimism

In the face of the evolutionary paths and key uncertainties above, this chapter takes the stance of *responsible optimism*. The three-layer stack provides new engineering possibilities, but technology itself does not determine outcomes; the same tools can become either an inclusive network or an instrument of regulatory arbitrage. The ultimate direction depends on choices of institutional design: whether education, risk control, and compliance can be embedded in the system's underlying logic determines whether autonomous finance empowers or preys.

Acknowledging systemic risk and irreducible tensions does not mean denying the potential value of autonomous finance. The builders of autonomous finance must seek a conditionally optimal path under the constraint of the three tensions, which requires combining the interdisciplinary wisdom of cryptography, financial engineering, economics, and law. More importantly, the evolutionary details of this complex adaptive system cannot be precisely predicted by anyone, so mechanisms for continuous iteration and agile adjustment are more valuable than a one-time perfect design.

32.7 Chapter summary

Starting from the architectural logic of the three-layer stack, this chapter analyzed the impact of autonomous finance along three dimensions—financial inclusion, global capital allocation, and systemic risk—and identified three irreducible structural tensions:

efficiency versus stability, permissionlessness versus consumer protection, and global integration versus sovereign plurality. Among the three possible evolutionary paths—gradual convergence, dual-track coexistence, and disruptive substitution—the ultimate form realized will depend on the interplay of regulatory attitude, technological maturity, and the speed of market adoption. The core conclusion of this chapter is that the three-layer stack possesses the engineering capacity to raise capital-allocation efficiency and expand the accessibility of financial instruments at the same time, but translating this capacity into genuine inclusion is limited by three constraints: financial literacy, the digital divide, and regulatory adaptation. Until these constraints are adequately addressed, the main beneficiaries of the three-layer stack will be middle-income groups that already possess digital access and basic financial awareness, rather than the most financially excluded at the very bottom. The value of autonomous finance lies not in building a perfect, contradiction-free system but in creating a governance mechanism capable of dynamically seeking the optimum within long-term tensions.

The next chapter turns from this chapter's forward-looking analysis to the theoretical level, systematically drawing together the analysis of the whole book—distilling its core propositions and a spectrum of confidence levels, clarifying unresolved questions and a research agenda, and offering the book's recommended courses of action for different groups of readers.

Summary and Research Outlook

In 2016, Arthur Hayes launched perpetual futures on BitMEX—a derivative contract that strips away the expiration date and uses the funding rate in place of delivery to anchor to the spot price. This design echoed the academic vision of macro-market instruments that Robert Shiller (1993) [1] had proposed, though that original proposal was never implemented in traditional finance. By 2025, nine years later, average daily notional trading volume in perpetual futures had settled in the hundreds of billions of dollars (according to CoinGlass's *2025 Crypto Derivatives Market Annual Report*, average daily notional turnover across crypto derivatives that year was roughly $260 billion, of which perpetual futures accounted for the overwhelming majority) [2]; they contributed more than 60% of the information share in Bitcoin's price discovery [3]; and derivatives turnover ran at roughly 3 times or more that of the corresponding spot market (reaching 5 to 10 times for major coins on a single leading exchange) [2]. This stands in sharp contrast to the early market documented a decade earlier by Makarov and Schoar (2020), which was characterized by cross-exchange spot arbitrage and price dislocations [4]. What began as a design compromise to solve practical problems in crypto trading has become one of the highest-volume categories of financial product in the world, and it is now expanding into foreign-exchange, equity-index, and commodity markets. From the perspective of microstructure theory, what makes this evolution significant is that a synthetic-exposure instrument that removed the constraints of expiry and delivery reshaped, within just a few years, where price discovery occurs, how liquidity is supplied, and how volatility is generated. This fact raises the central question of this chapter: after 33 chapters of systematic analysis of this mechanism and the markets in which it operates, which reliable regularities has the analysis ultimately revealed, and which unresolved problems does it leave behind?

This book takes institutional design as its through-line and begins with the game-theoretic mechanism of the funding rate. The funding rate is not a simple price-correction term but an institutional device that recasts price convergence as a problem of incentive compatibility, letting market participants' self-interested behavior anchor the price spontaneously, without intervention by any central authority. Over nine years of market operation, this mechanism has been tested by repeated episodes of extreme conditions, and its effectiveness has become a high-confidence empirical fact.

In the analysis of liquidity, the market maker's profit equation contains a structural flaw: adverse-selection risk and inventory costs rise in tandem as market volatility intensifies [5], so the production cost of liquidity is positively correlated with demand for it, leaving liquidity scarcest precisely when it is most needed. This countercyclical

fragility is a necessary consequence of profit maximization, not a behavioral bias. Along the volatility dimension, high-leverage liquidation cascades and the periodic pulses of the funding rate—beyond the traditional categories of informational and noise volatility [6]—create an institution-driven source of volatility that is independent of both fundamental information and trader irrationality [7].

Building on this, the book reframes market quality as a trade-off problem across five dimensions—transaction costs, price discovery, resilience, fairness, and accessibility—and argues that this trade-off presents a markedly different priority structure under normal, stressed, and crisis conditions. At the engineering level, trust decomposes into five independent layers: asset custody, matching and execution, clearing and settlement, data feeds, and governance decisions. Each layer can independently seek the optimal balance between trust-minimization and performance (Chapters 28–29). The evolution of artificial intelligence (AI) from a market participant into infrastructure marks a paradigm shift from "code is law" to "model is law." The methodological stance running through the analysis is that institutions determine microstructure, trade-offs are everywhere, and normal and crisis conditions follow different dynamics.

As the culmination of the book, this chapter distills the entire argument into seven core propositions and five cross-cutting themes. It uses a confidence spectrum to distinguish which conclusions have been cross-validated by multiple methods, which are supported only by preliminary evidence, and which remain logical inference or open conjecture, and it explicitly lays out the knowledge gaps and unresolved problems in the current theoretical framework. Beyond this, from the standpoint of disciplinary contribution, the chapter identifies five epistemological legacies that perpetual futures, as an object of analysis, bequeath to the theory of financial microstructure: making the institution-driven source of volatility explicit, a theory of the endogenous fragility of liquidity supply, the engineering of trust, a theory of 24/7 continuous markets, and the economics of synthetic exposure. It then maps out paths forward for researchers, practitioners, regulators, and students. After reading this chapter, the reader will possess a complete cognitive map distinguishing the known, the credible, the speculative, and the unknown, and can turn to Section 33.6 to find the path of action suited to their own role.

33.1 Core propositions

This section sets out the book's seven core propositions. Each proposition states its central conclusion and logical basis, and points to the chapters that support it. Section 33.2 presents the cross-cutting methodological perspective, and Section 33.5 sets out how the book advances the existing literature on financial microstructure.

In essence, perpetual futures are a general-purpose mechanism for generating synthetic exposure, not one confined to crypto assets. Traditional derivatives are constrained by the need for physical delivery and by expiration dates, which slice the time dimension into discrete contract cycles. Perpetual futures strip away both of these constraints and use the funding rate to maintain long-run convergence between the contract price and the spot price, providing traders with pure, open-ended price exposure [7]. This mechanism internalizes physical delivery and storage costs as a dynamic holding fee,

giving market participants synthetic exposure to any continuously priceable asset under a transparent cost structure. Its generality means that, wherever a reliable price-signal source and sufficient liquidity depth exist, perpetual futures can extend to domains such as foreign exchange, commodities, and macroeconomic indicators (Chapters 2–3 and Chapter 27). Contracts for difference (CFDs) and total return swaps in traditional finance likewise provide synthetic exposure, but they are limited by bilateral counterparty risk and finite market depth [8]. Perpetual futures reduce counterparty concentration through on-chain clearing and a multilateral funding-rate mechanism. Nevertheless, the collapse of Terra/LUNA in May 2022 shows that when the anchoring mechanism degenerates from an external spot price into a self-referential, endogenous loop, synthetic exposure can suffer catastrophic depegging. In that episode, the combined market capitalization of LUNA and UST—roughly $40 billion, of which UST accounted for about $18 billion—evaporated within about a week; this is the loss in that ecosystem's market capitalization, which is distinct from the whole-market loss figure the media often cite. The current confinement of perpetual futures to a few dominant asset classes stems more from regulatory constraints, liquidity depth, and path dependence than from the mechanism itself; but, as the depegging case above shows, that mechanism also has its boundaries once the external anchor degenerates into an endogenous loop.

The funding rate is an incentive-compatible device for achieving price anchoring in a decentralized environment, and its design logic is of a piece with the mechanism-design theory of Myerson (1981) [9] and Hurwicz (1972) [10]: in the absence of a central clearinghouse, the funding rate dynamically adjusts the holding costs borne by longs and shorts, so that price convergence emerges from participants' individual profit-maximizing behavior. When the contract trades at a premium, longs pay shorts; when it trades at a discount, the reverse holds, incentivizing arbitrageurs to eliminate price deviations of their own accord. At the same time, this periodic payment mechanism introduces a pulse effect into the microstructure: the mechanical repositioning around settlement times constitutes a source of price volatility independent of information flow. Different participant types respond to the rate in different ways—arbitrageurs are highly sensitive, trend traders relatively insensitive—giving the system a self-regulating capacity that maintains price anchoring without any central decision-maker. Budish et al. (2015) [11], in their analysis of the high-frequency trading arms race, offer a complementary perspective: frequent batch auctions, as an alternative market-design mechanism, likewise aim to achieve a superior market equilibrium by altering the structure of the game (Chapter 10).

Liquidity is not an inherent property that markets possess by nature; it is a scarce resource produced by market makers who bear adverse-selection risk and inventory costs. The market maker's profit equation contains a structural flaw: production cost is positively correlated with market demand [5]. As market volatility intensifies, adverse-selection risk and inventory risk rise together, forcing market makers to widen spreads or withdraw depth, so that the supply of liquidity dries up rapidly at the very peak of demand. This countercyclical fragility is not a behavioral bias on the part of market makers but a structural result of profit maximization under the assumptions of standard market-making models. In crypto markets, which lack a lender of last resort and

circuit-breaker protections, the collective retreat of market makers can readily trigger liquidation cascades and liquidity spirals [12] [13], amplifying a micro shock into a systemic crisis. The "Black Thursday" event of March 12, 2020, is a textbook case of this mechanism: over the two trading days of March 12–13, Bitcoin fell by roughly 50% cumulatively; on BitMEX alone, liquidations during this crash exceeded $700 million (on a broader, roughly 24-hour rolling-window basis, Chapter 12 gives a figure of more than $1.4 billion; the two figures use different statistical conventions), while bid-side order-book depth shrank to about $20 million at the most extreme moment, and liquidity evaporated far faster than participants could replenish it (Chapters 19–21).

Volatility is not a single risk metric but a mixture of four distinct drivers: informational volatility arises from fundamental updates; liquidity volatility arises from insufficient order-book depth; mechanistic volatility arises from liquidation cascades and funding-rate pulses; and transmission volatility arises from the amplification of local shocks by cross-market arbitrage networks [14]. The first two have been studied extensively by traditional microstructure theory; the latter two are products of the institutional design of perpetual futures and are independent of external information shocks [7]. Distinguishing the four sources of volatility bears directly on assessments of market quality and on regulatory decisions: a price move of the same magnitude, if driven by information updates, indicates that the market is efficiently digesting new information; if dominated by liquidation cascades, it points instead to a defect in system design (Chapters 22–24).

Market quality is a five-dimensional composite of transaction costs, price discovery, resilience, fairness, and accessibility, and inherent trade-offs exist among these dimensions [15]. Extremely low transaction costs may sacrifice market resilience, and an absolute insistence on fairness may constrain market-maker participation; no design achieves the optimum on all dimensions at once. These trade-offs are also state-dependent: the priority structure of market quality differs markedly across the three operating states of normal, stressed, and crisis conditions. A design that pursues efficiency under normal conditions may become a source of fragility in a crisis. Robust market design must therefore take the worst-case scenario as its binding constraint, ensuring that the system can still maintain its core functions under extreme shocks (Chapter 25).

Trust can be decomposed into five independent layers: asset custody, matching and execution, clearing and settlement, data feeds, and governance decisions. A traditional centralized exchange concentrates all five layers of trust in a single architecture, which confers a performance advantage but introduces a systemic single-point-of-failure risk. The collapse of FTX in November 2022 confirmed this judgment: roughly $8 billion in client funds was misappropriated under an opaque monolithic architecture, and the concentration of custody, matching, and settlement caused internal controls to fail completely. A fully on-chain model achieves maximal trust-minimization but is constrained by the throughput bottleneck of the blockchain. The theory of layered trust offers a solution that transcends this binary choice: at each layer, one independently seeks the optimal trade-off between trust and performance. For example, the asset-custody layer adopts a maximally trust-minimized on-chain mechanism to safeguard security, while the matching-and-execution layer retains an off-chain engine in pursuit of speed. This approach turns trust from an abstract institutional problem into a configurable

engineering parameter (Chapters 28–29).

AI's role in financial markets is evolving from participant to infrastructure. Early AI applications concentrated on algorithmic trading and high-frequency market making and were, in essence, sophisticated participants extracting value from the market under a given set of rules. As model capabilities have advanced, AI has begun to take on system-level functions such as dynamically adjusting margin parameters and parsing unstructured data, marking a paradigm shift from "code is law" to "model is law." The contribution of algorithmic trading to market price discovery already rests on a solid empirical footing [16]; building on this, AI further gives the system an adaptive, dynamic responsiveness that lets it optimize operating parameters in real time across a multidimensional state space. However, homogeneous models may, under certain conditions, trigger decision resonance and create a novel type of liquidity crisis. How to guard against AI-driven endogenous fragility while improving efficiency is a central question for the next generation of microstructure design (Chapter 31).

33.2 Theoretical threads running through the book

The seven core propositions are the book's explicit conclusions. Beneath them, five methodological threads run through the analysis across the book's eleven parts. These threads are not answers to any particular phenomenon but recurring analytical perspectives and epistemological stances that constitute the book's underlying logical framework.

Traditional microstructure theory treats market institutions as exogenous variables and analyzes price discovery and market-making behavior under a given set of rules. The book's first methodological thread treats the institution itself as an endogenous variable: the core microstructure features of perpetual futures markets can all be traced back to the underlying institutional design. The high-leverage margin regime endogenously creates mechanistic volatility (Proposition 33.1.4); the periodic settlement of the funding rate produces price pulses independent of information flow (Proposition 33.1.2); the absence of an expiration date removes the friction of contract rollovers but also removes the deadline for natural convergence; and around-the-clock trading eliminates overnight risk accumulation but also strips away the shock-absorber effect of traditional markets. Institutions are not the backdrop of the analysis but the first cause that shapes the form of the market.

This perspective offers direct guidance for policy and design. The effective way to change a microstructure phenomenon is not investor education or another layer of external regulation but a change in the very institutional design that produces it. The institutional-shaping effect remains strong across all parts of the book and peaks in Part 3 (the funding-rate mechanism). In evaluating any financial innovation, the first question is not its functional features but how its institutional framework alters the incentive structure of participants.

There is no cost-free efficiency improvement in financial markets. The book's second thread reveals the universality of trade-offs: high leverage lowers the cost of capital while amplifying systemic fragility (Propositions 33.1.3 and 33.1.4); market-maker priv-

ileges enhance liquidity but sacrifice fairness (Proposition 33.1.5); the permissionless principle improves accessibility but increases the risk of abuse; physical and logical boundaries exist between trust-minimization and performance-maximization (Proposition 33.1.6); and the rigid enforcement of compliance stands in tension with the flexibility needed for crisis response. These trade-offs are not design flaws but intrinsic features of a multi-objective optimization problem.

Acknowledging the universality of trade-offs is a design philosophy, not a pessimistic judgment about the evolution of markets. Effective system design does not seek to eliminate trade-offs but to find, under given constraints, the current optimal position on the Pareto frontier, while recognizing that this position moves dynamically as technological conditions and the regulatory environment change. The strength of this thread rises in the later parts and peaks in Part 8 (market quality): as the analysis shifts from single-dimension optimization to holistic assessment, trade-offs become the central issue.

The normal market and the crisis market operate on different logics and cannot be explained within a single unified theoretical framework. This thread ties together several of the book's propositions: liquidity is abundant under normal conditions but evaporates in a crisis (Proposition 33.1.3); volatility is predominantly informational under normal conditions but is taken over by mechanistic factors in a crisis (Proposition 33.1.4); and the priorities of market quality flip fundamentally across states (Proposition 33.1.5). Analysis that does not distinguish between states is not only incomplete but can lead to dangerous design decisions, because the optimal solution under normal conditions may be precisely the worst choice in a crisis.

State dependence requires market designers to build systems for two utterly different worlds at once. AI market makers can effectively enhance liquidity under normal conditions, but their homogeneous strategies may cause their collective behavior to converge during extreme events (Proposition 33.1.7). The strength of this thread rises gradually from Part 1 and stays high beyond Part 7, reflecting that the deeper one's understanding of the market becomes, the more state dependence emerges as an unavoidable core methodology.

Among all governance tools, transparency has the lowest cost and the highest net benefit. This thread connects propositions at both the micro and macro levels: at the micro level, price transparency directly affects arbitrage efficiency and the anchoring effectiveness of the funding rate (Proposition 33.1.2); at the macro level, the architectural transparency provided by on-chain infrastructure—guaranteed by cryptography and distributed consensus rather than by manual audit—turns trust from a dependence on institutions into a technological guarantee (Proposition 33.1.6). The systemic harm done by the opaque architecture of centralized exchanges has been confirmed repeatedly, and the core logic of embedded compliance is precisely to use architectural transparency to reshape the governance paradigm.

Transparency is not without limits. In certain settings, full transparency may conflict with privacy protection or, in AI-driven games, expose strategies. But as a foundational governance principle, increasing transparency is always an effective means of reducing information asymmetry and guarding against systemic risk. This thread peaks in Part 4 (price discovery) and again in Parts 9–10 (governance and engineering), reflecting the

dual role of transparency at both the micro-efficiency and macro-governance levels.

Technology changes the rules of financial markets but not the human nature of participants. On-chain transparency eliminates information asymmetry, smart contracts sharply reduce the possibility of asset misappropriation, and AI may remove humans' emotional reactions in extreme conditions. Yet the pursuit of high leverage, the tendency toward power concentration in decentralized governance, and the novel resonance risk created by the homogenization of algorithmic strategies all show that the basic features of human nature have merely taken on new forms as technology evolves (Propositions 33.1.3, 33.1.6, and 33.1.7). The need for trust is displaced by technology across different layers but never disappears.

This recognition constitutes the book's core design philosophy: robust system design should assume that participants will do the worst out of self-interest, and then use architecture and incentive mechanisms to make such behavior physically or logically impossible. This thread runs at a gentle baseline strength across all parts of the book and peaks in Part 11 (the future outlook): when looking ahead to an AI-dominated market, a clear-eyed understanding of human nature becomes especially important.

33.3 The confidence spectrum of the conclusions

Academic honesty requires researchers not only to state what they have found but also to mark clearly how confident they are in those findings. The analysis spanning 33 chapters has advanced a great many theoretical frameworks, empirical observations, and forward-looking inferences, but the epistemological status of these conclusions is not equal: some rest on massive volumes of high-frequency data and rigorous mathematical proof, some depend on preliminary observations of early protocols, and still others are logical extrapolations about future technological evolution. This section divides the book's core findings into four epistemological tiers, from highest to lowest confidence (high confidence, medium-high confidence, medium confidence, and exploratory conjecture), and, at the far end of the spectrum, sets out the current knowledge gaps. The confidence grading rests on three dimensions: the rigor of the theoretical foundation (whether there is a formalized causal logic), the breadth of empirical support (whether it has been cross-validated across independent datasets), and the adequacy of stress testing (whether it has been tested under extreme market conditions). Overall, the higher-confidence findings cluster at the micro-mechanism level, while the lower-confidence inferences mostly concern the direction of macro-level evolution—a distribution that reflects the difference between the rigor of microstructure analysis of local mechanisms and the inherent uncertainty in predicting system-level evolution.

High-confidence findings are conclusions that possess a solid theoretical foundation, have been cross-validated by multiple independent empirical studies, and have been tested under repeated episodes of extreme market conditions. These findings constitute the core premises for understanding perpetual futures markets.

The effectiveness of the funding-rate mechanism is among the most firmly established of these findings. Since BitMEX introduced perpetual futures in 2016, nine years of market data show that the funding rate can effectively maintain convergence between

the contract price and the spot price without intervention by any central authority [7]. Its core logic is pure economic reasoning: when the contract trades at a premium, longs pay shorts, directly eroding their return and incentivizing rational traders to close positions or open arbitrage positions. This self-regulating feedback mechanism has remained effective across bull, bear, and range-bound markets, and rate anomalies during extreme events have returned to normal within short cycles. He et al. (2024) [7] find that, over their sample period, the magnitude of the deviation between perpetual and spot prices declined by an average of about 11% per year, which the authors attribute to increasing arbitrage capital and intensifying competition (that is, the market gradually becoming more efficient) rather than to the speed at which a deviation reverts to the no-arbitrage price at any given point in time.

The leading role of perpetual futures in price discovery for major crypto assets is likewise a high-confidence finding. Applying the information-share methodology established by Hasbrouck (1995) [17], Alexander et al. (2020) [3] show empirically that the crypto derivatives market contributes more than 60% of the price-discovery information share; Makarov and Schoar (2020) [4] further confirm the key role of cross-market arbitrage in narrowing spreads; and Cong et al. (2023) [18] caution that wash trading must be filtered out when evaluating trading-volume data. High leverage and low friction give informed traders higher returns in perpetual futures markets, thereby concentrating the price-discovery function on the derivatives side.

On market-maker behavior, adverse-selection costs and inventory risk remain the core variables determining the supply of liquidity [5] [19]. Although the microstructure of crypto markets differs markedly on the surface from that of traditional equity markets, the market maker's profit equation—in which the sum of adverse-selection costs, inventory risk, and institutional costs determines quoted depth and spread width—is clearly reproduced in the high-frequency order-book data of perpetual futures, confirming the cross-market applicability of classical microstructure theory.

Volatility clustering in perpetual futures markets, and its anomalous intensity, have also been amply verified [14]. GARCH-model estimates [20] and high-frequency realized-volatility analysis consistently show that volatility shocks in this market are extremely persistent. The clustered arrival of information, the amplifying effect of leverage on price fluctuations, and the removal of the traditional overnight buffer by around-the-clock trading together produce volatility clustering more pronounced than in traditional markets. The roughly 50% cumulative decline in Bitcoin over March 12–13, 2020, and the multi-day amplification of volatility it triggered, are a textbook case of this feature.

The monolithic architecture of centralized exchanges carries systemic trust risk. The collapse of FTX in November 2022—roughly $8 billion in client funds misappropriated under an opaque architecture, with an internal backdoor program allowing affiliated parties to bypass automatic liquidation—confirmed that when matching, clearing, and custody are concentrated in a single opaque entity, the principal-agent problem is amplified to a systemic scale. This lesson became a core force driving on-chain financial infrastructure toward a layered trust architecture.

Medium-high-confidence judgments are conclusions that are logically well argued and supported by early empirical data but have not yet weathered a complete economic

cycle or extreme stress testing. At the current level of understanding, these judgments are highly reliable, yet room must be left for future data to revise them. The theoretical framework that decomposes the volatility of perpetual futures into four sources—informational, liquidity, mechanistic, and transmission (see Proposition 33.1.4)—belongs to this category. This framework has considerable explanatory power at the conceptual level, clearly distinguishing healthy price discovery from the noise introduced by institutional design. Precisely quantifying and separating these four volatility sources, however, still poses methodological challenges at the empirical level: existing econometric tools often require fairly strong identifying assumptions when handling highly nonlinear and endogenous high-frequency data, so the specific decomposition proportions still carry a nontrivial confidence interval (this identification difficulty is developed in detail in Section 33.4.1).

With regard to infrastructure architecture, we have ample reason to believe that, over the long run, a layered architecture will outperform both extremes, whether fully on-chain or fully off-chain. Decomposing trust into distinct layers—asset custody, matching and execution, clearing and settlement, and so on—and independently seeking the optimal trust-performance trade-off at each layer has a clear advantage in engineering terms. The asset-custody layer requires the highest security and should therefore adopt architectural trust solutions such as multi-signature wallets or hardware wallets; the matching layer has the highest performance requirements and can adopt a centralized or semi-centralized design in exchange for speed; and the clearing layer must balance determinism against flexibility and can adopt a hybrid approach. This design preserves the asset security of the blockchain while breaking through the limits that the consensus mechanism imposes on matching speed. However, the stability of such a complex architecture when processing tens of thousands of orders per second, and the reliability of cross-layer state synchronization, still require confirmation from larger-scale real-world deployment. The problem of cross-layer state synchronization deserves particular attention: when orders generated at the matching layer must be finally settled at the clearing layer, how can the state of the two layers be kept consistent at all times? How can state splitting be prevented under extreme network latency or system failure? Solutions to these engineering challenges are still in the exploratory stage.

On liquidity governance, the protocol-led market-making vault model is regarded as a highly promising mechanism innovation. By pooling retail capital and adopting algorithmic strategies, it partly mitigates the problem of market-maker capital monopoly and provides the protocol with an endogenous liquidity buffer. Data from early decentralized exchanges show that this model can effectively compress bid-ask spreads and improve market depth under normal conditions. Whether, under a one-sided crash or extreme volatility, it will trigger a liquidity-spiral drain through strategy homogenization or excessive risk exposure, however, still awaits empirical testing (see Section 33.4.2). Likewise, gradual liquidation mechanisms can, in theory, substantially reduce the mechanistic volatility triggered by liquidation cascades relative to traditional cliff-edge liquidation. Early results from some exchanges bear this out. Yet how to dynamically calibrate the optimal liquidation-penalty parameters and step sizes for the liquidity characteristics of different assets remains a complex optimization problem.

Medium-confidence inferences are reasonable extrapolations based on current trends

and economic logic; their path to realization is constrained by multiple uncertain factors such as technological bottlenecks, regulatory policy, and strategic interaction among market participants, and they indicate possible directions of development. The foremost conjecture is that the perpetual futures mechanism will move beyond crypto assets into traditional financial domains such as foreign exchange, commodities, and macro equity indices. The generality of funding-rate anchoring means there is no fundamental obstacle to this cross-domain expansion at the mechanism level. The low-friction character of synthetic exposure holds enormous appeal for traders seeking pure price speculation. However, the deeply entrenched regulatory barriers of traditional financial markets, the inertia of existing clearing infrastructure, and the reliance of traditional assets on physical delivery constitute enormous institutional resistance. Just how broad and deep this expansion can ultimately become remains an open question.

Another important conjecture concerns the transformation of AI's role in financial markets. We expect AI to evolve gradually from a mere trading participant into market infrastructure itself. From high-frequency trading algorithms to dynamic risk engines and on to predictive liquidation systems, AI is taking over ever more foundational market functions. This evolution from value extraction toward value creation is, as a matter of economic logic, an inevitable result of the pursuit of efficiency. But the timetable for this process is hard to predict; it depends not only on breakthroughs in large language models and reinforcement learning but, more importantly, on the financial system's tolerance for uninterpretable algorithms.

As AI penetrates more deeply, "model is law" will become an important supplement to, and even a partial replacement for, the "code is law" paradigm. The rigid rules of smart contracts guarantee deterministic execution but also make them slow to respond to complex, unexpected events. Introducing well-trained and well-validated AI models to handle governance decisions and risk-parameter adjustments under ambiguous conditions is a reasonable direction for improving system resilience. However, this conjecture faces enormous governance challenges: How can the model's training data be kept from contamination? How can the model be prevented from hallucinating during extreme, long-tail events? How can probabilistic model outputs be incorporated into deterministic financial contracts? There are as yet no mature solutions to these questions, which makes this inference relatively uncertain.

Exploratory conjectures are long-range extrapolations that lack an empirical foundation; they serve more to expand the boundaries of understanding and to point out strategic directions worth long-term attention than to offer testable or immediately tradable short-term predictions. One bold conjecture is that decentralized perpetual futures markets will ultimately become the reference-pricing venue for the world's major assets. This conjecture rests on a premise: as on-chain liquidity continues to aggregate and transaction costs keep approaching their physical limits, the most informationally efficient market will naturally acquire pricing power. Should this vision come true, traditional exchanges would degenerate into followers of liquidity. But this process must overcome extremely high network-effect barriers, and it faces strong resistance from sovereign states unwilling to cede pricing power over core financial assets.

A further conjecture is the eventual formation of the "autonomous financial network"—

the three-layer stack, defined in Chapter 32, composed of an asset layer, an infrastructure layer, and an agent layer. In this conception, a financial stack made up of smart contracts, decentralized oracles, and AI agents would be able to issue assets, match trades, manage risk, and perform clearing entirely autonomously, without the intervention of any human intermediary. This is an extreme technological utopia; it requires the throughput of the underlying public chain to leap by orders of magnitude, cross-chain interoperability to achieve seamless connection, and the entire system to withstand nation-state-level computational attacks. For the foreseeable future, this conjecture will remain at the proof-of-concept stage.

A key technological conjecture underpinning the vision above is a breakthrough in semantic oracles. Traditional numerical oracles can only transmit discrete price data, whereas a semantic oracle parses natural language, legal text, or real-world events into verifiable on-chain state; its AI-infrastructure prerequisites are set out in Chapter 31. It is expected to understand and verify complex natural-language texts, legal contracts, and even real-world news events and to translate them into on-chain executable logic. If this technology can be realized, it will fully unlock the potential of "perpetual futures on everything," allowing any social event or economic indicator with consensus value to be financialized. However, the ambiguity of natural language and the limitations of AI comprehension mean that the reliability of semantic oracles will, for a long time to come, struggle to meet the exacting requirements of high-value financial transactions.

At the end of the confidence spectrum, we must honestly confront the questions that currently lie entirely beyond our capacity to know. Admitting ignorance is among the most valuable qualities in scientific research: it guards against theoretical hubris and points the way for future exploration. First, we do not know how large a liquidity shock the deep homogenization of AI strategies would trigger in an extreme black-swan event (the definition of its critical threshold is discussed in Section 33.4.1). The market has not yet experienced an "algorithmic flash crash" set off jointly by thousands of agents sharing similar underlying models and training data, and, for lack of a historical sample, this novel form of systemic risk cannot be accurately assessed by existing stress-testing models.

Second, we do not know where the optimal system-level leverage limit should be set in a decentralized perpetual futures market. The leverage ratio bears not only on capital efficiency but, more directly, on the destructive power of a liquidation cascade. It is a dynamically changing endogenous variable that depends on market depth, the volatility regime, and participants' risk preferences. The very search for a static, universal optimal leverage ratio may, in theory, be misconceived.

We also do not know whether fully decentralized governance mechanisms can remain effective in managing ultra-large-scale, extremely complex financial infrastructure. Historical experience shows that, as an organization grows in scale, decentralized governance often falls into inefficiency, capture by interest groups, or de facto oligarchic control. In an on-chain world unconstrained by a mandatory legal framework, how to design a governance mechanism that both prevents power concentration and preserves agile decision-making remains an unsolved sociological problem.

Moreover, we cannot foresee how sovereign states will ultimately mount a systematic re-

sponse to this permissionless, cross-border autonomous financial network. This already exceeds the scope of economics and microstructure theory and enters the domain of international political economy and national security strategy. In the contest between the coercive force of regulation and the censorship resistance of technology, whether the final equilibrium is outright suppression, conditional co-optation, or parallel coexistence, no one can give a definite answer at present.

Finally, we do not know how much of the theoretical framework built in this book will retain its explanatory power after a decade of technological iteration and market evolution. Market microstructure is a complex adaptive system in perpetual motion, especially in crypto finance, a field whose pace of evolution is measured in months. Perhaps in the near future, new institutional designs and technological breakthroughs will completely overturn the "stylized facts" we hold to be certain today. Yet it is precisely this endless evolution that gives the theory of financial microstructure its enduring research value. The current knowledge gaps are exactly the starting point for the next generation of researchers.

33.4 Unresolved problems and the research agenda

A good book not only answers questions but also poses new ones. In this systematic dissection of the microstructure of perpetual futures across 33 chapters, we have attempted to build a theoretical framework that explains the operating mechanisms of this emerging financial instrument. Yet as the analysis deepened, we became ever more aware of the limits of the current theory. Scientific progress often arises not from repeatedly confirming the known but from honestly confronting the unknown. What follows are problems that surfaced repeatedly over the course of the book's analysis but that, constrained by current data conditions, theoretical tools, or the stage of historical development, could not—and should not—be forced to a resolution within this book. These unresolved problems constitute the research agenda for the next stage of financial microstructure theory.

Figure 33-1 organizes the unresolved problems discussed in this section into a structured roadmap by research category (theoretical, empirical, and design) and time horizon (short-term, 1–3 years; medium-term, 3–7 years; and long-term, more than 7 years), offering researchers at different stages a set of prioritized entry points.

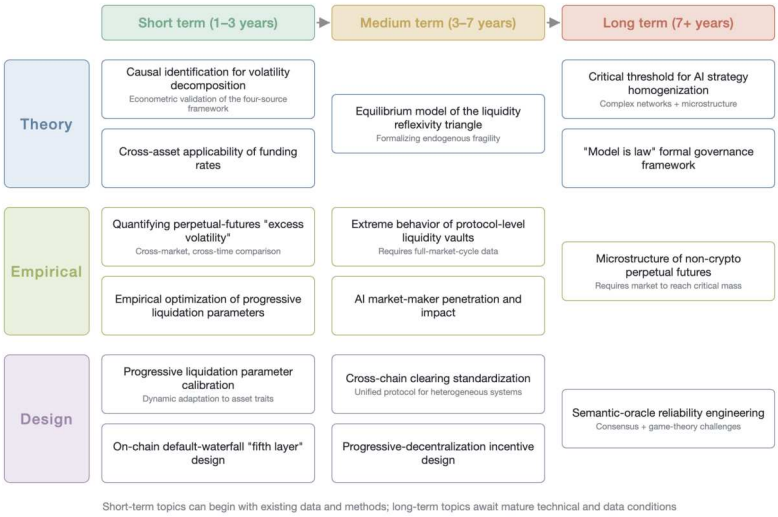

Figure 33-1. Research-agenda roadmap for unresolved problems: a research-priority matrix organized by category (theoretical/empirical/design) and time horizon (short-/medium-/long-term), where the entries are the unresolved problems raised in this book, compiled by the author and not empirical data

On the theoretical side, although the book has proposed a series of conceptual frameworks, translating them into rigorous formal models still faces major challenges. The first is the problem of rigorous causal identification for the four-source volatility decomposition. We deconstruct the volatility of perpetual futures into four sources—informational, liquidity, mechanistic, and transmission—and this conceptual distinction offers an important perspective for understanding market states. With the current econometric toolbox, however, separating these four components within high-frequency price sequences remains an unsolved problem. Existing decomposition methods often rely on strong assumptions—for example, that information shocks and liquidity frictions are mutually independent—but under extreme market conditions this independence assumption tends to fail. Future research will need to develop more refined identification strategies, possibly by introducing nonlinear dynamical models or drawing on higher-dimensional datasets, in order to quantify the different volatility sources precisely.

The second is the formal modeling of the liquidity reflexivity triangle. Through qualitative analysis, the book has revealed the reflexive loop among market-maker inventory, price volatility, and liquidity supply, pointing to the endogenous fragility whereby liquidity is scarcest when it is most needed. But turning this intuitive insight into a closed-form dynamic equilibrium model remains a formidable task. Traditional market-maker models typically assume an exogenous price process, whereas here the price process is itself endogenously determined by the collective behavior of market makers. Building such a macro-microstructure model that encompasses multiple equilibria and nonlinear feedback requires not only overcoming extremely high mathematical complexity but also striking a delicate balance between theoretical elegance and real-world explanatory power.

The third theoretical difficulty is defining the critical threshold for AI-strategy homogenization. As the penetration of algorithmic trading and AI market makers rises, strategy convergence becomes a systemic risk that cannot be ignored. When enough market participants use similar models and data sources, algorithms originally intended to dampen volatility may resonate under particular triggering conditions and set off an instantaneous drain of liquidity. But how much homogenization counts as "too homogeneous"? Is there a critical threshold that can be rigorously defined, beyond which market resilience undergoes a phase-transition-like collapse? Answering this question requires a deep fusion of complex-network theory with microstructure models—undoubtedly a major frontier for future theoretical research.

Finally, a formalized governance framework for "model is law" is likewise urgently needed. In exploring the evolution of AI from market participant to market infrastructure, we have foreseen a future in which algorithmic models may replace traditional code as the core of rule enforcement. Unlike deterministic smart-contract code, however, an AI model is inherently probabilistic, and its decision process often has the uninterpretable character of a black box. How can such a probabilistic, non-deterministic decision mechanism be incorporated into existing legal and economic frameworks of liability? When an autonomously operating risk-control model makes a misjudgment that causes enormous losses, how should responsibility be assigned? Building a formalized governance theory compatible with probabilistic logic is a prerequisite for realizing a truly autonomous financial network.

The validity of theory lies in empirical testing. On the empirical side, because the crypto-asset market has a short history and a complex data structure, many key hypotheses still await further verification. First and foremost is the precise quantification of the "excess volatility" of perpetual futures. Although in theory high leverage and the funding-rate mechanism introduce additional volatility, accurately measuring the specific share of this mechanistic volatility in total volatility requires systematic comparison across markets, across time, and across asset classes. Current empirical research is often limited by a lack of out-of-sample data and struggles to control for confounding variables such as the macroeconomic environment and changes in regulatory policy. Future work will need to build a larger and more standardized microstructure database and apply advanced panel-data techniques before it can deliver statistically significant, definitive conclusions.

In addition, the real-world performance of protocol-based liquidity vaults under extreme market conditions remains an open empirical question. As an institutional innovation for addressing the endogenous fragility of liquidity, such vaults have shown potential to improve liquidity under normal conditions. Yet the true test of any financial institution always comes in a crisis. Because such mechanisms are still young, they have not yet weathered a systemic shock on the scale of the global financial crisis. When faced with the concurrent pressures of extreme selling, oracle failure, and network congestion, will these vaults serve as an effective buffer that stabilizes the market, or will design flaws accelerate their collapse? Answering this empirically will require more time and more "battle testing."

The true penetration and impact of AI market makers in crypto markets is likewise

hard to quantify empirically. Although algorithmic trading is widely seen as increasingly prevalent, the anonymity of on-chain identities and the concealment of trading strategies make it hard for researchers to distinguish accurately between the order flow of human traders and that of AI algorithms. The lack of reliable classification data makes it extremely difficult to assess AI's specific impact on market liquidity, price-discovery efficiency, and volatility characteristics. Future empirical research may need to draw on more advanced machine-learning classification techniques, or rely on high-granularity anonymized data provided at the exchange level, before it can gradually shed light on this question.

Finally, the market-microstructure characteristics of non-crypto-asset perpetual futures are an important empirical blind spot. As a thought experiment, the book has explored the possibility of extending the perpetual futures mechanism to traditional assets such as foreign exchange, equities, and commodities. At present, however, the trading volume on platforms attempting to launch such products remains too small to provide enough observations for reliable empirical analysis. Traditional assets and crypto assets differ fundamentally in their underlying value anchor, the structure of market participants, and the regulatory environment; how will these differences reshape the microstructure behavior of perpetual futures? Answering this question must wait until the relevant markets reach a certain degree of maturity and scale of liquidity before substantive empirical exploration can begin.

Beyond the theoretical and empirical challenges, in financial engineering and system design the book also leaves a series of problems unsolved. One of the most pressing is the design of a final recovery and resolution mechanism beyond the on-chain default waterfall. In the traditional central-counterparty clearing system, once all the front-line risk buffers have been breached, the ultimate backstop responsibility is typically borne by the central bank or the sovereign state; this is an external public-credit backstop, not an ordinary tier inside the default waterfall. In an on-chain financial network that pursues decentralization and permissionlessness, however, such an external government backstop does not exist. When an extreme black-swan event causes all clearing mechanisms within the system to fail and the bankruptcy shortfall cannot be covered, how should the system design its last line of defense? Is it an optimal auto-deleveraging mechanism, the issuance of a system debt token, or some socialized loss-mutualization protocol not yet invented? Finding an ultimate risk-buffer solution in the absence of sovereign-credit backing is a necessary path for on-chain finance to reach maturity.

The reliability engineering of semantic oracles (see Section 33.3.4) is another highly challenging design problem. Introducing large-language-model-based AI into an oracle network inevitably brings the risks of "hallucination" and adversarial attacks. How can a robust consensus mechanism be designed to ensure that multiple independent AI nodes, when confronting ambiguous or even maliciously constructed real-world information, output consistent and accurate semantic-parsing results? This is not only a technical problem in natural language processing but also a complex engineering challenge involving game-theoretic incentive design.

On the evolution of organizational architecture, the incentive design for "progressive decentralization" remains a problem not yet fully solved. In their initial phase, many

on-chain protocols depend on a core team for centralized development and operation, and promise to hand control gradually to the community. In reality, however, the team often lingers in the centralized phase for a long time—whether out of vested interests or distrust of the community's governance capacity—so that "progressive" becomes "never." How can sophisticated token-economics design and hard-coded smart-contract time-locks create an irreversible incentive mechanism under which the core team is not only willing but mathematically compelled to relinquish power step by step along the roadmap? This requires us to seek more powerful constraint tools within mechanism-design theory.

Finally, the standardization of cross-chain clearing constitutes a major design bottleneck for the future of multi-chain interoperability. As liquidity grows increasingly fragmented across different blockchain networks, it is becoming the norm for users to hold related assets and positions on multiple chains at once. To improve capital efficiency and reduce systemic risk, cross-chain margin sharing and net settlement become especially necessary. Yet blockchains differ enormously in consensus mechanism, finality-confirmation time, and smart-contract execution environment; how can a unified, secure, and efficient cross-chain clearing standard be established among these heterogeneous systems? This requires not only securing cross-chain message passing but also designing a global clearing algorithm that can tolerate asynchronous execution and partial network partitions. The absence of such a standard remains the main obstacle preventing on-chain financial networks from optimizing capital efficiency globally.

33.5 Disciplinary contributions and epistemological legacy

The book's disciplinary contribution lies not in analyzing an emerging market as such but in the way the extreme institutional design of perpetual futures exposes blind spots long obscured within traditional microstructure theory. The institutional infrastructure of traditional markets—designated market makers, central-counterparty clearing, and market-closing conventions—masks several deep contradictions. Once perpetual futures strip away these protective institutional layers, the essential features of microstructure become visible under extreme conditions, giving rise to five epistemological legacies.

The classic framework established by O'Hara (1995) [6] divides volatility into two categories: informational volatility (from fundamental updates) and noise volatility (from liquidity imbalances or irrational behavior). This dichotomy has strong explanatory power in traditional equity and futures markets, where liquidation rules and trading institutions are relatively mild and the frictions they generate are usually subsumed under noise in the broad sense. Perpetual futures, however, break this pattern: high-leverage liquidation engines force selling when a price crosses a trigger threshold, disregarding fundamental information, and periodic funding-rate settlement induces the mechanical repositioning of arbitrage capital at fixed points in time. The mechanical buying and selling pressure this produces [7] neither reflects new information nor stems from trader irrationality but is a direct product of the logic of system design. On this basis, the book expands the information/noise dichotomy into a four-source framework—informational, liquidity, mechanistic, and transmission—making institution-driven volatility explicit as an independent analytical category, and it poses a new question for future research:

to what extent does the institutional design of any emerging market endogenously create additional volatility? Only by separating out institution-driven volatility, as far as it can be identified, can regulators distinguish the healthy cost of price discovery from pure friction that architectural optimization can mitigate.

The classic models of Kyle (1985) [21] and Glosten and Milgrom (1985) [5] tend to treat liquidity as an exogenous background condition, reducing the market maker to a passive provider seeking a static equilibrium between adverse-selection costs and inventory costs; and the designated-market-maker system and stable credit support of traditional markets further obscure the intrinsic fragility of liquidity supply. Analysis of perpetual futures markets, by contrast, shows that liquidity is essentially a commodity produced by market makers, and that its production equation contains a structural flaw: production cost is positively correlated with demand. Under normal conditions, adverse selection and inventory risk are low, and market makers tend to supply liquidity far in excess of demand; once the market shifts into a high-volatility state, risk costs balloon exponentially, and the production logic of liquidity collapses with them. This countercyclical fragility is not a matter of any moral failing or irrational panic on the part of market makers but a structural result of profit maximization under the adverse-selection and inventory-cost structure [5]. It rewrites our understanding of market resilience: the effective way to sustain liquidity during a crisis is not to make moral appeals or issue administrative decrees but to change the underlying risk-return structure of market makers, or to reshape the production logic of liquidity through institutional innovations such as protocol-level liquidity vaults.

The mainstream microstructure literature assumes by default that trading takes place within a complete institutional infrastructure, in which central counterparties, securities depositories, and state regulation form a network of trust [6]; asset security, fairness of matching, and settlement finality are treated as given premises, and the question of trust is left to law and institutional economics. The crises in crypto markets [22] [23]—and especially the systemic failures of centralized exchanges—demonstrate, however, that in an environment lacking state backing, trust is a scarce, central variable that can break down at any moment. The book therefore turns trust from an abstract institutional problem into a concrete engineering problem and proposes the concept of the trust stack: it decomposes a financial transaction into five layers—asset custody, matching and execution, clearing and settlement, data feeds, and governance decisions—and explores at each layer the trade-off frontier between trust-minimization and performance-maximization (Chapters 28–29). This provides a new first principle for financial-system design: the designer no longer faces a binary choice between wholesale centralization and wholesale decentralization but independently seeks the optimal architectural solution at each layer; and future microstructure theory must place trust architecture alongside liquidity and volatility as a foundational dimension for assessing market quality.

Most existing microstructure theory is built on the assumption that the market has opening, closing, and non-trading cycles: the closed period is regarded as a buffer for digesting information; the open and the close carry special price-discovery functions; and concepts such as overnight risk, opening gaps, and closing-price manipulation form the core vocabulary of traditional analysis. Even though the foreign-exchange market

achieved near-around-the-clock trading well before crypto markets did [24], its weekend breaks and the relatively limited microstructure research devoted to it left this assumption largely unshaken for a long time. Perpetual futures markets combine around-the-clock trading with high leverage and the absence of an expiration date, producing microstructure features different from those of the foreign-exchange market: the lack of a closed-period buffer gives price shocks a stronger long-memory effect over time, and volatility clustering is more pronounced than in traditional markets; around-the-clock pricing, meanwhile, fills the pricing vacuum that traditional assets face during the Asian or European sessions, making the global price-discovery process more continuous. This finding calls for redefining the dynamic relationship between information arrival and price adjustment, for exploring market makers' cross-time-zone inventory-management strategies in the absence of time boundaries, and for designing new dynamic risk-control systems for continuous markets—the traditional time-slice-based circuit-breaker mechanism no longer applies here.

The objects of analysis in traditional financial theory are usually anchored to real assets or their direct derivatives: a stock represents ownership of a company; a commodity future carries an obligation of physical delivery; and even complex derivatives have definite expiration dates and exercise conditions. These rigid constraints force prices to converge over time, and traditional arbitrage models and pricing formulas are essentially organized around the expiry constraint; CFDs and total return swaps, although they likewise provide synthetic exposure, are limited by bilateral counterparty risk and finite market depth (see Section 33.1.1). Perpetual futures, by contrast, create a new class of financial instrument—one with no expiration date, no physical delivery, and price anchoring achieved purely through the funding rate's endogenous game-theoretic mechanism [7]. What the trader trades is nothing but pure exposure to price movements, and its economic nature and risk characteristics pose new challenges to traditional derivatives-pricing theory. The book thus establishes the economics of synthetic exposure as a new analytical category, one that calls for building an entirely new theoretical framework: the anchoring efficiency and failure conditions of the funding rate across different states await systematic study; and when this mechanism extends to domains such as foreign exchange and commodities, its reshaping effect on the global risk-transmission network and the distribution of liquidity must also be assessed. The economics of synthetic exposure thus provides the core theoretical framework for understanding the digitalized financial networks of the future.

33.6 Recommendations for different readers

The book's argument now nears its close. This section offers readers of different backgrounds concrete paths of action that build on this book.

What the book offers academic researchers is not a closed set of conclusions but an open research agenda. The unresolved problems listed in Section 33.4—such as the causal identification of four-source volatility, the formal modeling of the liquidity reflexivity triangle, and the critical threshold of AI-strategy homogenization—can all serve as starting points for independent research projects. Hypotheses that merit priority testing include whether the share of mechanistic volatility in total volatility grows nonlinearly

as the leverage ratio rises; whether protocol-level liquidity vaults accelerate rather than relieve liquidity drains under extreme conditions; and whether the anchoring efficiency of the funding rate still holds once it is extended across asset classes. Recommended data sources include the high-frequency order-book data of Kaiko and CoinMetrics, the on-chain metrics of Glassnode, and the public liquidation logs of the various protocols. The book's analytical frameworks—the four-source volatility decomposition, the state-machine model, and trust-stack theory—combined with classical microstructure tools such as market-making quote models [25] and informed-trading models [26], are not confined to crypto markets and can serve as general-purpose theoretical tools for the microstructure analysis of emerging markets.

The book offers practitioners three directly applicable decision frameworks. For market makers, the triple-cost decomposition of the profit equation (adverse selection, inventory, and institutional cost), combined with the four-source identification of volatility, forms the basis for dynamically adjusting quoting strategies under normal and stressed conditions. Specifically, when the share of mechanistic volatility rises, one should give priority to reducing depth rather than widening the spread. For exchange architects and protocol designers, the five-layer decomposition of the trust stack provides an engineering framework for evaluating architectural choices: prioritize trust-minimization at the custody layer, prioritize performance at the matching layer, and adopt a gradual rather than cliff-edge design at the clearing layer. For investors, the five-dimensional market-quality model offers a structured method for evaluating trading venues, while the state-machine perspective is a reminder that, in assessing market resilience, one must distinguish normal-state performance from stressed-state performance.

The book offers regulators tools in three directions. Architectural guarantees of asset segregation and information disclosure are the most direct regulatory instrument: requiring trading platforms to implement verifiable asset segregation at the custody layer is low in cost and measurable in effect. Calibrating leverage limits, by contrast, must rest on microstructure analysis: the book's four-source volatility decomposition shows that the higher the share of mechanistic volatility in a market, the lower the optimal leverage ceiling should be. Embedded compliance—encoding regulatory requirements into the execution logic of smart contracts—offers a technological path for shifting from ex post punishment to real-time monitoring, and its core logic is to use the architectural transparency of on-chain infrastructure to reduce the cost of regulation.

Students are advised to choose one of the following reading paths, according to their interests, as an entry point. Derivatives-pricing track: Chapter 10 (the game theory of funding rates) → Chapter 13 (price discovery) → Chapter 17 (arbitrage risk), with an emphasis on mechanism design and information economics. Market-microstructure track: Chapter 19 (the market maker's profit equation) → Chapter 20 (the endogeneity of liquidity) → Chapters 22–24 (volatility), with an emphasis on the application of classical microstructure theory in a new market. System-design track: Chapter 28 (the trust stack) → Chapter 29 (clearing architecture) → Chapter 31 (AI infrastructure), with an emphasis on engineering and governance design. After exploring a particular topic in depth, one can gradually expand into adjacent areas through the cross-references between chapters.
