About the Author **vi**

Part I. Foundations **1**

The Distinctiveness of Digital Assets Compared with Traditional Assets **2**
1.1 The trust architecture of traditional finance . . . 3
1.1.1 The complete journey of a trade . . . 3
1.1.2 The five layers of trust . . . 6
1.1.3 The trust tax: a unified view of institutional cost . . . 9
1.1.4 The rationale for the trust tax . . . 11
1.2 The six distinctive properties and the compression of the trust tax . . . 12
1.2.1 Permissionlessness: compressing the entry tax . . . 12
1.2.2 Atomic divisibility: compressing the granularity barrier . . . 14
1.2.3 Settlement finality: compressing the time tax . . . 15
1.2.4 Around-the-clock trading: compressing temporal fragmentation . . . 16
1.2.5 Smart-contract execution: compressing the intermediary tax . . . 17
1.2.6 On-chain transparency: the opacity tax and the transparency paradox 18
1.3 The composability thesis . . . 20
1.3.1 The interaction matrix of the six properties . . . 20
1.3.2 Financial primitives impossible in traditional finance . . . 21
1.3.3 The dark side of composability . . . 22
1.4 Microstructure reconstruction and the transformation of the risk surface . 24

1.4.1 The reconstruction of the three microstructure elements 24
1.4.2 The transformation of the risk surface 25
1.4.3 Three trust paradigms 27
1.5 Chapter summary 29
References 30

Derivatives Markets and the Rise of Perpetual Futures **33**
2.1 The trust evolution of derivatives 34
2.1.1 Personalized trust and forward contracts 34
2.1.2 Institutionalized trust and the futures revolution 35
2.1.3 Options and nonlinear payoffs 35
2.1.4 A unified functional framework 36
2.1.5 Algorithmic trust and perpetual futures 37
2.2 The three structural conflicts 37
2.2.1 Temporal mismatch 38
2.2.2 Liquidity fragmentation 38
2.2.3 Trust mismatch 39
2.2.4 Ruling out the alternatives 39
2.3 The core mechanisms of perpetual futures 42
2.3.1 The funding rate 42
2.3.2 Mark price and the liquidation mechanism 45
2.3.3 Inverse contracts and linear contracts 47
2.3.4 The cost of abolishing the expiry date 48
2.4 Market landscape and ecosystem evolution 49
2.4.1 Market size and price discovery 49
2.4.2 The democratization of leverage 50
2.4.3 Leverage-cycle dynamics 51
2.4.4 Risks unique to DEXs 55
2.4.5 Regulatory evolution 57
2.5 Chapter summary 58

The Distinctive Value of Digital Assets and the Future of Finance **62**
3.1 An economic reexamination of the four distinctive properties 63
3.1.1 Permissionlessness and contestable markets 64
3.1.2 Around-the-clock continuous trading and the transformation of constraints 66
3.1.3 The scope of atomic settlement 67
3.1.4 The power and cost of programmability 70
3.2 The institutional convergence thesis 71
3.2.1 The on-chain deployment of traditional finance 71
3.2.2 The institutionalization of on-chain finance 73
3.2.3 The competitive compression of the trust tax 73
3.2.4 The institutional-convergence significance of the BUIDL fund . . . 75
3.3 The trust-tax compression curve and the three-horizon framework 76
3.3.1 The compression-difficulty gradient 76

3.3.2 H1: Stablecoin settlement and crypto-native derivatives 79
3.3.3 H2: Tokenized securities and institutional DeFi 80
3.3.4 H3: Programmable money and autonomous finance 81
3.3.5 Differences in the trust needs of the three horizons 82
3.4 Stablecoins: a structural migration of the settlement layer 83
3.4.1 The meaning of $33 trillion in settlement volume 83
3.4.2 The network effects and escape velocity of stablecoins 85
3.4.3 The upper-layer effects after the settlement layer is established . . 86
3.4.4 The structural risks of stablecoins 86
3.5 Asset tokenization and on-chain settlement 87
3.5.1 The economic logic of asset tokenization 87
3.5.2 The architectural advantages of on-chain settlement 89
3.5.3 Three surmountable challenges 90
3.6 The impossibility boundaries 92
3.6.1 The sovereignty boundary 92
3.6.2 The physical-world interface 93
3.6.3 The governance paradox 94
3.6.4 Maximizing within boundaries 95
3.7 Chapter summary 95

Part II. The Ecosystem **100**

Participants and Behavior in Perpetual Futures Trading **101**
4.1 The participant classification framework 102
4.1.1 Functional classification 102
4.1.2 The two ultimate sources of profit 103
4.1.3 Behavioral classification 106
4.1.4 The hidden costs of the negative-sum game 108
4.1.5 Limitations of the classification 109
4.2 Behavioral analysis of the six core participant types 109
4.2.1 Market makers 109
4.2.2 Informed traders 113
4.2.3 Arbitrageurs 114
4.2.4 Mechanism parasites 116
4.2.5 Speculators and futile traders 119
4.2.6 Liquidators 120
4.3 The game network among participants 123
4.3.1 Market makers and informed traders 123
4.3.2 Market makers and mechanism parasites 124
4.3.3 Profit-motivated traders and futile traders 125
4.3.4 Speculators and the liquidation mechanism 126
4.3.5 The complete map of profit flows 128
4.4 The threefold reshaping by the digitally native environment 130
4.4.1 The fluidization of roles 131

4.4.2 The algorithmization of the game . . . 132
4.4.3 The transparency-fragility paradox . . . 134
4.4.4 The compounding effect of the threefold reshaping . . . 135
4.5 AI agents: the rise of a seventh participant type . . . 136
4.5.1 From automation to autonomous agency . . . 137
4.5.2 AI agents' competition for the two profit sources . . . 137
4.5.3 Differentiated impact on the six participant types . . . 139
4.5.4 Three entirely new forms of the game . . . 140
4.5.5 Revisions to the analytical framework . . . 142
4.6 Comparison with traditional finance . . . 143
4.6.1 The invariant underlying logic . . . 144
4.6.2 The changed modes of implementation . . . 144
4.6.3 Entirely new species and phenomena . . . 146
4.7 Chapter summary . . . 146

Service Providers and the Ecosystem of Perpetual Futures Trading 150
5.1 The risk substitution theorem and the service provider's trilemma . . . 151
5.1.1 The functional dimensions of the trade lifecycle . . . 151
5.1.2 The risk substitution theorem . . . 153
5.1.3 The service provider's trilemma . . . 155
5.1.4 The verifiability ladder . . . 157
5.2 The functional-separation architecture of traditional finance . . . 160
5.2.1 The multi-intermediary flow of a futures trade . . . 160
5.2.2 The institutional rationale for functional separation . . . 162
5.2.3 The CCP default waterfall mechanism . . . 163
5.2.4 The efficiency cost of functional separation . . . 166
5.3 The functional bundling of centralized exchanges . . . 167
5.3.1 The CEX's bundling of five roles . . . 168
5.3.2 The definition and composition of the bundling tax . . . 170
5.3.3 The efficiency advantages of the bundling model . . . 172
5.3.4 Comparing the CEX and CCP risk waterfalls . . . 173
5.3.5 The limits of proof of reserves . . . 175
5.3.6 The FTX and Bybit failure cases . . . 176
5.4 On-chain trading models . . . 178
5.4.1 Self-custody and atomic settlement . . . 178
5.4.2 A comparison of three execution models . . . 180
5.4.3 App-chain architecture and validator centralization . . . 182
5.4.4 Architecture audit and verifiability rating . . . 184
5.4.5 The on-chain risk waterfall . . . 186
5.5 Cross-architecture risk isomorphism . . . 189
5.5.1 Adverse selection and impermanent loss . . . 189
5.5.2 Margin cascades and liquidation cascades . . . 190
5.5.3 Market fragmentation and cross-chain fragmentation . . . 191
5.5.4 Closing gaps and low-liquidity amplification . . . 192
5.5.5 The cross-modal risk transmission path . . . 193

5.6 Effects on market microstructure . . . 196
5.6.1 The reconstruction of price discovery . . . 196
5.6.2 The evolution of liquidity supply . . . 197
5.6.3 Structural differences in transaction costs . . . 198
5.6.4 The distribution of systemic risk . . . 199
5.7 Chapter summary . . . 200

The Evolution and Trade-offs of Perpetual Futures Market Structure 206
6.1 The trade lifecycle . . . 207
6.1.1 Centralized exchanges . . . 208
6.1.2 General-purpose public-chain DEXs . . . 210
6.1.3 Application-chain DEXs . . . 213
6.1.4 Structural comparison . . . 216
6.2 The competition-mode migration thesis . . . 218
6.2.1 Latency competition in CEXs . . . 218
6.2.2 Information competition in general-purpose public-chain DEXs . . . 219
6.2.3 Mechanism competition in application-chain DEXs . . . 220
6.2.4 A unified comparison of the competition modes . . . 221
6.2.5 The drivers of competition-mode migration . . . 224
6.3 Strategic MEV . . . 226
6.3.1 Atomic MEV and strategic MEV . . . 226
6.3.2 Typical forms . . . 229
6.3.3 Defending against strategic MEV . . . 232
6.3.4 The path toward institutionalizing MEV . . . 233
6.4 The price-discovery migration hypothesis . . . 235
6.4.1 Structural drivers . . . 236
6.4.2 Critical mass and network effects . . . 238
6.4.3 A cautious reading of the current evidence . . . 238
6.4.4 The shaping of trader behavior . . . 240
6.5 The evolution of risk distribution . . . 242
6.5.1 The risk visibility-manageability proposition . . . 242
6.5.2 Statistical properties of risk . . . 244
6.5.3 Cross-paradigm risk transmission . . . 247
6.6 The paradigm endgame . . . 249
6.6.1 Coexistence and the competitive landscape . . . 250
6.6.2 Convergence dynamics . . . 251
6.6.3 Expanding the impossible triangle . . . 253
6.6.4 Open problems . . . 257

Part III. Microstructure 265

Orders and the Language of Perpetual Futures Trading 266

7.1 The signaling function of orders . . . 267
7.1.1 The trading function and the signaling function . . . 267
7.1.2 The signal-strength spectrum . . . 269
7.1.3 The microfoundations of adverse selection . . . 272
7.1.4 The intent-execution gap . . . 274
7.2 Basic order types . . . 277
7.2.1 Market orders . . . 277
7.2.2 Limit orders . . . 278
7.2.3 Stop-loss and take-profit orders . . . 278
7.2.4 The maker-taker fee model and order selection . . . 280
7.3 Advanced order types . . . 282
7.3.1 Time-control orders . . . 283
7.3.2 Size-hiding orders . . . 283
7.3.3 Execution-constraint orders . . . 284
7.3.4 Algorithmic orders: TWAP and VWAP . . . 284
7.3.5 Conditional orders . . . 287
7.4 The strategic dimensions of perpetual futures . . . 288
7.4.1 The leverage dimension . . . 289
7.4.2 The liquidation dimension . . . 290
7.4.3 The time dimension . . . 291
7.4.4 The choice of margin mode . . . 293
7.4.5 A unified decision framework . . . 294
7.5 The commitment property of on-chain orders . . . 296
7.5.1 The privacy of CEX orders . . . 297
7.5.2 The public-commitment property of on-chain orders . . . 298
7.5.3 The MEV exposure surface of orders . . . 298
7.5.4 The order-protection mechanisms of application chains . . . 302
7.6 The execution-architecture spectrum and the reshaping of order semantics 303
7.6.1 A comparison of the three execution architectures . . . 304
7.6.2 The order lifecycle . . . 306
7.6.3 The order-cancellation mechanism . . . 308
7.6.4 Conditional-order triggering . . . 310
7.6.5 The order-matching mechanism . . . 313
7.6.6 State-management constraints . . . 315
7.7 The order strategies of market participants . . . 317
7.7.1 The order strategies of market makers . . . 317
7.7.2 The order strategies of arbitrageurs . . . 318
7.7.3 The order strategies of speculators . . . 319
7.7.4 The order strategies of hedgers . . . 320
7.7.5 The order strategies of liquidators . . . 320
7.7.6 Participant identification based on order flow . . . 322
7.8 A three-dimensional framework for risk analysis . . . 325
7.8.1 Defining the three dimensions . . . 325
7.8.2 Applying the three-dimensional risk matrix . . . 326
7.8.3 Practical implications for risk management . . . 328
7.9 Order-flow analysis . . . 329

7.9.1 The composition of order flow . . . 329
7.9.2 Order-flow toxicity and VPIN . . . 331
7.9.3 The distinctive signals of perpetual futures order flow . . . 332
7.9.4 From orders to the order book . . . 335

Preface

Why This Book Exists

I arrived at this subject twice.

The first time was in traditional finance and trading, where I learned that a market is never just a place where prices meet — it is a trust machine two centuries in the making, built on central counterparties, multi-layered clearing, and regulation, and yet it never resolved one fundamental contradiction: institutionalized trust is itself the greatest single point of failure. From the collapse of Lehman Brothers to the implosion of FTX, every crisis asks the same question — can we build a financial system that does not depend on intermediary credit? The second time was in blockchain, where I watched a generation of engineers try to answer it, rebuilding those same functions — custody, matching, clearing, settlement, price discovery — from first principles, in the open, with code standing in for the institutions the rest of finance takes for granted. The perpetual future sat at the center of that effort: the instrument that, more than any other, became the native language of these new markets, and the clearest proof so far that price discovery itself can be permissionless.

We live in an age when information has never been cheaper. Ask a model, search a forum, read a hundred threads, and fragments of the answer will appear in seconds. Yet if you want a single, systematic account of how permissionless perpetual markets actually work — from the anatomy of a single order to the macro question of whether these markets might one day help price the world — you will not find it. The knowledge exists, but it is scattered across exchange documentation, academic papers written in different dialects, audit reports, and the tacit intuition of practitioners who rarely write things down. Abundance of information is not the same as structure. This book is my attempt to supply the structure: to connect the microstructure of a single trade to the architecture of a global, on-chain financial system, and to do it with the seriousness the subject deserves.

Who This Book Is For

This book is written for the reader who wants to understand *why*, not only *how*:

- **Traders and practitioners** who already use these markets and want a rigorous model of the machinery beneath the interface — funding, liquidation, order books, liquidity, and the reflexive dynamics that turn ordinary days into cascades.

- **Builders and engineers** designing exchanges, protocols, oracles, and risk systems, who need to see how each design choice propagates from the microstructure outward.
- **Researchers and students** of market microstructure, financial economics, and distributed systems, who want a coherent framework and an evidence map rather than a collection of anecdotes.
- **Policymakers and the intellectually curious**, who sense that something structurally new is happening and want an honest account of both its promise and its fragilities.

You do not need to be a quant or a Solidity developer. You do need a willingness to think carefully.

What You Will Gain

By the end, you should be able to trace a single order from intention to execution; explain how funding rates, liquidation, and margin jointly hold a perpetual market to reality — and how, under stress, they fail; reason about price discovery, information efficiency, arbitrage, liquidity, and volatility as one connected system rather than isolated topics; and evaluate, regulate, and ultimately imagine *building* a better version of these markets. The aim is not to give you predictions to trade on, but a set of durable mental models that outlive any particular protocol or cycle. Along the way you will meet several analytical frameworks of my own — among them a four-source decomposition of volatility and a five-dimensional evaluation of market quality — offered not as final answers but as tools you can pick up, test, and sharpen.

How This Book Is Organized

The book has thirty-three chapters grouped into ten parts, and those parts build in five layers.

- **The foundation (Part I, Chapters 1–3)** asks what digital assets and perpetual futures actually are, and why they deserve to exist at all.
- **The ecosystem (Parts II–III, Chapters 4–9)** turns to who trades these instruments, the infrastructure they depend on, and how a single trade becomes a price — culminating in Hyperliquid as a worked case study of an on-chain order book.
- **The theoretical core (Parts IV–VIII, Chapters 10–24)** is the heart of the book: pricing mechanisms (funding, liquidation, margin), information and efficiency, arbitrage and anomalies, liquidity, and volatility — the deep operating logic of the market.
- **The engineering (Part IX, Chapters 25–30)** follows a "diagnose first, then prescribe" arc: measuring market quality and the economics of regulation, then designing trust, decentralized clearing, and automated governance — closing with a thought experiment on what happens if perpetual futures come to price the world.

- **The future (Part X, Chapters 31–33)** looks at AI as market infrastructure, the possibility of autonomous on-chain finance, and where all of this may be heading — ending not with a conclusion but with the next question.

Each part can be read on its own, but the arguments compound: the stop-loss order in Chapter 7 becomes the liquidation cascade of Chapter 11 and the volatility of Chapter 22; the three futures sketched in Chapter 3 are the ones judged in Chapter 33. Read straight through and you will feel the loops close.

The Landscape in 2026

As I write, perpetual futures have become the dominant instrument by volume in digital-asset markets — and the model is spilling beyond crypto, with perpetuals now written on equities, commodities, foreign exchange, and more. Meanwhile, the line between centralized and decentralized venues is visibly dissolving. On-chain order books that seemed like research toys a few years ago now clear meaningful flow; oracles, clearing, and margin logic increasingly live in public code; and regulators across major jurisdictions are moving from denial to design. It is a moment of unusual plasticity — the rules of this market are still being written, which is precisely why understanding its microstructure matters now rather than later. The choices made in the next few years about liquidation engines, oracle governance, and incentive design will harden into the plumbing of a global system. And a deeper shift is already visible at the edges: algorithms are moving from being tools of the market to being its infrastructure — quoting, hedging, clearing, and increasingly enforcing the rules themselves. Code defines those rules, algorithms execute them, and consensus verifies them; the outline of an autonomous financial system is emerging from theory into practice.

Why I Believe in This Future

I will be honest about my bias: I believe in the permissionless future. Not as an ideology and not as a promise that everything will go well — this book spends many of its chapters on exactly how these markets break — but as a direction: a long migration from permission to permissionlessness, from institutional trust to algorithmic trust, traced through the microstructure where that migration is actually decided. A world in which the core functions of finance are open, programmable, globally reachable, and auditable by anyone is, to me, a better world than the one we inherited, and I have chosen to spend my working life helping build it. This book is the most useful thing I know how to contribute to that project: an attempt to understand the thing clearly, so that we can build it well.

About the Author

Eric Cheung writes from a vantage point that spans both sides of this subject. Over a decade — from a PhD into hands-on R&D — he has come to understand how traditional finance actually works and where its problems lie. He is a trader himself, and he brings deep, practical experience in blockchain research and development. That combination — close enough to the markets to know how they behave under stress, and close enough to the technology to know how it is actually built — runs through every chapter. He believes in the future of permissionless finance.

Part I
Foundations

Core question: What exactly are digital assets and perpetual futures, and by what right do they exist in the world?

The Distinctiveness of Digital Assets Compared with Traditional Assets

In January 2024, the U.S. Securities and Exchange Commission (SEC) approved the first spot Bitcoin exchange-traded funds (ETFs). Net inflows over the first full year (2024) reached approximately $35 billion; by the end of 2025, assets under management had climbed into the hundreds of billions of dollars, and 13F filings showed that institutional investors had become major holders [1]. The immediate catalyst was Grayscale's 2023 courtroom victory over the SEC: the court ruled that the SEC's rejection of Grayscale's application to convert its Bitcoin trust into an ETF lacked a reasonable basis, forcing the agency to approve the product under judicial pressure rather than through any genuine shift in its regulatory stance. The regulatory trajectory for digital assets thus remains deeply uncertain. The seventh annual global crypto hedge fund report, jointly published by AIMA and PwC, found that 55% of the hedge funds surveyed had added digital assets to their portfolios, nearly double the under-30% share of roughly two years earlier [2]. Together these figures mark the passage of digital assets from fringe experiment to the core of global institutional asset allocation. Yet in November 2022 the collapse of FTX erased more than $8 billion in customer assets [3]. Hundreds of billions of dollars in institutional inflows, set against the sudden evaporation of billions, define the tension of the present moment: institutional allocation has reached systemic scale, yet the safety infrastructure has not matured to match it. That tension frames the chapter's central question. Is the difference between digital assets and traditional assets merely a set of technical features to be enumerated, or is it a more fundamental reorganization of the trust paradigm?

Answering it requires first understanding, in precise terms, the institutional logic of traditional finance. This chapter opens with the full journey of an ordinary stock trade, following the sequential involvement of at least nine independent institutions, a settlement cycle longer than 24 hours, and successive layers of capital lockup. From that journey it distills the five-layer functional architecture of trust in traditional finance: asset custody, trade execution, clearing and settlement, data verification, and rule governance. Each layer has suffered a defining failure, and each failure has prompted a new round of institutional repair. The institutional costs abstracted from the journey and its failures, namely settlement delay, compliance overhead, entry barriers, information asymmetry, and cross-border friction, appear unrelated but share a single root.

In the absence of technological trust, society must build trust through institutions; because those institutions are costly, their cost passes systematically to market participants. This chapter unifies these dispersed costs under a single analytical concept, the trust tax, and uses it to show, dimension by dimension, how the six distinctive properties of digital assets (permissionlessness, atomic divisibility, embedded settlement finality, around-the-clock continuous trading, smart-contract execution, and on-chain transparency) compress that systemic cost from different directions.

Once these properties are examined individually, a deeper structural feature emerges: they interact multiplicatively. Financial primitives impossible in traditional finance, such as flash loans, maximal extractable value (MEV), and protocol-level arbitrage, all emerge from several properties acting at once. Composability is at once a channel for innovation and a channel for contagion. On-chain transparency, even as it removes old information barriers, creates a new asymmetry rooted in the capacity to process information, so that fairness itself must be redefined. More fundamentally, this transformation changes not only how markets operate but the statistical character of risk itself. Traditional finance faces a risk surface of low-frequency but systemic shocks; digital assets face one of high-frequency shocks of highly variable magnitude, and the two demand fundamentally different approaches to risk management. Finally, the layered blending of three trust paradigms (institutional trust, platform trust, and architectural trust) offers a framework for choosing rationally between the two systems, one that moves beyond a simple binary.

These analytical tools form the starting point for the chapters that follow. The market for digital assets is not a simple narrative of decentralization replacing centralization; it is the largest natural experiment in financial history, using trillions of dollars of real capital to test, in real time, which elements of two centuries of financial institutions are essential, which can be replaced by technology, and which will reveal their indispensability only in the next crisis.

1.1 The trust architecture of traditional finance

The depth of the digital-asset transformation can be measured only against a full grasp of the institutional logic of traditional finance. This section therefore follows a single trade from start to finish, through the hands of at least nine independent institutions, and abstracts from that journey the five layers of trust on which traditional finance rests. It then unifies the institutional costs these functions generate under the analytical concept of the trust tax and argues that those costs, though high, buy real services.

1.1.1 The complete journey of a trade

The complexity of the traditional financial system is not the product of redundant design; it is the institutional response, evolved over two centuries, to a fundamental problem: how to transfer value safely among strangers who do not trust one another. This apparatus is best understood not from an abstract architecture diagram but by tracing a single trade from order submission to asset delivery, identifying at each step why a given institutional node exists and what it costs.

Alice decides to buy 100 shares of Microsoft stock. Through her broker's trading software she enters a limit buy order: 100 shares of MSFT at $450 or below. Behind this action, the broker, the first layer of intermediation between investor and market in traditional finance, performs three functions. Account management requires Alice to complete identity verification and anti-money-laundering (AML) screening when she opens the account; this is the first threshold of market access, ensuring that a participant's identity is traceable and accountable within the legal framework. Risk management and credit provision allow Alice to trade on leverage in a margin account, for which the broker monitors her margin ratio in real time and retains the right to liquidate her positions when risk exceeds limits. Smart order routing searches across more than 10 public exchanges and dozens of alternative trading systems for the best execution price. The SEC's Regulation NMS requires brokers to meet a best-execution obligation for their clients, one of the regulator's core requirements [4].

Between Alice and the market, the traditional financial system forms a clear pyramid. At the top are regulators, such as the SEC, the CFTC, and national central banks, which set rules, conduct oversight, and define the operating boundaries of the entire market. In the middle are infrastructure institutions, such as exchanges, central counterparties, and central securities depositories, which perform the core functions of price discovery, risk management, and asset delivery. At the bottom are client-facing intermediaries, such as brokers, market makers, and custodian banks, the channels through which investors reach the market. Trust flows from top to bottom: the broker at the bottom is trustworthy because the exchanges and clearing institutions above bind it to their rules, and those middle-tier institutions carry authority because the regulators at the top vouch for them. This hierarchical dependency means that a failure at any layer can unsettle the trust foundation of every layer above and below it. Yet the hierarchy also provides firewall isolation: each layer's institutional design can arrest contagion independently. The central counterparty (CCP) default waterfall, for instance, is itself an institutional firewall at Layer 3, designed precisely to contain an individual member's default losses within that layer. This firewall stands in sharp contrast to the flattened contagion paths of on-chain composability, which Section 1.3.3 examines.

Alice's limit buy order is routed to the Nasdaq exchange, where it enters the central limit order book. Harris (2003) [4] notes that the central limit order book is the core mechanism through which modern securities markets achieve effective price discovery, whereas on-chain order books face different constraints in latency and front-running risk, a subject taken up in later chapters. All unfilled limit orders are ranked by price priority and then time priority: higher-priced buy orders and lower-priced sell orders take precedence, and orders at the same price are ranked by arrival time. When a new market order arrives, it fills against the best available counterparty price and works down the book. This process is anonymous, automatic, and completed within microseconds. Through it the exchange aggregates countless dispersed, anonymous trading intentions into a public, continuous, and widely accepted transaction price, which is the essence of price discovery. On the book sits a limit sell order placed by a trader, Bob: 200 shares of MSFT at $450. Alice's 100-share buy order matches Bob's sell order, and the matching engine executes the trade within microseconds. Alice's 100 shares are filled at $450, and the remaining 100 shares of Bob's order stay on the book.

The exchange sends trade confirmations to both brokers.

Yet making a trade is not the same as completing it. At this moment the two parties have merely reached a legally binding contract, a promise to exchange assets and funds at some future point; no transfer of the assets or funds themselves has yet occurred. From here the trade enters the more complex phase of post-trade processing. The gap between execution and asset delivery is the very source of all the institutional complexity of traditional finance: it creates a window of counterparty-risk exposure, and the entire post-trade apparatus exists to manage the defaults, errors, and systemic risks that may arise within that window.

The post-trade phase brings in the single most important institutional innovation of traditional finance: the central counterparty. In the U.S. equity market, post-trade processing follows a T+1 settlement cycle, and before May 2024 it ran as long as T+2. The National Securities Clearing Corporation (NSCC), a subsidiary of DTCC, interposes itself in every trade through a legal process known as novation, becoming the seller to every buyer and the buyer to every seller. This novation is completed during a batch process on the evening of the trade date; until then, the two parties still bear the credit risk of their original counterparties. The original contract between Alice and Bob is replaced by two independent contracts, Alice with the NSCC and the NSCC with Bob, so that neither party owes a delivery obligation directly to the other. As long as the NSCC does not default, the trade's final completion carries an institutional guarantee. This arrangement lets market participants trade with anonymous counterparties in confidence, and it deepens market liquidity substantially. To manage the concentrated risk it assumes, the NSCC builds a multi-layered defense, the loss-sharing waterfall, whose layer-by-layer absorption sequence is detailed in Figure 1-1 of Section 1.1.2. Through strict membership admission, initial and variation margin posted against unsettled positions, and a default fund contributed jointly by all clearing members, it ensures that the clearing system keeps operating even if a member defaults. At the same time, the NSCC performs multilateral netting across the thousands of trades in a single day, offsetting a given clearing member's buys and sells in the same asset to compute a final net position. This reduces the volume that actually requires settlement by an order of magnitude and markedly lowers operating costs and liquidity needs.

Final asset delivery is carried out by the central securities depository, the DTC, also a DTCC subsidiary. The DTC is the centralized ledger that holds and records ownership of U.S. securities. Settlement is completed through delivery versus payment (DVP): the delivery of securities and the payment of funds are mutually conditional and occur simultaneously, eliminating principal risk, a principle realized more completely on-chain in the form of atomic settlement. Only after the final book-entry update on T+1 are 100 shares of MSFT formally credited to Alice's securities account, and only then does Bob receive the corresponding funds.

A seemingly simple purchase of 100 shares involves, in the back office, the sequential participation of at least nine independent institutions (broker, exchange, matching engine, clearing corporation, central counterparty, depository, payment system, regulator, and various data-service providers); it takes more than 24 hours, freezes substantial capital during settlement, and generates friction at every step. According to the post-

transition assessment jointly published by SIFMA, ICI, and DTCC, the NSCC clearing fund fell by an average of about $3 billion after the move to T+1, a decline of 23% [5]. Even under a T+1 cycle, then, settlement delay still levies a considerable cost in time. The internal logic of traditional finance becomes clear here: settlement delay buys the time that risk management requires, and centralized institutions supply the credit guarantees that make anonymous trading possible. These intermediation steps, compliance reviews, and waiting periods constitute the institutional cost society pays to keep trading safe in the absence of technological trust.

1.1.2 The five layers of trust

Alice's trading journey yields the five-layer functional architecture of trust in traditional finance. These layers are not the product of a single design; they are the accumulated sediment of two centuries of repeated failure, repair, further failure, and further repair. Each layer carries a core promise, and each has dedicated institutions to secure it. The primary lens for understanding these layers is not their flaws but the real protection they afford participants, protection that makes possible the worldwide allocation of hundreds of trillions of dollars.

The asset-custody layer ensures that client assets are strictly segregated from the intermediary's own assets. In the United States, SIPC insures each brokerage account up to $500,000 (of which $250,000 covers cash), and the FDIC insures bank deposits up to $250,000. These institutionalized safety nets allow ordinary savers and investors to participate in the market with confidence, without needing to understand the workings of the financial system. Alice need not assess her broker's solvency; the institution has made that judgment for her. The trade-execution layer ensures that orders are handled fairly, through independent exchanges and the best-execution obligation. The SEC's Regulation NMS requires brokers to seek the best price for clients across multiple venues rather than routing orders to whichever venue most benefits the broker itself [4]. At the clearing-and-settlement layer, the CCP mechanism expresses the protective power of traditional institutional design in its most concentrated form. Figure 1-1 presents the multi-layered defensive structure of the CCP loss-sharing waterfall: losses are absorbed starting with the defaulter's own resources and progressing to industry-wide mutualization, on the core principle that whoever creates the risk bears the loss first.

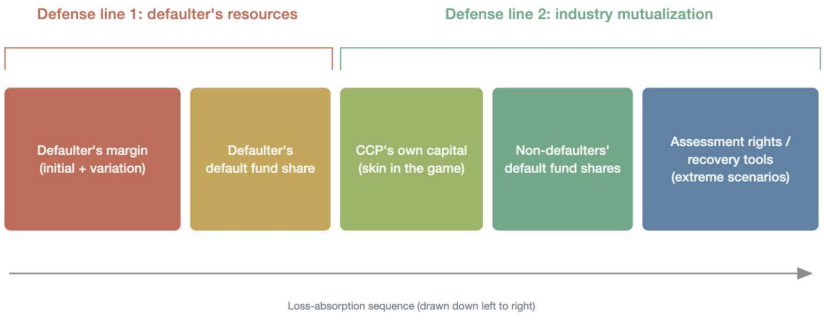

Figure 1-1. The CCP loss-sharing waterfall: when a clearing member defaults, losses are absorbed layer by layer in a preset order, extending from the first line of defense (the defaulter's own resources) to the second (industry mutualization), protecting the entire financial system's continued operation (the tiers indicate the sequence of loss absorption, and their widths do not represent proportional amounts; the default-management auction is a disposal step preceding the financial waterfall, and the tail includes assessment rights and recovery tools)

Most major CCPs contribute a portion of their own capital to the default waterfall, positioned ahead of the default fund contributions of non-defaulting members (the exact proportion and arrangement vary by institution and jurisdiction). This skin in the game ensures that the CCP has ample economic incentive to manage risk prudently. The waterfall defense withstood an extreme test in the 2008 financial crisis: when Lehman Brothers failed, tens of thousands of unsettled derivatives contracts were involved, yet the CCP system ultimately completed all clearing, and not a single CCP itself defaulted [6]. The data-verification layer ensures the authenticity of market prices through independent audits and regulated data vendors, providing trustworthy inputs for asset pricing and risk management. The rule-governance layer ensures the legitimacy and predictability of rule changes through the legislative process and the judicial system, giving market participants a stable set of expectations; a complete system of legal remedies, from arbitration to litigation to class action, offers investors a clear path of recourse.

The cumulative effect of these five layers of protection is a kind of trust free of understanding, the institutionalized expression of what Luhmann (1979) [7] defined as system trust. Most people need not understand the CCP default waterfall to entrust their savings to the stock market with confidence; this default trust is precious social capital accumulated over two centuries of institutional track record. But system trust exhibits a threshold effect: it accumulates gradually and is lost suddenly. Each layer of protection, however, has also suffered a defining failure that revealed the boundary of institutional safeguards. Table 1-1 sets out the five trust functions layer by layer, listing for each its core promise, the specific institutional arrangements that deliver it, and its most consequential historical failure. From the $1.6 billion scandal of MF Global's misappropriation of client funds at Layer 1 (asset custody) to the LIBOR manipulation affecting the pricing of $350 trillion in financial products at Layer 4 (data verification), each failure precisely exposed the boundary of the corresponding layer's safeguard.

Layer	Trust function	Core promise	Institutional implementation	Defining failure
Layer 1	Asset custody	Assets will not be misappropriated	CSD/DTC; SIPC insurance ($500,000 per account); FDIC deposit insurance ($250,000)	MF Global (2011): the futures broker behind the eighth-largest bankruptcy in U.S. history misappropriated $1.6 billion of segregated client funds to speculate on European sovereign debt [8]
Layer 2	Trade execution	Orders are executed fairly	Independent exchanges; best-execution obligation; market-surveillance systems	Dark pool scandals (2014–2016): dark pools operated by major banks such as Barclays systematically allowed high-frequency trading firms to front-run client orders; the SEC imposed $70 million in penalties [9]
Layer 3	Clearing and settlement	Trades will be delivered	CCP default waterfall; multilateral netting	Lehman Brothers (2008): the bankruptcy of the world's fourth-largest investment bank required the emergency handling of tens of thousands of unsettled OTC derivatives contracts, exposing the fatal weakness of OTC derivatives that lacked central clearing [6]
Layer 4	Data verification	Prices and data are authentic	Regulated data vendors; independent audits; benchmark-rate administrators	LIBOR manipulation (2012): the world's most widely referenced benchmark rate was systematically manipulated by more than 10 banks for years, affecting the pricing of over $350 trillion in financial products, with cumulative fines exceeding $9 billion [10]
Layer 5	Rule governance	Rule changes are lawful and transparent	SEC/CFTC; legislative process; judicial system	Post-2008: the financial crisis exposed systemic failures of the regulatory apparatus (the SEC failed to detect Madoff's 17-year Ponzi scheme), prompting the sweeping institutional repair of the Dodd-Frank Act [6]

Table 1-1. The five-layer trust functions of traditional finance and their defining failures (Data source: public records of the respective regulators [8][9][6][10]. Case-selection criterion: each layer's case is a landmark event with a completed regulatory investigation and an impact large enough to drive

institutional reform)

These failures should not be read simply as institutional incompetence. On the contrary, each prompted stricter institutional repair, and the system's capacity for self-correction is itself part of institutional trust. After MF Global, the CFTC strengthened the requirements for segregating client funds; after the LIBOR scandal, benchmark-rate setting shifted from banks' self-reported quotes to calculation from real transaction data; after the 2008 crisis, the Dodd-Frank Act brought previously unregulated OTC derivatives into central clearing and raised CCPs' capital and risk-control standards across the board. This cycle of failure, repair, further failure, and further repair yields three conclusions: trust is an institutional product that must be produced continuously rather than a natural endowment; the cost of failure is real and quantifiable; and these five functions give the later analysis a precise target as digital assets attempt to replace institutions with technology. Architectural trust must prove that it delivers at least an equivalent level of protection at each layer, or honestly acknowledge which layers it cannot yet replace. This five-layer structure is developed further in the verifiability ladder of Chapter 5 and the trust-stack design of Chapter 28.

1.1.3 The trust tax: a unified view of institutional cost

Alice's journey and the five layers of trust distill into a single unifying concept: the trust tax, the systemic cost society pays to maintain orderly trading in the absence of technological trust. The concept overlaps with, but is sharply distinct from, the transaction-cost economics of Williamson (1985) [11]. Williamson attributes transaction costs to two behavioral assumptions, bounded rationality and opportunism, and they span a broad range of costs such as search, bargaining, and monitoring. The trust tax is a specific subset of transaction costs: it concerns only the institutional costs that arise because the parties to a trade cannot establish trust at the technological level. Search and bargaining costs are not part of the trust tax, because they persist even under complete trust. The analytical value of this distinction is that it identifies precisely which costs digital assets can compress: architectural trust can replace part of what institutional trust does, but it cannot eliminate trust-independent frictions such as search and bargaining costs. The many seemingly unrelated trust costs of the traditional financial system all trace to the same root, and they are levied across six dimensions.

> The trust tax: the institutional cost society bears because it cannot establish trust at the technological level, the specific subset of transaction costs that architectural trust can compress.

These six dimensions are not an arbitrary list; they are extracted systematically from Alice's trading journey in Section 1.1.1, each corresponding to a class of observable institutional friction. Liquidity fragmentation (the splitting of liquidity across exchanges) and standardization costs (incompatible protocols across markets) are also real market frictions, but their root cause is coordination rather than an absence of trust, and they are therefore excluded from the trust-tax framework.

The settlement-delay tax manifests as the capital lockup and counterparty-risk window

created by the T+1 settlement cycle. Alice's funds are locked from T to T+1, unavailable for other trades, with counterparty-risk exposure exceeding 24 hours. As noted in Section 1.1.1, even though T+1 reduced the clearing fund by about $3 billion [5], the delay tax itself remains considerable. Figure 1-2 presents the historical evolution of the U.S. securities settlement cycle from T+5 to T+1 over more than three decades, each shortening demanding an industry coordination cycle on the order of a decade.

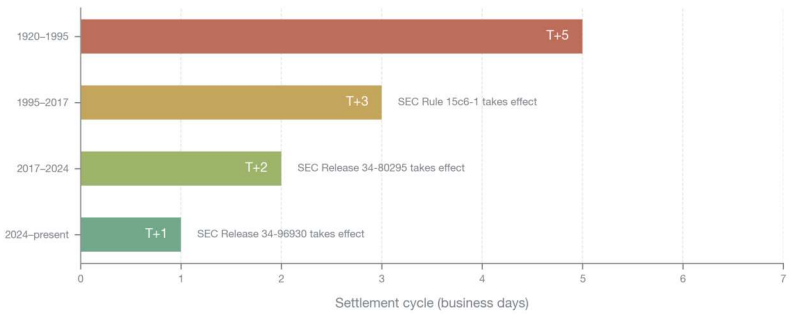

Figure 1-2. The historical evolution of the U.S. securities settlement cycle (Data source: SEC Rule 15c6-1, SEC Release 34-80295, SEC Release 34-96930 [5]; as of June 2026, T+1 remains the settlement cycle in force)

Each shortening released frozen capital, but the path itself reveals how entrenched settlement delay is: even when the technology had long permitted faster settlement, institutional inertia and coordination costs still held reform to a roughly decade-long cadence.

The trading-hours-fragmentation tax arises because restricted trading hours prevent information from being priced continuously. The New York Stock Exchange's regular session runs from 9:30 to 16:00 Eastern time, and the London Stock Exchange's from 8:00 to 16:30 Greenwich Mean Time; both close on weekends and public holidays. The U.S. stock market has roughly 252 trading days a year, meaning that on about 31% of days it does not trade at all. Information accumulates continuously while the market is closed but cannot be reflected in prices until it reopens, producing opening gaps and weekend risk exposure. If Alice holds positions in both New York and London, she also faces hedging difficulties created by the incomplete overlap of the two sessions.

The intermediary tax comes from the operating costs of brokers, clearinghouses, custodian banks, and similar institutions, costs ultimately borne by investors. Alice's trade passes through at least nine intermediaries, each with operating costs, compliance costs, and profit objectives. According to industry data cited by DTCC in advancing the T+1 reform, clearing and settlement is the main component of post-trade operating expenditure in traditional finance, accounting for roughly 20% to 25% [5]. The entry tax manifests as the licenses, capital requirements, and compliance thresholds that exclude the vast majority of potential participants. Alice must pass identity verification and AML screening before she can open an account; a market maker needs millions of dollars in capital and a months-long approval process; and the threshold for CCP clearing membership is higher still. Each entry barrier narrows the pool of participants and

limits competition.

The opacity tax arises from the information asymmetry that barriers to data access open up between institutions and retail investors. Professional-grade market-data terminals cost tens of thousands to hundreds of thousands of dollars a year [12], and Alice cannot obtain market data of the quality available to institutional investors. The LIBOR scandal [10] further demonstrated that even with institutional safeguards, key market data can still be manipulated through collusion among a handful of insiders; the question of who watches the watchers has never been fully resolved in traditional finance. The jurisdictional tax comes from the legal, time-zone, and currency frictions of cross-border transactions. According to World Bank data, the average cost of a global cross-border remittance is about 6.35% of the amount sent (based on a $200 remittance benchmark, first-quarter 2024 data; 6.4% in the fourth quarter of 2023) and takes three to five business days [13]. This figure reflects the cost structure of small retail remittances; institutional cross-border transfers are completed through the SWIFT/CLS system, and the percentage cost of large transfers is markedly lower. The trust tax is levied in structurally different proportions across participant tiers. If Alice wants to buy shares listed in London, she faces time-zone differences, exchange-rate risk, and multiple regulatory-compliance requirements all at once.

The analytical value of the trust-tax concept is that it unifies dispersed institutional costs into a single causal account: every cost traces to the same root. Parties cannot trust one another at the technological level, so institutions must supply that trust; and because institutions are costly, the cost is passed on. The five-layer function defines what trust must do; the trust tax measures what it costs. This framework gives precise coordinates for the analysis that follows: each of the six distinctive properties will be shown to compress some dimension of the trust tax, and the value of any financial innovation can be measured by how much trust tax it compresses against how much new cost it introduces.

1.1.4 The rationale for the trust tax

The trust tax is not useless institutional redundancy; it corresponds to four classes of real service. Systemic stability is the first. In the 2008 financial crisis, the CCP default waterfall proved to be the key institutional safeguard for the continued operation of the global financial system: as noted in Section 1.1.2, not a single CCP itself defaulted in the Lehman crisis [6]. The cost of this stability (the margin system, default funds, operating costs) is precisely the trust tax. Investor protection is the second: the institutionalized SIPC/FDIC safety net described in Section 1.1.2 lets the vast majority of people participate in the market with confidence, without understanding how the financial system works, and in doing so mobilizes trillions in capital. FTX's loss of more than $8 billion in customer assets [3] shows exactly what the absence of such protection costs. The FTX disaster was in essence a failure of the platform-trust model, not a defect of on-chain architectural trust: a centralized platform reproduced, in a new form, the misappropriation risk of traditional intermediaries, a distinction systematized in Section 1.4.3. Legal recourse is the third service. When a trading dispute arises, traditional finance provides a complete system of legal remedies from arbitra-

tion to litigation to class action, and investors have clear legal standing and a path of recourse. In on-chain finance, once assets are transferred through a code vulnerability or an attack, there is almost no legal mechanism for recovery; irreversibility is both a feature and a cost. The cumulative effect of institutional reputation is the fourth service. Two centuries of track record have created a default trust, the trust free of understanding discussed in Section 1.1.2. Although the DYOR culture of on-chain finance is healthier in principle, in practice it places the entire burden of risk management on each user. Behavioral-finance research shows that, faced with information overload, individual investors typically do not conduct genuinely independent research but rely on social proof and narrative shortcuts, which in crypto communities take the form of following KOLs, imitating smart-money addresses, and FOMO-driven decisions. The gap between the principle and the practice of DYOR is systemic, and self-directed diligence is unrealistic for most ordinary people.

The right question, then, is not how to abolish the trust tax but whether its current level far exceeds the value of the services it provides, and whether technology can deliver an equivalent level of service more efficiently. The existing evidence suggests that it can, but with one important qualification. Some dimensions of the trust tax can be compressed completely by technology: atomic settlement eliminates the T+1 delay, and on-chain transparency removes information barriers. Others can currently be compressed only in part; here the governance layer's trust tax stands out. The question of who has the right to modify the code is one the code itself cannot answer, and discretion in extreme cases may still require human judgment. At the governance layer, this projects the power and limits of *code as law* that Lessig (2000) [14] described (elaborated in Section 1.2.5). Whether the trust tax has an incompressible floor, whether some trust functions cannot in principle be replaced by code, is a question that runs through the entire book and is examined formally in the final chapter. Acknowledging the value of the trust tax while arguing that it can be compressed is the analytical stance that raises the book's framework above the one-dimensional narrative in which traditional finance is inefficient and digital assets are omnipotent.

1.2 The six distinctive properties and the compression of the trust tax

The six distinctive properties of digital assets are not a flat inventory of technical features; each property is a direct response to one dimension of the trust tax. This section adopts a single analytical framework throughout: the target of the trust tax, the technical response of digital assets, and the cost and limits of that response.

1.2.1 Permissionlessness: compressing the entry tax

The entry tax is the most perceptible dimension of the trust-tax system in traditional finance. From identity verification and anti-money-laundering screening for individual investors, to the capital and technical requirements imposed on market makers, to the top-tier banking credentials required of the clearing members of a central counterparty, traditional finance is essentially a system of nested permissions in which each layer

narrows the range of participants. Across the five layers of trust, the entry threshold at each layer is a direct expression of the entry tax.

Public blockchains fundamentally restructure this logic. Access rules are defined by code rather than administrative approval, and anyone who complies with the protocol's rules can participate. On Uniswap, for example, any user can interact directly with the smart contract to trade tokens, or become a de facto market maker by providing liquidity, without approval from any institution. The marginal cost of deploying a smart contract is minimal and the exit cost is zero; trust derives not from institutional endorsement but from the open-source nature of the code and the mathematical determinism of the protocol. Users retain full control of their assets by holding their private keys—a fundamental departure from the identity-based, permissioned system of traditional finance. Baumol's (1982) [15] theory of contestable markets provides an economic framework for understanding this shift: the persistent threat of potential competition forces incumbents to hold prices near marginal cost, systematically compressing the scope for rent-seeking. On-chain activity is not entirely free of sunk costs—gas fees, impermanent loss, and smart-contract deployment costs all constitute de facto entry barriers—but these costs are several orders of magnitude lower than the millions of dollars in capital and months-long approval cycles required to become a market maker in traditional finance. Market-making thus shifts from the privilege of a few institutions to open competition in which anyone can participate, and thousands of retail participants pool idle assets into liquidity pools whose total value locked reaches tens of billions of dollars. In execution quality (slippage and the capacity to absorb large orders) and dynamic price adjustment, however, automated market makers (AMMs) still lag well behind professional market makers, and liquidity providers bear the risk of impermanent loss. Even so, this permissionless model of liquidity provision has no precedent in traditional finance. On order-book decentralized exchanges (DEXs) such as Hyperliquid, permissionlessness likewise means that anyone can submit orders, yet effective market-making still requires sophisticated pricing algorithms and low-latency infrastructure; a lower entry threshold does not eliminate competitive advantage. This order-book model more accurately reflects the market structure that is the central subject of this book.

Permissionlessness compresses not only the entry tax but also the jurisdictional tax, in three directions at once. By removing geographic entry barriers, protocols on public blockchains treat users worldwide identically, without cross-border account opening or multiple layers of regulatory approval. Around-the-clock trading eliminates time-zone fragmentation. Atomic settlement eliminates cross-border settlement delay. A traditional cross-border remittance takes 3 to 5 business days and costs about 6.35% of the amount remitted (for the basis of this figure, see Section 1.1.3) [13], whereas an on-chain transfer completes in seconds to minutes and typically costs less than $1 on Layer 2 networks or low-gas-fee chains, though on Ethereum mainnet the cost can reach tens of dollars during periods of congestion. Together, these three shifts systematically compress the jurisdictional tax, moving financial services from the constraints of geographic jurisdiction toward global uniformity at the protocol level.

Permissionless access also lowers the cost of malicious behavior. It sits, at the same time, in growing tension with legal compliance obligations: the Financial Action Task

Force (FATF) Travel Rule [16] and the European Union's Markets in Crypto-Assets (MiCA) regulation are beginning to constrain technical permissionlessness from the legal side, and technical accessibility is not the same as legal accessibility. A lower entry threshold also lowers the cost of fraud: according to CertiK, crypto-asset losses from security incidents totaled approximately $3.35 billion over the course of 2025 [17]. Permissionlessness has also given rise to new strategic behaviors such as MEV bots and sandwich attacks, which preserve price efficiency while introducing new fairness problems. The net social benefit of permissionlessness depends on the maturity of the accompanying safeguards—disclosure regimes, reputation systems, and investor-protection tools.

1.2.2 Atomic divisibility: compressing the granularity barrier

Beyond licensing and compliance barriers, the entry tax also operates along an easily overlooked dimension, granularity—the institutional constraint on an asset's minimum tradable unit. When a single Class A share of Berkshire Hathaway trades above $600,000, the minimum investment unit is itself an entry barrier that excludes the vast majority of investors. The divisibility of traditional assets is tightly constrained by physical, legal, and institutional factors: a stock split requires a complex corporate action, trading distinguishes between round lots and odd lots, and price movements are limited by a minimum tick of $0.01 [4].

Digital assets remove these constraints at the protocol level. A single bitcoin can be divided into 100 million satoshis, and ether is divisible into as many as 10^{18} base units. On chain, transferring 0.000001 BTC is no different at the protocol level from transferring 1,000 BTC. In microstructural terms, this atomic divisibility means that prices can be distributed across a nearly continuous spectrum, giving the order book a price granularity far finer than that of traditional markets and thereby, in principle, improving the precision of price discovery. Combined with low transaction costs, atomic divisibility makes micropayments economically viable and provides the technical foundation for entirely new business models such as streaming payments and per-second billing. Together with the trend toward asset tokenization, atomic divisibility becomes the technical precondition for any asset to be split into arbitrarily small fractions and circulated worldwide—whether a tokenized U.S. Treasury fund or the tokenized real estate that may emerge in the future [18].

This property is not without cost. Excessively fine price granularity increases the complexity of the order book: when prices can be specified to 18 decimal places, liquidity is dispersed across an enormous number of price levels, the order book becomes *wide and shallow*, and effective liquidity may actually decline. Divisibility precision at the asset level must, however, be distinguished from the tick-size setting at the trading level. On real on-chain order-book DEXs, the tick size is set explicitly by protocol parameters—for a BTC/USD perpetual futures contract, for instance, the tick size is typically $0.1 to $1—far coarser than the smallest divisible unit of the underlying token; the risk of a wide, shallow book therefore arises more from the continuous price curve of AMMs than from the order book. This is also one of the sound reasons traditional markets impose a minimum tick. Price precision exhibits diminishing marginal returns: once

precision exceeds a trader's decision resolution, additional precision no longer creates economic value. An extremely low minimum investment threshold democratizes access, but it may also attract risk-unaware small investors who bear disproportionate losses in highly volatile markets.

1.2.3 Settlement finality: compressing the time tax

The time tax is one of the costliest dimensions of the trust-tax system. Alice's funds are locked between day T and day T+1, and this time gap has given rise to an entire institutional apparatus—central counterparties, margin systems, and loss-sharing waterfalls. Layer 3 of the five layers of trust is precisely the institutional response to this time gap.

Digital assets compress trade and settlement cryptographically into a single atomic operation: to trade is to settle. Once a transaction receives a sufficient number of network confirmations, the probability that it will be reversed falls exponentially with each additional confirmation. Different consensus mechanisms provide different types of finality guarantee. Bitcoin provides probabilistic finality; industry convention treats a transaction as effectively irreversible after 6 block confirmations (about 1 hour). Ethereum proof-of-stake (PoS) reaches economic finality—backed by validators' economic stake—after approximately 12.8 minutes. Purpose-built application chains typically reach finality on subsecond-to-second timescales. Whatever the type, this finality is secured by the computational resources or economic stake that the network commits, not by the promise of any centralized institution. In its 2025 annual report, the Bank for International Settlements (BIS) emphasizes that atomic settlement is a core feature of the next generation of monetary and financial systems: it allows assets to be exchanged simultaneously and thereby, in principle, eliminates principal risk [19]. Capital efficiency improves fundamentally as a result: market makers can recycle inventory more quickly, and operational friction across the financial system falls markedly. Atomic settlement, however, comes at a cost: while it eliminates the net-settlement time window, it also means that every transaction requires full, immediate funding, correspondingly raising the system's demand for instantaneous liquidity. Whether an equivalent batch-settlement mechanism (such as frequent batch auctions) exists on chain is an open design question.

Atomic settlement eliminates the settlement cascade—the chain of defaults triggered when one party fails to deliver on time, of which the domino effect set off by the collapse of Lehman Brothers is the classic case—but it cannot eliminate the liquidation cascade: the positive-feedback loop in which falling prices trigger forced liquidations, selling pressure, further declines, and still more liquidations. Atomic settlement not only fails to halt the liquidation cascade; by executing efficiently it may even accelerate the cascade's spread, compressing a liquidation process that takes days to weeks in traditional finance into minutes to hours. The factors that accelerate a liquidation cascade include the maintenance-margin ratio, the smoothing of the mark price, and the size of the insurance fund; Chapter 11 analyzes these design choices systematically, in its treatment of the endogenous reflexivity of leverage and liquidation. The focus of risk thus shifts from whether the counterparty will perform to three new dimensions:

whether the protocol code is correct, whether there is sufficient liquidity amid extreme volatility, and whether external data inputs are reliable. In perpetual futures, the mark price depends on oracle price feeds, and an oracle failure or manipulation can directly trigger an erroneous liquidation—neither a code vulnerability nor a liquidity problem, but a reliability risk in external data. This is the substitution of risk, not its elimination.

> The settlement cascade and the liquidation cascade are two fundamentally different mechanisms of risk transmission. Atomic settlement eliminates the former but may accelerate the latter—which explains why on-chain finance, having eliminated counterparty risk, still experiences violent shocks.

1.2.4 Around-the-clock trading: compressing temporal fragmentation

The fragmentation of trading hours makes it impossible to price information continuously. The regular trading session of the New York Stock Exchange covers only 6.5 hours of each business day, and information that arises during the remaining hours cannot be reflected in prices immediately. Blockchain networks have no concept of a market open or close: any piece of information can be priced immediately, turning the hard constraint of being unable to trade into the soft constraint of trading costs that vary across the hours of the day. Trading activity worldwide follows a cyclical rotation of liquidity over each 24-hour period. Figure 1-3 depicts this global liquidity cycle: trading activity across the three major time zones overlaps in successive waves, with liquidity concentrating in the overlap windows and falling markedly during the late-night gaps.

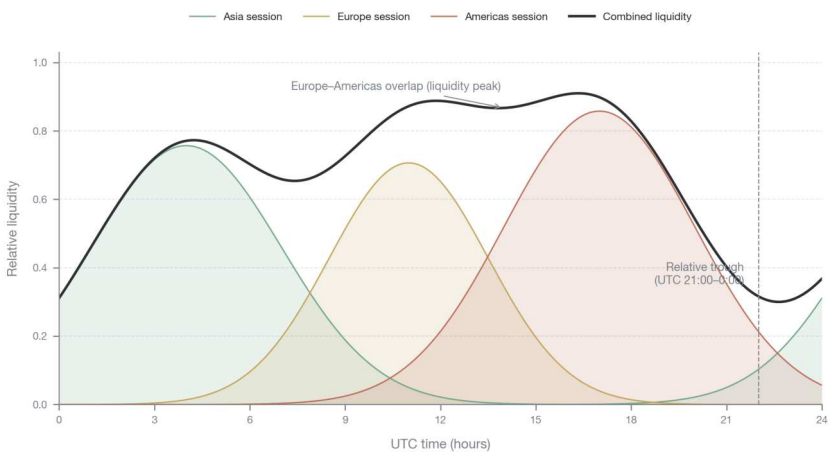

Figure 1-3. The 24-hour global liquidity cycle of digital-asset markets—the overlapping liquidity of the three major time zones: Asia, Europe, and the Americas (schematic modeling, not measured volume; because digital assets trade continuously 24/7, their troughs are shallower than those of foreign-exchange markets, and the timing of the overlap peaks drifts slightly with daylight saving time)

The activity peak of the Asian session typically falls between 1:00 and 7:00 UTC, and the European session between 8:00 and 14:00 UTC; when the European and American

sessions overlap (roughly 13:00 to 15:00 UTC), the market reaches its daily liquidity peak, while liquidity falls to a trough between 21:00 UTC and 0:00 the following day. During this low-liquidity window, the bid-ask spread can widen to several times its peak-session level, order-book depth drops noticeably, and the market-impact cost of large trades rises accordingly; this day-night variation in execution quality is a hidden cost specific to around-the-clock markets. Such cyclical rotation of global liquidity requires market makers and high-frequency trading firms to build global teams and infrastructure that continuously cover every session. The weekend effect—rising volatility accompanied by falling liquidity—already has systematic empirical support in crypto markets: Baur et al. (2019) [20], analyzing the intraday and cross-day patterns of Bitcoin trading volume and returns, confirm the statistical significance of this pattern.

Around-the-clock trading eliminates the systemic gap risk caused by market closures, but it does not eliminate price jumps caused by discontinuous liquidity or extreme events: when order-book depth thins abruptly during a low-liquidity period, a large order or a sudden news item can still produce a substantial price discontinuity. At the same time, around-the-clock trading removes three implicit protective functions that market closures once provided. After the close, market makers have time to reassess inventory, adjust models, and clear risk exposures; in an around-the-clock market this window for risk reassessment no longer exists, and market makers must manage all risk in real time under continuous operation. The suspension of trading during a closure dampens the immediate transmission of panic selling; in an around-the-clock market a liquidity crisis can spread without restraint in the thin-liquidity environment of the small hours. During a closure, an exchange can update its risk-control models and repair technical vulnerabilities; in an around-the-clock market such maintenance must be performed while the system is running. Exchanges in traditional markets have begun to explore extending trading hours: the Depository Trust & Clearing Corporation (DTCC) and Ernst & Young have discussed the possibility of a transition toward around-the-clock settlement [21], and BlackRock, in market research from the same period, likewise argues that 24-hour trading has structural implications for capital markets [22]. This reflects, in part, the competitive pressure that the around-the-clock trading model of digital assets exerts on traditional market structure; but it also demonstrates that around-the-clock operation is not without cost—otherwise traditional markets would have adopted it long ago.

1.2.5 Smart-contract execution: compressing the intermediary tax

The intermediary tax arises from the costs of interpreting and enforcing legal contracts, the inefficiency of manual processes, and the operating overhead of multiple layers of intermediaries. In traditional finance, each of the five layers of trust requires a specialized institution to operate it, and these operating costs constitute the core of the intermediary tax.

Smart contracts encode the terms of a financial agreement as a program that executes automatically on the blockchain, replacing ambiguous natural language with deterministic computation and human-intensive performance with automated execution. Lessig (2000) [14] presciently observed that code would become a regulatory force of deci-

sive influence in cyberspace, its power deriving both from its determinism and from its unavoidability. Smart contracts systematically replace the core functions of traditional intermediaries and have given rise to entirely new market mechanisms such as AMMs, decentralized lending, and algorithmic stablecoins. MakerDAO—a decentralized issuance system built from a cluster of smart contracts—shows that certain financial functions once borne mainly by sovereign institutions can be implemented in code [23]. This functional substitution, however, faces a challenge of legal characterization: MakerDAO's 2024 restructuring and rebranding to Sky was driven in part by regulatory pressure; DAI faces the risk of being classified as electronic money or a payment instrument in several jurisdictions; and MiCA imposes strict reserve and compliance requirements on stablecoin issuance. Once deployed, an AMM-based decentralized exchange executes its core matching function automatically through smart contracts, at very low marginal operating cost and without the back-office operations teams, physical trading infrastructure, and tiered compliance departments that a traditional exchange requires. Order-book DEXs such as Hyperliquid and dYdX v4, however, run on purpose-built application chains and require the continuous operation of a validator or sequencer network; although their total operating cost is far below that of a traditional exchange, it is nowhere near zero.

The principle of *code as rule* carries an inherent tension. Code cannot exercise discretion, cannot handle extreme situations its designers did not foresee, and, when code is law, the vulnerabilities in that code are executed automatically as well. According to Immunefi, losses from hacks and fraud of all kinds in 2023 alone amounted to approximately $1.8 billion (of which hacks accounted for about $1.6 billion, mostly related to DeFi smart contracts); this figure encompasses many distinct attack types—smart-contract logic flaws, cross-chain bridge attacks, and oracle manipulation—each with a different risk profile and defensive strategy [24]. Code must be upgraded, and the question of who has the authority to modify the code is itself a governance problem that only an institution can answer. Code as rule does not escape human governance entirely; it merely shifts the focus of governance from the enforcement of rules to their modification. Replacing legal compliance with code audits is not costless: formal verification and security audits themselves constitute a new trust tax, typically costing tens of thousands to hundreds of thousands of dollars depending on the complexity of the contract—though this remains far below the cost of traditional legal compliance.

1.2.6 On-chain transparency: the opacity tax and the transparency paradox

The opacity tax arises from information barriers: the information asymmetry between institutions and retail investors, and the monopolization of key market data by a handful of institutions. Layer 4 of the five layers of trust exists precisely to address the risk that data may not be truthful, yet this verification is itself opaque—the LIBOR scandal [10] demonstrated that data can still be manipulated even under institutional safeguards.

On a public blockchain, every transaction record and state change is publicly inspectable, and anyone can audit it independently. The actual degree of transparency,

however, depends on the underlying architecture: there is a marked difference between the full openness of Ethereum mainnet and the partial centralized operation of application chains (Hyperliquid's sequencer, for example, is operated by the team), where the accessibility and auditability of data depend on the transparency built into the sequencer's design. On-chain data-analytics platforms such as Dune Analytics, Nansen, and Arkham Intelligence parse, aggregate, and visualize raw data, greatly lowering the barrier to data analysis. For the first time, retail investors have the opportunity to obtain raw data of almost the same scope as institutions; yet democratizing access to data is not the same as democratizing decision quality. Behavioral-finance research suggests that greater access to information may increase overconfidence and trading frequency rather than improve investment decisions. The source of trust shifts, in part, from institutional brands and regulatory licenses to open-source code and verifiable data.

While it compresses the opacity tax, on-chain transparency creates a paradox of its own—the transparency paradox. In traditional finance, information asymmetry originates in differential rights of access to data, whereby some participants can reach information that others cannot. In on-chain finance, all participants can observe the same raw data, yet information asymmetry does not thereby disappear; it shifts from an asymmetry of access rights to an asymmetry of processing capability. Participants with stronger computational infrastructure and algorithmic capability can extract tradable signals more quickly from the same public data. Greater transparency therefore does not eliminate the information advantage but shifts the dimension of competition from data acquisition to data processing. MEV is the concentrated expression of this paradox: a public mempool makes all pending transactions visible to everyone, yet only searchers with the fastest infrastructure and the most sophisticated algorithms can convert that visibility into profit. The European Securities and Markets Authority (ESMA, 2025) [25] notes that MEV searchers typically pay more than 90% of their revenue to block proposers, making the right to order transactions a scarce resource; to address this, the Ethereum community has developed proposer-builder separation (PBS), which attempts to channel this competition from disorderly gaming into an orderly, market-based auction. Two forms of MEV must be distinguished, however: Ethereum-style public-mempool MEV (governed through the PBS architecture) and application-chain sequencer-style MEV, in which the sequencer determines transaction ordering—closer to a traditional exchange's last-look privilege. Later chapters analyze the MEV problems specific to order-book DEXs. Although on-chain markets are fully transparent, they are not necessarily fairer than traditional markets; the very definition of fairness needs to be re-examined—one of the central topics of the market-quality evaluation in Chapter 25.

> The transparency paradox: on-chain finance moves the competitive dimension of information asymmetry from the right to access data to the capability to process it. Transparency does not equal fairness.

Pseudonymity is also not the same as anonymity. The possibility of linking on-chain addresses to real-world identities through transaction-graph analysis has raised privacy concerns. The search for a balance between radical transparency and necessary privacy

is a key driver of frontier cryptographic techniques such as zero-knowledge proofs [26].

Each of these six distinctive properties compresses the trust tax along a different dimension: permissionlessness compresses the entry tax and the jurisdictional tax; atomic divisibility compresses the granularity dimension of the entry tax; embedded settlement finality compresses the time tax; around-the-clock trading compresses the trading-hours-fragmentation tax; smart contracts compress the intermediary tax; and on-chain transparency compresses the opacity tax. The mapping between the six properties and the six dimensions of the trust tax is not one-to-one but many-to-many: permissionlessness, for instance, compresses both the entry tax and the jurisdictional tax, while around-the-clock trading and atomic settlement jointly act on the time-related dimensions of the trust tax. This cross-mapping foreshadows the multiplicative interaction effects discussed in the next section. Thus far, however, each of these six analyses has proceeded in isolation, and the relationships among the dimensions have not yet been examined. Yet deep multiplicative interactions exist among the six properties, and it is these interactions that create entirely new financial primitives impossible in traditional finance.

1.3 The composability thesis

The previous section analyzed the six distinctive properties one by one, using the compression of the trust tax as its framework, but that property-by-property analysis obscured a deeper fact: the disruptive force of the six properties comes not from any single feature but from the multiplicative interactions among them. Schär (2021) [27], in the Federal Reserve Bank of St. Louis Review, was the first to analyze the economic implications of DeFi composability systematically, and Harvey, Ramachandran, and Santoro (2021) [28] extended this framework to institutional investment. Building on these analyses, this section shows both how the multiplicative effect of composability creates financial primitives impossible in traditional finance and how the same mechanism serves as a channel for risk contagion.

1.3.1 The interaction matrix of the six properties

Traditional finance can partially realize any one of the six distinctive properties—the extension of trading hours is being actively explored [21], and trials of T+0 settlement are under way—but it cannot realize all six at once; and it is precisely the simultaneous presence and interaction of all six that create the financial primitives impossible in traditional finance.

Table 1-2 presents, as a 6×6 symmetric matrix, the interaction effects produced by pairwise combinations of the six properties. Each cell in the matrix represents not the simple superposition of two features but the entirely new capability that emerges from their multiplicative interaction; several of these combinations give rise to financial primitives that are, in principle, impossible within the architecture of traditional finance.

	Permissionless	Divisible	Atomic settlement	24/7	Programmable	Transparent
Permissionless	—	Democratized micro-investing	Instant settlement with no entry barrier	Anyone, anywhere, anytime can participate	Anyone can deploy a protocol	Anyone can audit
Divisible		—	Atomic transfer of tiny amounts	Continuous streaming micropay-ments	Programmable precise fractions	Complete record of micro-transactions
Atomic settlement			—	Around-the-clock instant settlement	Flash loans	Fully verifiable settlement process
24/7				—	Continuous operation of the funding rate	Real-time monitoring
Programmable					—	MEV
Transparent						—

Table 1-2. The interaction matrix of the six distinctive properties (Data source: compiled by the author)

The 15 interaction cells above the diagonal display not the individual effect of each of the six features but the emergent results of 15 combinations. Three of these cells—flash loans, the continuous operation of the funding rate, and MEV—represent emergent products of paradigmatic significance: in traditional finance they are not merely unrealized but impossible to realize under that architecture.

1.3.2 Financial primitives impossible in traditional finance

The flash loan is the product of three interacting features: permissionlessness, atomic settlement, and programmability. Within a single atomic transaction, one can borrow, use, and repay any amount of an asset; if repayment fails, the entire transaction automatically reverts, achieving an instantaneous loan with zero collateral and zero risk. The Aave protocol pioneered this mechanism in 2020 [29]. In traditional finance, lending requires credit review (permissioned), incurs settlement delay (non-atomic), and involves manual approval (non-programmable); because none of these three preconditions is met, the flash loan is in principle impossible under that architecture. Flash loans change the economics of arbitrage: whereas arbitrage in traditional finance requires substantial upfront capital, flash loans make zero-collateral arbitrage possible (the real execution costs include gas fees, priority-fee payments in MEV competition, and infrastructure investment). They raise market efficiency while also lowering the cost barrier to attacks, and they are widely used for arbitrage, collateral swaps, and self-liquidation.

MEV arises from the interaction of three features: around-the-clock trading, transparency, and programmability. Because the market never closes, arbitrage opportuni-

ties persist continuously; because all pending transactions are visible to everyone in the public mempool, a program can analyze them within milliseconds and execute ahead of them. In traditional finance, comparable front-running is subject to a triple constraint: strict legal prohibition, non-public information, and exchanges' self-regulation. MEV is the economic embodiment of the transparency paradox. It both guards market efficiency (arbitrage corrects mispricing) and erodes fairness (sandwich attacks harm ordinary users); this dual nature makes the governance of MEV a central topic to which the Ethereum ecosystem continually devotes research resources [25].

Protocol-based arbitrage, exemplified by Ethena, combines three features: around-the-clock trading, atomic settlement, and programmability. Because the market runs continuously, the funding rate can settle automatically every 8 hours, and settlement is atomic; this allows the strategy of shorting perpetual futures while buying spot to earn the funding rate to be packaged into a single smart contract that anyone can join with one click and that manages billions of dollars in assets [30]. In traditional finance, this strategy cannot be turned into a protocol, for three reasons. First, settlement is not atomic: in a traditional arbitrage trade, the spot purchase and the derivative short settle through different clearing channels with a lag of several days, so the two cannot be packaged into a single indivisible operation. Second, rate settlement is not automated: adjusting the rate on a traditional interest rate swap or futures contract requires manual processes and multi-party confirmation. Third, access is not permissionless: a traditional trade of this kind requires an International Swaps and Derivatives Association (ISDA) master agreement, a prime-brokerage relationship, and a minimum position of millions of dollars. In addition, the maturity structures do not match: traditional futures have an expiry date and a basis trade has a definite convergence endpoint, whereas the absence of any expiry date for perpetual futures exposes a funding-rate strategy to the structural difference of an indefinite horizon—which is at once a precondition for turning the strategy into a protocol and a distinctive source of its risk. The simultaneous absence of these preconditions means that turning the strategy into a protocol is, in principle, impossible under the architecture of traditional finance, not merely difficult. Ethena's architecture packages a strategy once exclusive to institutional hedge funds into open, permissionless, protocol-level financial infrastructure. Its risk dimensions cannot be ignored, however: Ethena's hedging positions are concentrated on a handful of centralized exchanges, creating significant counterparty-concentration risk; the funding rate can turn negative for extended periods, so the yield on USDe can reverse into a loss; and USDe faces the risk of being classified as a security. More fundamentally, the degree to which Ethena is a protocol has a clear boundary: its core hedging operations rely on the platform trust of centralized exchanges rather than on pure architectural trust, so in the classification of trust paradigms in Section 1.4.3 it straddles two modes.

1.3.3 The dark side of composability

The multiplicative effect of composability runs both ways: it amplifies innovation and risk alike. When the output of protocol A becomes the input to protocol B and then serves as collateral in protocol C, a single failure in A propagates instantly to B and C, at a speed approaching the block time of the blockchain. Werner et al. (2022) [31], in a systematic review of DeFi, characterize this inter-protocol dependence as the core

structural source of risk contagion in on-chain finance.

The collapse of Terra/LUNA in May 2022 was an extreme demonstration of composability acting as a channel for risk contagion [32]. After UST lost its peg, LUNA entered a negative-feedback loop; several lending protocols that relied on UST as collateral underwent cascading liquidations; the entire DeFi ecosystem was shaken; and roughly $40 billion in market value (the total value of the LUNA and UST ecosystem, of which UST accounted for about $18 billion) evaporated within days. Behavioral-finance factors also played a substantial role here: Anchor Protocol's 19.5% "fixed yield" constituted a classic yield illusion, drawing many risk-unaware retail investors into overconcentrated allocations; and during the collapse, panic narratives spread on social media no slower than liquidations propagated on chain. The dark side of composability is not only technical and structural but also behavioral. This case is the intersection of composability with the settlement-cascade/liquidation-cascade distinction: atomic settlement accelerated the contagion, and composability widened its reach. Especially dangerous here is wrong-way risk: the core problem for protocols that relied on UST as collateral was that the value of the collateral and the positions it secured collapsed in the same direction under stress, a hidden correlation that is systematically underestimated in normal times.

The flash-loan attack on Euler Finance in March 2023 illustrated another contagion pathway. The attacker exploited a logic flaw in the Euler protocol and, through a series of flash-loan transactions, amplified the scale of the attack to extract about $197 million (the funds were later returned by the attacker). Because several DeFi protocols had deposited assets in Euler or used it as a source of yield, the impact of the attack extended far beyond Euler itself: protocols that depended on Euler, including Balancer, Angle Protocol, and Idle Finance, suffered losses simultaneously. Inter-protocol dependence in DeFi exhibits a highly concentrated hub-and-spoke topology in which a few core protocols anchor many dependency chains, so that an attack on a hub has a disproportionate systemic impact. The case is another clear instance of composability risk: inter-protocol dependence spreads the impact of a single vulnerability along the dependency chain to the entire protocol network.

Composability drives the marginal cost of financial innovation toward zero, but it also greatly accelerates the contagion of financial risk: intra-chain contagion can complete within a single transaction, or even a single block—faster than one block interval (in the Euler attack, the attacker extracted about $197 million within a few blocks)—whereas cross-chain contagion, constrained by bridging and oracle latency, spreads comparatively slowly. Innovation and risk contagion use the same set of inter-protocol call mechanisms, and this constitutes the core structural contradiction of on-chain finance. Protocol design in on-chain finance should not pursue maximum composability; it must strike a balance between the efficiency gains of composability and the contagion of risk—a subject taken up in depth in Chapter 20, on the endogenous fragility of liquidity, and Chapter 29, on the design of the clearing and settlement architecture.

> The core contradiction of composability: innovation and risk contagion share the same set of inter-protocol call mechanisms. This contradiction cannot be eliminated, only managed.

1.4 Microstructure reconstruction and the transformation of the risk surface

The transformations set in motion by the six distinctive properties and their composability ultimately converge into a systematic reconstruction of market microstructure and a fundamental transformation of the statistical properties of risk. Using the classic framework of Harris (2003) [4], this section summarizes the reconstruction of three elements—participants, processes, and information—then argues why the risk surfaces of the two financial systems require fundamentally different risk-management methodologies, and finally proposes a layered, hybrid framework of three trust paradigms.

1.4.1 The reconstruction of the three microstructure elements

The reconstruction of these three elements—participants, processes, and information—by digital assets has recurred throughout the analysis of the six distinctive properties in Sections 1.2.1 through 1.2.6; here it is consolidated within the Harris framework.

The reconstruction at the level of participants is the broadest in scope. Roles change from fixed identities defined by licenses to fluid states attached to wallet addresses: a single address can act as trader, market maker, arbitrageur, and liquidator on the same day. Automated economic agents—MEV searchers and liquidation bots, for example—become significant new market participants, and the traditional microstructure dichotomy between informed and uninformed traders no longer fully applies. The competitive structure flattens from a tiered, franchised hierarchy into open competition, but this can also lead to rent dissipation: competitors expend substantial resources contesting a fixed pool of MEV rents, driving the net social benefit toward zero. The PBS architecture is essentially a way to reduce this dissipation by converting disorderly competition into an auction mechanism. Chapter 4 develops a detailed model of seven categories of participants.

At the level of processes, once atomic settlement (Section 1.2.3) eliminates the T+N window of risk exposure, the focus of risk management shifts from assessing counterparty credit to auditing code security [19]. Smart contracts (Section 1.2.5) encode intermediary functions, structurally reducing operating costs. The atomicity of settlement guarantees the composability of financial operations, and the mode of innovation changes from designing new products to combining existing protocols.

At the level of information, information asymmetry shifts, as described in Section 1.2.6, from the right of access to processing capability. Tracking smart-money addresses and imitating their trades has become a common strategy, but it may intensify herding. The basis of trust changes from institutional brands to open-source code and verifiable data. The concept of privacy is redefined, and techniques such as zero-knowledge proofs are seeking a balance between radical transparency and necessary privacy [26].

The reconstruction of these three elements is the convergent expression, at the microstructure level, of the six distinctive properties. Building on this, two further questions arise: how these changes have altered the statistical properties of risk, and how the sources of trust should be reorganized.

1.4.2 The transformation of the risk surface

The risks of traditional finance and of digital assets differ not only in type but also fundamentally in their statistical properties, and therefore cannot be addressed with the same risk-management methodology. In his seminal paper, Mandelbrot (1963) [33] first demonstrated that the distribution of financial returns does not follow a normal distribution but instead exhibits fat tails—that is, extreme events occur with a probability far higher than the normal assumption predicts. Taleb (2007) [34] further argued that humans systematically underestimate the probability and impact of extreme events, and that traditional risk-control frameworks, designed under the normality assumption, fail systematically in a fat-tailed world. The risk surface of digital assets is an extreme expression of the fat-tailed world that Mandelbrot and Taleb described.

Table 1-3 compares the risk surfaces of the two financial systems along five dimensions: frequency, shock distribution, visibility, recovery speed, and risk-control tools. Each of the five dimensions points to the same conclusion: the risks of the two systems differ not in degree but in kind, and no single risk-management methodology can address both.

Dimension	The risk surface of traditional finance	The risk surface of digital assets
Frequency	Low—major crises occur on average once every 10 to 15 years [35]	High—protocol vulnerabilities and attacks occur weekly
Shock distribution	High-impact—once it occurs, it is systemic	Variable impact—most events have limited effect, but the tail is extremely fat
Visibility	Often invisible before a crisis, attributed only afterward	Many risks are visible on chain, but visible does not mean manageable
Recovery speed	Slow—institutional repair is measured in years	Fast—protocol repair is measured in days to weeks, but it may also be irreversible
Risk-control tools	VaR, stress testing, the Basel framework—based on the low-frequency, high-impact assumption	Require a new methodology that handles high-frequency small events and rare catastrophic events at once

Table 1-3. Comparison of the risk surfaces of traditional finance and digital assets (Data source: compiled by the author based on [35])

Figure 1-4 contrasts this difference in statistical properties with two probability-distribution curves: the tail probability of a fat-tailed distribution decays far more slowly than that of the normal (thin-tailed) distribution, and extreme events several standard deviations from the mean occur far more frequently than the normal assumption predicts. This is precisely why traditional value at risk (VaR) models fail systematically in on-chain markets.

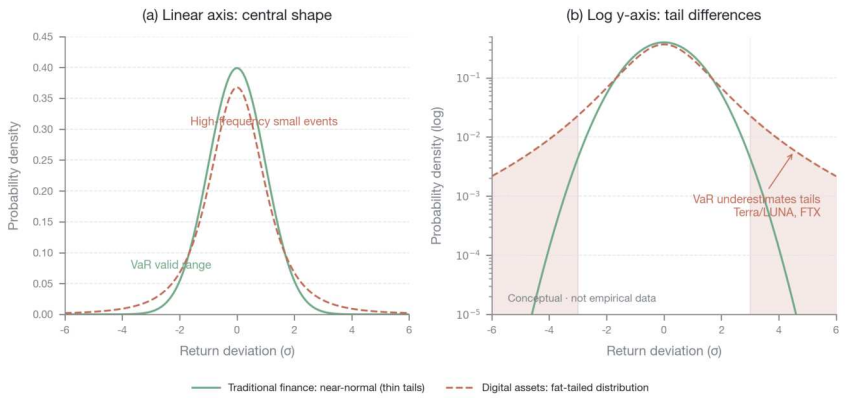

Figure 1-4. Comparison of the risk distributions of traditional finance and digital assets—the difference in tail probability between the normal (thin-tailed) distribution and the fat-tailed distribution (conceptual/theoretical illustration; the fat tail is modeled with a Student's t-distribution with 3 degrees of freedom; the Terra/LUNA and FTX labels in the figure are illustrative examples of tail events, not measured data points; the right panel uses a logarithmic vertical axis to highlight the tail difference; theoretical basis: Mandelbrot 1963 [33], Taleb 2007 [34])

To ask whether digital assets are more dangerous or safer is the wrong question. The right question is how the risk surfaces of the two systems differ and what different tools are needed to manage them. The risk surface of traditional finance is a distribution of low-frequency but systemic shocks. Reinhart and Rogoff's (2009) [35] systematic study of eight centuries of financial crises shows that banking crises recur on average every 10 to 15 years but are highly clustered and transmit across borders—and that traditional finance is not without high-frequency operational-risk events either (the 2010 U.S. stock-market flash crash, for instance, erased trillions of dollars in market value within minutes). The risk surface of digital assets is a distribution that is high-frequency and highly variable in the scale of its shocks: protocol vulnerabilities occur weekly, most with limited impact, but occasionally catastrophic. More striking still, the two risk surfaces are not independent: with the approval of Bitcoin exchange-traded funds (ETFs) and the entry of institutional investors, the correlation between digital assets and traditional finance rises markedly in periods of stress, and institutions that hold both asset classes become contagion channels when they deleverage, so the two are beginning to show signs of mutual contagion. This recognition is a prerequisite for understanding the risk analysis in Chapters 20 through 24.

The transformation of the risk surface also means that existing financial-regulatory frameworks such as Basel III—whose core parameter assumptions, such as the 10-day holding period in VaR and the 30-day stress period in the liquidity coverage ratio, are designed for the risk surface of traditional finance—may fail in two directions: overreacting to high-frequency small events (because the traditional framework treats any event as a potential systemic risk) while at the same time being underprepared for genuine tail risk (because the traditional framework's stress-test scenarios may not cover the extreme situations specific to on-chain markets, such as protocol-level vulnerabilities and the superposition of composability contagion and liquidation cascades). Investors accustomed to traditional finance may misread the high-frequency volatility of on-chain

markets as higher risk. Prospect theory shows that the psychological pain of frequent small losses can exceed their economic impact, prompting premature exit, while their underestimation of the probability of rare large losses leaves them underprepared for genuine tail risk. Systemic events on the scale of Terra/LUNA and FTX require a fundamentally different mental model and risk budget.

While compressing the traditional trust tax, digital assets introduce an entirely new cost structure. The security tax is the cost of smart-contract security audits and formal verification. As noted in Section 1.2.5, the one-time audit fee (tens of thousands to hundreds of thousands of dollars) is only the starting point: ongoing expenditures include bug-bounty programs (ranging from hundreds of thousands to millions of dollars), re-audits after contract upgrades, the operation of real-time monitoring systems, and the capital tied up in an insurance fund—and even after all of this, zero vulnerabilities cannot be guaranteed. The gas tax is the execution cost of on-chain transactions, which can spike tens of times over during network congestion and render small transactions economically infeasible. The private-key management tax is the cognitive burden and operational risk users bear in managing their own private keys: losing a private key means permanent loss of the assets, with no forgot-password recovery mechanism. Based on an analysis of dormant on-chain addresses, Chainalysis (in a 2020 report) estimated that about 3.7 million bitcoin—roughly 20% of the supply at the time—were permanently inaccessible because of lost private keys (this estimate rests on a dormancy heuristic and is somewhat contested, since it may conflate long-term holders with genuinely lost coins, though its order of magnitude is widely cited in the industry) [36]. The smart-contract vulnerability tax comprises the asset losses caused by exploited code flaws—irreversible and with no legal recourse [24]. The MEV-extraction tax is the hidden cost that competitive extraction of transaction-ordering rights imposes on ordinary users [25]. The governance-uncertainty tax shows up as low participation in DAO voting and the risk of governance attacks. Digital assets do not eliminate the trust tax; they replace an old trust tax with a new one. The standard for judging this paradigm shift is not whether the new trust tax is zero but whether its total is significantly lower than the old one and whether its distribution is fairer.

1.4.3 Three trust paradigms

Moving beyond the binary opposition of centralization and decentralization, trust can be organized into three paradigms. The concept of architectural trust builds on Werbach's (2018) [37] systematic analysis of blockchain trust mechanisms. Werbach distinguishes three traditional modes—peer-to-peer trust, Leviathan trust (state coercion), and intermediary trust—and argues that the blockchain creates a new trust architecture, one that establishes trust through technical design rather than interpersonal relationships or institutional authority. This chapter develops that analysis further into a threefold division of institutional trust, platform trust, and architectural trust; the introduction of platform trust reflects the key role that centralized platforms (such as FTX) play in practice in the digital-asset domain, a category not yet fully analyzed in Werbach's original framework.

Institutional trust draws on law, regulation, and specialized institutions; it offers a 200-

year track record, legal recourse, and consumer protection, but it is costly, opaque, slow, and difficult to enter, and the LIBOR scandal [10] proved that it can be manipulated by insiders. Platform trust draws on the operator of an exchange or platform; it offers high performance and a good user experience but depends entirely on a single entity, and the collapse of FTX [3] demonstrated the catastrophic consequences of that dependence—platform trust is essentially a repackaging of traditional centralized trust in the digital domain. Architectural trust draws on code, cryptography, and decentralized consensus; it is verifiable, globally accessible, and independent of any single entity, but it faces challenges such as code vulnerabilities, limited performance, and governance difficulties.

The three paradigms are not substitutes for one another; they can be mixed across layers. At the asset-custody layer, the self-custody approach of architectural trust eliminates, through private-key control, the risk of assets being misappropriated by a single centralized entity, but self-custody introduces a new spectrum of operational risks—key management, physical security, and disaster recovery. At the trade-execution layer, the centralized matching engine of platform trust offers an irreplaceable performance advantage in high-frequency settings, whereas the decentralized exchange of architectural trust is more competitive in transparency and censorship resistance; the optimal choice depends on the specific use case. Notably, the most successful on-chain order-book DEXs today (such as Hyperliquid and dYdX v4) adopt a hybrid architecture, in which centralization at the ordering and matching level coexists with on-chain settlement; this engineering compromise should not be classified simply as one paradigm or the other but as a pragmatic combination of the two. At the clearing and settlement layer, the atomic settlement of architectural trust eliminates the settlement cascade but cannot prevent the liquidation cascade, and extreme circumstances may still require the discretion that institutional trust provides. History already offers precedents: in the JELLY incident of March 2025, Hyperliquid's validator committee voted to delist the token and liquidate positions at a manually set price, and after The DAO incident of 2016 the Ethereum community reversed transactions through a hard fork—both instances in which architectural trust, under extreme stress, degenerated into discretionary decisions by a small number of people. At the data-verification layer, the on-chain transparency of architectural trust eliminates the possibility of LIBOR-style manipulation, but oracles (which bring off-chain data on chain) still require a degree of trust. At the rule-governance layer, the ultimate discretion and final arbitration that the legal and judicial systems of institutional trust provide in extreme cases remain, for now, irreplaceable; the question of who has the authority to modify the code still requires human judgment, and low participation in DAO governance and the risk of governance attacks together cast doubt on the reliability of pure architectural trust at this layer. In 2022, the Office of Foreign Assets Control (OFAC) sanctioned Tornado Cash, demonstrating that state power can intervene directly in protocol-level permissionlessness (a 2024 ruling of the Fifth Circuit later overturned the sanctions, and OFAC removed the entity from the Specially Designated Nationals (SDN) list in March 2025—a reminder that the exercise of state power is itself subject to judicial checks). The freezing orders that courts in several countries have developed in crypto-asset recovery cases, in turn, demonstrate that legal recourse is extending onto the chain.

The optimal financial infrastructure is neither fully decentralized nor fully centralized;

it is a layered architecture that makes the most reasonable choice of trust paradigm at each layer. This insight is systematized into concrete engineering choices in Chapter 5's spectrum of verifiability and Chapter 28's design of the trust stack. Combining the three paradigms with the trust-tax framework closes the loop: institutional trust carries the highest trust tax but the most comprehensive service; platform trust carries a moderate trust tax but an extremely high concentration risk; and architectural trust carries the lowest trust tax but incomplete service coverage. The optimal combination selects, at each layer, the paradigm with the lowest trust tax that still provides an adequate level of service—an engineering optimization problem, not an ideological stance.

1.5 Chapter summary

This chapter has assembled a complete analytical toolkit for understanding digital assets—the largest-scale natural experiment in financial history. The five layers of trust reveal the internal structure of traditional finance's trust architecture; each layer has a reason to exist, and each has failed at some point. The trust tax unifies the entire institutional cost of traditional finance into a causally explicable whole whose root cause is the absence of trust; the architecture of digital assets compresses this tax through technical means, but compression is not free, and the trust tax has its rationale. The composability thesis shows how the multiplicative interactions among the six distinctive properties create financial primitives impossible in traditional finance—flash loans, MEV, and protocol-based arbitrage—while composability is at the same time a channel for risk contagion. The transparency paradox establishes that on-chain transparency does not equal fairness: the dimension of competition shifts from who possesses information to who can process it fastest. The transformation of the risk surface demonstrates that the statistical properties of risk in the two financial systems are fundamentally different—not a question of more dangerous or safer, but one that requires different risk-management methodologies. The three trust paradigms provide a framework for choosing among different sources of trust, mixed across different functional layers, and the optimal solution is a layered, hybrid engineering problem.

These six concepts form a logical chain—from root-cause analysis (the trust tax), to technical response (the six distinctive properties), to emergent effects (the composability thesis and the transparency paradox), to risk reconstruction (the transformation of the risk surface), and finally to the reorganization of trust (the three trust paradigms)—and this chain is the starting point for the analysis developed in the chapters that follow.

The most far-reaching product of this experiment is perpetual futures—with an annual notional trading volume of about $86.2 trillion (on a centralized-exchange basis; about $92.9 trillion including decentralized exchanges) and accounting for more than 90% of crypto-derivatives trading volume [38]. Crypto-derivatives volume data, however, suffer from wash trading, so actual volume may be lower than the reported figures, and notional volume is inflated by high leverage; traditional exchange-traded derivatives lack a uniform annual notional-principal measure (the Futures Industry Association (FIA) counts by number of contracts—about 180 billion worldwide in 2024), making the two difficult to compare directly. Perpetual futures are the subject of the next chapter. The emergence of perpetual futures was no accident: it is the concentrated expression, in the

derivatives domain, of the composability of the six distinctive properties. In a market that trades continuously around the clock and settles in real time, the fixed-expiry design of traditional futures comes into structural conflict with the market's continuity. The theoretical conception of perpetual futures was proposed by Shiller (1993) [39], and BitMEX first engineered it in crypto markets in 2016. By abolishing the expiry date and introducing the funding-rate mechanism—which functionally replaces the price-convergence role of the expiry date—perpetual futures became a derivative form highly consonant with the continuous structure of this market, and they are the central object of the analysis that follows in this book.

Derivatives Markets and the Rise of Perpetual Futures

By CoinGecko's top-10 perpetual-exchange measure, crypto perpetual futures trading volume reached $92.9 trillion in 2025, of which centralized exchanges accounted for roughly $86.2 trillion and decentralized exchanges (DEXs) for roughly $6.7 trillion. Decentralized perpetual volume grew by roughly 3.5 times over the prior year's roughly $1.5 trillion, reaching approximately 4.5 times that level (about +347%) [1] [2]. A product that BitMEX did not formally launch until May 13, 2016 grew from nothing, in less than a decade, into one of the most important pricing and leverage infrastructures in the digital-asset market. Early BitMEX data show that derivatives markets lead BTC price discovery [3], and later research indicates that the regulated CME bitcoin futures market performs an important price-discovery function [4]. Together, this evidence shows that digital-asset price discovery has migrated substantially toward highly liquid derivatives markets, but it does not reduce to the claim that all spot prices mechanically track all perpetual futures (see Section 2.4.1).

This raises two questions: what problem does the design of perpetual futures solve, and what new cost does it introduce? Chapter 1 argued that the institutional costs of traditional finance can be unified as a trust tax, and that the six distinctive properties of digital assets compress this tax through multiplicative interaction. It closed by identifying perpetual futures as the composability product of these six properties in the domain of derivatives: the combination of 24/7 continuous trading, programmable rules, and atomic settlement creates a structural conflict between the fixed-expiry design of traditional futures and the continuous nature of digital assets. By abolishing the expiry date and introducing a funding rate mechanism, perpetual futures became the most natural form of derivative in this new environment. But being the *most natural* form does not make it *costless*. This chapter's central position is that perpetual futures are not an upgraded version of traditional futures but a costly design trade-off; only by understanding what they gain and what they lose can one understand this market.

This chapter retells the 400-year history of derivatives as three leaps in trust technology: personalized trust, institutionalized trust, and algorithmic trust. On that basis, it identifies three structural conflicts between traditional futures and digital assets—temporal mismatch, liquidity fragmentation, and trust mismatch—and shows how the two core design innovations of perpetual futures, together with their market outcome, address each conflict directly. It then analyzes the structural costs that accompany

these innovations and uses a leverage-cycle model to reveal the market's endogenous fragility. These frameworks are prerequisites for the book's later analysis: the multiple economic natures of the funding rate, the endogenous logic of the liquidation cascade, and the migration of the trust paradigm in decentralized perpetual futures.

2.1 The trust evolution of derivatives

The 400-year evolution of derivatives can be retold as three leaps in trust technology. Forward contracts rely on bilateral, personalized trust; futures contracts achieve institutionalized trust through standardization and the central counterparty (CCP); and perpetual futures achieve algorithmic trust through predefined rules and economic incentives. This section examines the trust logic and limitations of forwards, futures, and options in turn, distills a unified functional framework, and shows how perpetual futures complete the third leap in derivatives design.

2.1.1 Personalized trust and forward contracts

The forward contract is the logical starting point for all financial derivatives. Its definition is straightforward: a customized over-the-counter (OTC) agreement that binds two parties to buy or sell an underlying asset on a specified future date at a price agreed today. The wheat-forward trades between farmers and flour mills in the nineteenth-century American Midwest illustrate the basic form of intertemporal risk management: the farmer locks in the autumn selling price, the mill locks in its raw-material cost, and each sheds its exposure to future price uncertainty. Hull (2022) [5] notes that this risk-transfer function is the economic foundation of all derivatives.

The core dilemma of the forward contract is counterparty credit risk. If the autumn market price of wheat is far above the agreed contract price, the farmer has a strong incentive to default; if it is far below, the same is true of the mill. Without a neutral and powerful guarantee of performance, the forward market's size is limited by its radius of trust: it can operate only within a circle of acquaintances bound by social ties [5]. Illiquidity compounds the problem. Every forward contract is customized and can barely be transferred to a third party; once a position is established, the only exits are performance and default. The forward market is essentially a network of countless isolated bilateral credit relationships rather than a single, liquid market.

Viewed through the trust-layer framework of Chapter 1, the fundamental problem of the forward contract is that it has no independent trust-function layer: no independent custody, no independent clearing, and no independent data verification. All trust functions are folded into a single bilateral relationship, so if one party's credit collapses, the entire contract collapses. The forward contract therefore pays a very high tax for trust, in the form of a constrained market size and counterparty risk; every potential transaction beyond the radius of trust goes unconsummated because the cost of trust is too high.

2.1.2 Institutionalized trust and the futures revolution

Futures contracts answered the trust bottleneck of the forward through two core institutional innovations. Standardization converted the customization of the forward into uniform specifications—contract size, grade of the underlying, delivery date, and delivery location were all fixed—creating fungibility: any contract for a given month is identical to every other contract for that month. This fungibility lays the foundation for free transfer and markedly improves liquidity. The founding of the Chicago Board of Trade in 1848 marked the institutional starting point of this model [5]. The CCP interposes itself in every trade through novation, becoming the seller to every buyer and the buyer to every seller; it consolidates countless dispersed bilateral credit relationships into concentrated trust in a single central institution, fundamentally resolving counterparty risk.

The CCP's risk-management architecture centers on a loss-sharing waterfall: strict membership admission ensures that only well-capitalized institutions can participate; the margin system requires clearing members to post initial and maintenance margin and to submit to daily mark-to-market; and the default waterfall draws in turn on the defaulter's margin, the CCP's own capital, and the guarantee fund contributed by non-defaulting members. This architecture converts the problem of *trusting a person* into the problem of *trusting an institution*. The CCP's credit rating far exceeds that of any individual trader, but the CCP itself becomes a systemic node. *Concentrating risk in order to manage risk* is the inherent contradiction of the CCP model—a point Chapter 1 developed in its analysis of the chain reaction triggered by Lehman Brothers' collapse.

Viewed through Chapter 1's five-layer trust-function lens, futures contracts realize, through specialized institutions, the trust functions that forward contracts lacked: the exchange provides fair execution, the CCP provides clearing, custodian banks hold margin, and regulators impose rule-based constraints. Institutionalizing trust extended the market's reach from a circle of acquaintances to strangers worldwide. This extension raises the trust tax, because each independent trust-function layer needs a specialized institution to run it, with its own operating costs and compliance requirements; yet the liquidity and risk-management efficiency it releases far exceed that incremental tax. The inherent contradiction of the CCP model—whether technological means can inherit the CCP's risk-management function while avoiding its centralization risk—sets up the third leap.

2.1.3 Options and nonlinear payoffs

Options moved beyond the linear payoff of futures, granting the holder a right rather than an obligation and creating an asymmetric risk structure. The buyer of a call profits when the underlying rises and loses only the premium when it falls, combining limited downside with unlimited upside. The buyer of a put, conversely, gains protection when the underlying falls, retaining upside while hedging downside risk.

Black and Scholes (1973) [6] solved the central problem of option pricing, showing that an option's price is determined by five factors: the price of the underlying, the strike price, the risk-free rate, the time to expiry, and volatility. Their core insight is that the

higher the volatility, the greater the option's value. In the highly volatile digital-asset market, this relationship implies that options should, in theory, command a relatively high premium. The empirical outcome is the opposite: options have not become the dominant derivative in the digital-asset market, and crypto option trading volume in 2025 was far below that of perpetual futures [1]. This *thing that did not happen* demands explanation just as much as the pronounced dominance of perpetual futures.

From the standpoint of trust technology, the innovation of options lies in the payoff structure, not in the trust mechanism. Options rest on the same institutionalized-trust foundation as futures: exchange matching, CCP clearing, and margin management. The options clearing corporation—epitomized by the Options Clearing Corporation (OCC) in the United States—is structurally isomorphic to the futures CCP. Options therefore extend derivatives within the payoff space rather than mark a new leap in the trust paradigm. This distinction helps explain why options have failed to displace perpetual futures in the crypto market: options solve a payoff-structure problem, whereas perpetual futures solve a trust-paradigm problem, and the latter is the more fundamental challenge facing the digital-asset market.

Preliminary clues point in three directions. Although the nonlinear payoff of options is theoretically superior, for most crypto-market participants, who engage primarily in directional speculation, the linear payoff of futures is more intuitive and easier to grasp. Behavioral finance offers a deeper explanation: mental accounting leads traders to perceive an option premium as a *certain loss*, while leveraged margin is filed as a *temporary loss that may yet be recovered*, and this framing systematically favors futures over options. Market-making in options is also far more complex than in linear contracts, because market makers must manage five risk dimensions at once (delta, gamma, theta, vega, and rho); under the crypto market's limited liquidity, this complexity widens quoted spreads and thins depth. Most fundamentally, one core input to option pricing—the time to expiry—runs into structural difficulty in a product designed without an expiry date, a point analyzed in Section 2.2.4.

2.1.4 A unified functional framework

All derivatives, whether the structurally simple forward or the intricately designed option, serve four core economic functions. Risk transfer moves risk from those unwilling to bear it to those willing to bear it, allocating risk more efficiently across society. Price discovery, through traders' buying and selling, incorporates information and expectations into derivative prices, giving the whole economy forward-looking signals. The pioneering study by Garbade and Silber (1983) [7] provided a classic empirical framework for price discovery in futures markets, and its methodology has strongly shaped later research on price discovery in digital-asset markets. Capital efficiency, through the margin system, lets traders control positions of relatively large value with little capital. Liquidity provision, through standardization and centralized trading, attracts many traders and market makers, so participants can enter and exit at any time and at relatively low cost.

Through institutionalized trust, traditional derivatives have served global capital markets for more than a century, with exchanges such as CME, ICE, and Eurex processing

tens of trillions of dollars in contract volume each year. But this system rests on a set of basic assumptions about trading hours, jurisdiction, and trusted intermediaries. When those assumptions collide with the native characteristics of digital assets, structural conflicts become unavoidable. Section 2.2 develops these conflicts systematically.

2.1.5 Algorithmic trust and perpetual futures

The path from theory to practice passed through three milestones. Shiller (1993) [8] proposed a perpetual, delivery-free futures contract that would adjust the deviation between the contract price and the underlying index through an overnight financing rate. In traditional finance, the idea sat unused, overlooked by academics for more than two decades for lack of an application. In 2011, developers implemented a preliminary inverse bitcoin futures contract on the ICBIT exchange, demonstrating technical feasibility; limited in scale and influence, it nonetheless carried the idea from theory to a working prototype. On May 13, 2016, BitMEX formally launched the XBTUSD perpetual futures contract [9], turning the concept into market reality. Two core design innovations—abolishing the expiry-and-delivery date and anchoring the price through a funding rate—together with their market outcome, the concentration of liquidity in a single contract, established BitMEX as the paradigm for digital-asset derivatives.

The trust mechanism of perpetual futures no longer rests on the personalized trust of a circle of acquaintances, and it also reduces reliance on the institutionalized trust of the traditional CCP; instead, it hands part of risk control to predefined algorithmic rules and economic incentives. Through internal transfer payments among traders, the funding rate achieves price anchoring through a market-based negative feedback loop. The two settings differ. On a centralized exchange (CEX), anchoring still relies on platform matching, the mark price, the margin system, the insurance fund, and auto-deleveraging (ADL) rules; only in the DEX setting does it approach an architectural trust jointly constituted by code, oracles, sequencing, and governance. How these two innovations and their market outcome address the structural conflicts between traditional futures and digital assets is argued in Sections 2.2 and 2.3.

2.2 The three structural conflicts

The institutional design of traditional futures embeds three assumptions: discrete trading hours, geographically defined jurisdiction, and centralized trusted intermediaries. The native characteristics of digital assets (continuous global trading 24/7, the absence of jurisdictional boundaries, and code as the basis of trust) conflict with these assumptions not as technical friction but as a fundamental incompatibility between two market paradigms. Transplanting traditional futures directly into the digital-asset world therefore entails structural friction, and the market needs a derivative that fits digital assets more closely. Perpetual futures are one of the principal responses to this need; they are not an incremental improvement on traditional futures but a fundamental redesign built for the native character of digital assets—round-the-clock, globalized flow. The argument proceeds along three dimensions: temporal mismatch, liquidity fragmentation, and trust mismatch.

2.2.1 Temporal mismatch

One of the core assumptions of traditional futures is a fixed, discrete expiry date: the contract has a defined life cycle and is delivered or rolled over before expiry. The digital-asset market runs around the clock and year-round, with no open and no close, no weekends, and no holidays, and information must be priced continuously. This conflict generates friction along three dimensions.

The first friction concerns the expiry date. Long-term holders must roll over repeatedly—closing the contract about to expire and opening a new, more distant one—and so bear double the transaction costs and basis risk. In the highly volatile crypto market, basis fluctuations during the roll window can wipe out weeks of trading profit. The second concerns trading hours. Even when traditional futures extend trading through electronic sessions, they remain constrained by weekends, holidays, daily settlement, and the contract life cycle, whereas the digital-asset market generates information continuously, day and night. When information accumulates during a market closure or a low-liquidity window but cannot be fully priced, the result can be price gaps and interruptions in risk management. The third concerns informational continuity. Traditional futures struggle to provide fully continuous price discovery for digital assets, which generate information around the clock.

The essence of this conflict is that the temporal structure of traditional futures was designed for traditional assets. The information flow and trading activity of traditional assets follow a natural daily and weekly cycle, and digital assets break that cycle. Forcing a continuous information flow into a discrete contract structure necessarily produces friction. Roll costs deserve careful economic accounting here. The concentration of trading volume in the front-month contract is a general phenomenon in futures markets—whether for crude oil or Treasury futures, the front-month contract typically accounts for the vast majority of volume—so the concentration of volume in CME bitcoin front-month futures [10] is not itself specific to digital assets. The more direct mechanism is this: perpetual futures remove the choice of maturity from the product structure, so traders need not choose among front-month, quarterly, and back-month contracts, nor roll over repeatedly to hold a continuous position. This is why a single contract that never has to be rolled naturally attracts more concentrated liquidity.

2.2.2 Liquidity fragmentation

Traditional futures meet demand across different maturities through multiple monthly contracts (front-month, back-month, quarterly), each month forming an independent liquidity pool. A digital asset is globally unified: BTC, unlike oil, has no delivery location, and, unlike Treasuries, no differing maturities; in essence it calls for a single, maximally deep liquidity pool. The multi-month design scatters across several pools the liquidity that ought to be concentrated in one, leaving each pool too shallow and raising the impact cost of large trades. In the digital-asset market, where liquidity is already thin relative to traditional markets, this fragmentation is especially costly.

Liquidity fragmentation is closely tied to price discovery. Precisely because multi-month futures cannot provide enough depth, price discovery for digital assets cannot proceed effectively within traditional futures. The market needs a product that gathers all

liquidity in one place. By abolishing the expiry date, perpetual futures concentrate all trading depth in a single contract, achieving a high degree of liquidity aggregation. This is not a marginal improvement but a paradigm shift from *liquidity dispersed across multiple temporal dimensions* to *liquidity concentrated in a single contract with no temporal dimension*.

Yet while perpetual futures eliminate fragmentation in time, they do not eliminate it in space. Perpetual futures on the same underlying are spread across dozens of exchanges—Binance, OKX, Bybit, dYdX, and Hyperliquid each run independent order books—and their depth is not shared, so fragmentation shifts from the temporal to the spatial. Under normal conditions, cross-exchange arbitrageurs effectively close this spatial gap, hedging across platforms whenever a price gap appears and keeping prices consistent among exchanges. In extreme markets, however, arbitrageurs face capital constraints (margin is locked on multiple exchanges and cannot be moved between them) and execution constraints (an exchange may restrict new position-opening or suspend withdrawals), so spatial fragmentation reemerges precisely when unified liquidity is most needed. Section 2.3.1 develops the analysis of arbitrageurs' fragility in extreme environments.

2.2.3 Trust mismatch

The trust foundation of traditional futures is the CCP—a centralized, regulated, well-capitalized institution. Participants trust the CCP, and the CCP trusts its members, forming layer upon layer of nested institutional trust. The core value of the digital-asset community is verifiability: it seeks permissionless trust guaranteed by code. This philosophical incompatibility generates conflict at three levels.

The CCP model requires high entry barriers: membership, capital, and compliance review are prerequisites for participation, at odds with the permissionless access of digital assets. The CCP's operations are opaque to outside participants—its core processes, such as risk-management models, margin calculations, and shortfall-handling procedures, are not public—conflicting with the radical transparency of on-chain systems. And the CCP is a single point of failure whose collapse can trigger a systemic crisis, contrary to the distributed resilience that digital assets pursue. This conflict is not a technical obstacle but a fundamental tension between two trust paradigms; Chapter 1's analysis of the three trust paradigms maps here onto the derivatives market. Perpetual futures provide, through the funding rate mechanism, an algorithmic-trust solution that does not depend on a CCP; but the solution is imperfect, and its costs are developed in Sections 2.3 and 2.4.

2.2.4 Ruling out the alternatives

If abolishing the expiry date and adapting to a round-the-clock market are the core requirements, at least two other products could serve similar functions: the perpetual option and the contract for difference (CFD). Understanding why perpetual futures won out helps pinpoint their distinctive value.

The perpetual option faces a structural market obstacle. One core input to option pricing is the time to expiry, and time-value decay is a fundamental feature of options.

Abolishing the expiry date sends the time to expiry to infinity, and the standard Black-Scholes framework for European options no longer applies. In theory, a perpetual American option does have a closed-form solution—Merton (1973) [11] derived the analytical pricing formula for the perpetual American put, and Hull (2022) [5] sets it out systematically—and academics and practitioners have proposed innovations such as everlasting options. The two must be kept distinct. Merton's perpetual American option is a mathematical object whose pricing depends on solving for the optimal exercise boundary and assumes the holder can exercise at any moment; everlasting options, by contrast, are a product design that rolls a series of short-dated options into long-term exposure through a funding-rate mechanism similar to that of perpetual futures, so the holder makes no exercise decision but pays a continuous financing cost. The core obstacle to the perpetual option is therefore not theoretical feasibility but the practical constraints of liquidity and complexity. As Section 2.1.3 showed, the nonlinear payoff of options and the five-dimensional complexity of market-making make it hard to build competitive market-making depth under crypto-market liquidity conditions. Options thus have distinctive value in the crypto market, particularly for institutional tail-risk hedging, but for these structural reasons they cannot become the dominant derivative.

The CFD has existed in traditional finance for decades. It, too, is a synthetic derivative (no expiry date, high leverage, no need to hold the underlying) and looks very much like a perpetual future. Yet the two differ fundamentally in structure. Under the typical B-book model, the counterparty to a CFD is the broker or platform: the user bets against the platform, the platform profits from the user's losses, and a structural conflict of interest exists. Some CFD brokers adopt the A-book model, hedging client order flow to external liquidity providers; the broker then does not profit directly from client losses, but the A-book model is not the norm in the retail CFD market. Perpetual futures, by contrast, match a trader's order against other traders' orders through an order book, so the market discovers the price, the platform earns fees, and users' gains and losses are not directly tied to the platform. A CFD's price-anchoring mechanism varies by model: under the B-book model, anchoring depends on the broker's reputation and regulatory constraints and is essentially an unverifiable promise; under the A-book model, the price tracks the underlying market's liquidity but has no explicit algorithmic anchor. Either way, the anchor is unverifiable: the user cannot independently audit whether the price is fair. The funding rate of a perpetual future supplies a mathematically verifiable algorithmic anchor instead. The distinctive position of perpetual futures is thus clear: they combine the convenience of a CFD (no expiry date, synthetic exposure, high leverage) with the market-based price discovery of futures (order-book matching eliminates the platform-user conflict of interest), and, through the algorithmic anchor of the funding rate, they strike an effective balance among degree of innovation, simplicity, and market-makability. In 2021, the United Kingdom's Financial Conduct Authority (FCA) banned the sale of crypto derivatives to retail consumers, and the European Securities and Markets Authority (ESMA) has held that crypto assets should be classified by reference to the boundary of financial instruments [12] [13]. This suggests that, as a matter of legal classification, perpetual futures may be brought within the CFD or other derivatives frameworks and subjected

to the associated leverage limits, negative-balance protection, and retail-investor protection rules—a risk discussed further in Chapter 26 (for regulatory evolution, see Section 2.4.5).

In sum, the two core design innovations of perpetual futures map onto the three structural conflicts above: abolishing the expiry date addresses temporal mismatch, the funding rate addresses trust mismatch, and the concentration of liquidity in a single contract—the market outcome of these two innovations—addresses liquidity fragmentation. The innovations and the outcome are mutually dependent: abolishing the expiry date lets liquidity concentrate, but it also removes the hard anchor of expiry convergence, which is why the funding rate is needed as a substitute soft anchor. Section 2.3 turns to the internal logic of these mechanism designs.

Figure 2-1 places the four forms—forward, futures, option, and perpetual—on a timeline, corresponding to the three leaps of personalized, institutionalized, and algorithmic trust.

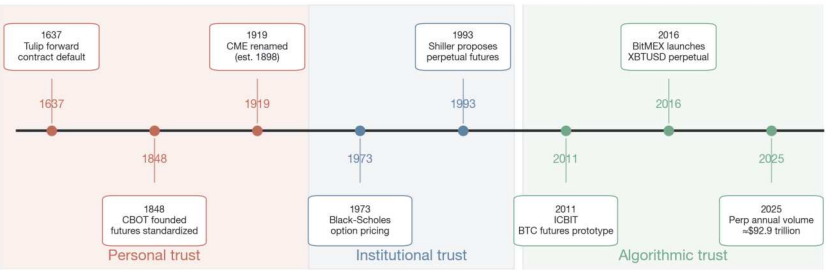

Figure 2-1. Timeline of derivatives evolution—the three leaps in trust mechanisms (Data source: Hull 2022 [5], Shiller 1993 [8], Hayes 2016 [9]; the roughly $92.9 trillion figure for 2025 annual perpetual futures volume shown in the figure follows [1][2])

The difference in payoff structure between futures and options is a key premise for understanding why perpetual futures rose to dominance. Figure 2-2 juxtaposes the two payoff curves: the futures payoff is linear and symmetric, while the option payoff is asymmetric (the downside is capped at the premium and the upside is theoretically unbounded). It is precisely this contrast between linear and nonlinear that drives the divergence in market-making complexity, cognitive barriers, and use cases described in Sections 2.1.3 and 2.2.4.

2.3 The core mechanisms of perpetual futures

This section examines the internal logic behind the design of perpetual futures. Their operation relies on two core mechanisms: the funding rate, which achieves price anchoring, and the mark price and liquidation mechanism, which achieve risk control. It also turns on two key design dimensions: the convexity difference between inverse and linear contracts, and the structural costs of abolishing the expiry date.

2.3.1 The funding rate

The funding rate is the core design innovation of perpetual futures. It is a fee settled directly between holders of long and short positions at regular intervals—commonly every 8 hours on mainstream exchanges, and every hour or continuously on some—whose direction and magnitude depend on the deviation between the perpetual price and the spot index price. The funding rate is not a fee charged by the exchange but an internal transfer payment among traders. Its common calculation framework is $\text{rate}_{8h} = \text{interest component}_{8h} + \text{premium component}_{8h}$; that is, the two components are summed over a single funding interval (such as 8 hours). Some exchanges set the interest component as a fixed term close to 0.01% per 8 hours, while others use different interest rates, caps and floors, and dynamic-adjustment mechanisms; the premium component is typically computed from a time-weighted average of the perpetual price's deviation from the spot index and is the main source of variation in the rate. Exchanges differ significantly in sampling frequency, weight-decay method, and the setting of caps and floors, and Chapter 10 develops a detailed comparison of the formulas.

Its core logic is a negative feedback loop: when the perpetual price is above spot, the funding rate is positive, longs pay shorts, the cost of being long rises, and longs are encouraged to close while new shorts enter, which pushes the price back down; the reverse holds when the perpetual price is below spot. Spot-futures arbitrageurs are the key force behind the anchoring mechanism: when the rate is positive, they short the perpetual while buying spot to earn the rate, placing selling pressure on the perpetual and buying pressure on spot and so accelerating the close of the gap. In extreme markets, however, arbitrageurs face multiple constraints, so the anchoring mechanism

is most likely to fail precisely when it is most needed. The margin on a short perpetual position is continuously eroded as the underlying price rises, and in extreme cases the arbitrageur is exposed to liquidation; cross-exchange arbitrage requires capital to be locked separately on the spot and derivatives exchanges, doubling the total capital committed with none of it usable across venues; and an exchange may restrict new position-opening or suspend withdrawals, directly blocking the arbitrage. These constraints mean that arbitrageurs—the force that holds the anchor—may be squeezed out or retreat voluntarily in extreme environments, which forms the microfoundation of the soft anchor's fragility and echoes the analysis in Section 2.3.4.

Ackerer, Hugonnier, and Jermann (2025) [14] derived an explicit pricing formula for perpetual futures under a framework of no frictions, continuous trading, and no arbitrage, proving mathematically that the funding rate mechanism can guarantee consistency between the futures price and the spot price and giving this negative feedback loop a rigorous theoretical basis. The model's core assumptions—especially frictionlessness and continuous trading—do not necessarily hold under real crypto-market conditions, which is itself a starting point for understanding how the rate deviates in extreme markets.

Figure 2-3 presents the internal logic of this negative feedback loop: when the perpetual price deviates from spot, the funding rate adjusts automatically with the deviation, guiding the price back by changing the cost of holding long and short positions. The figure also shows the two paths of premium and discount and the role of spot-futures arbitrageurs in accelerating convergence.

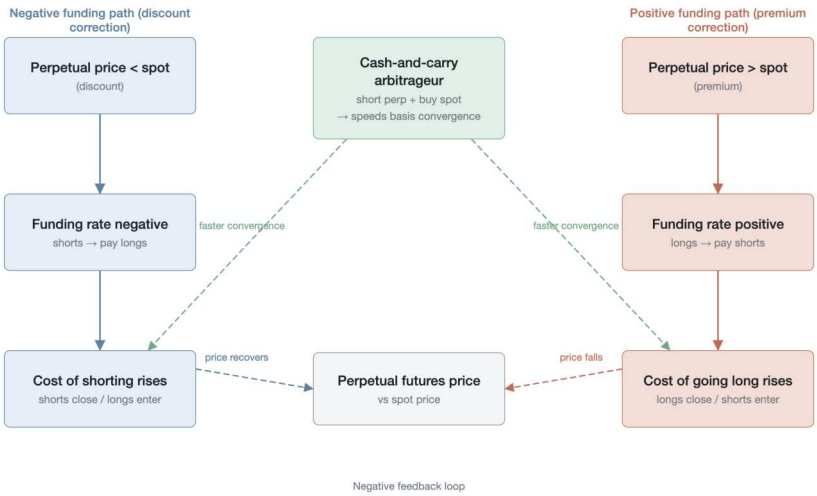

Figure 2-3. The negative feedback loop of the funding rate price-anchoring mechanism—the funding rate is positive when the perpetual price is above spot (longs pay) and negative when it is below spot (shorts pay), so a deviation automatically produces an opposing economic incentive (Data source: Ackerer, Hugonnier & Jermann 2025 [14])

Under extreme market conditions, the funding rate behaves in ways far more complex than this description suggests: it can spike to thousands of percent on an annualized basis, becoming a punitive tax on holding a position and triggering large-scale position

adjustments and further volatility. Chapter 10 develops the analysis of the rate's game-theoretic structure and extreme behavior.

The economic nature of the funding rate extends well beyond that of an anchoring tool. Its first nature is that of the continuous form of the traditional cost of carry. Traditional futures pricing follows the cost-of-carry model, in which the futures price equals the spot price plus the cost of carry; the cost of carry is embedded in the basis, and the more distant the expiry, the larger the basis. Perpetual futures abolish the expiry date and eliminate the explicit term basis, but they cannot eliminate the cost of carry: it shifts from being embedded in the price to being paid explicitly and continuously through the funding rate. A positive funding rate equals the cost of being long and can also be read as the implied interest rate on borrowed risk exposure. The Bank for International Settlements (BIS) working paper by Schmeling, Schrimpf, and Todorov shows that crypto carry can reach very high levels in some periods and that its returns relate to trend-chasing demand, limited arbitrage capital, and crowded-trade risk [15]. This is not a free lunch but the market's equilibrium pricing of leverage demand, funding constraints, and risk-bearing. The funding rate is in essence a real-time, explicit, and fragmented version of the basis.

Its second nature is that of a real-time market-sentiment indicator. Traditional sentiment indicators—the volatility index (VIX), based on option-implied volatility, and the put-call ratio, based on option volume—are complex to compute, limited in update frequency, and dependent on the liquidity of the options market. The funding rate provides a more direct, higher-frequency signal: a rate that stays positive and rises indicates that leveraged longs are accumulating and systemic fragility is rising. A positive rate, however, need not signal pure speculative long accumulation, because a large volume of delta-neutral basis trades also pushes the rate positive, and these arbitrage positions do not feed a liquidation cascade, so systemic fragility is far lower than when speculative longs dominate. The rate must therefore be read together with the increment (rather than the stock) of open interest, the distribution of liquidation thresholds, and spot-market capital flows; on its own it is a necessary but insufficient sentiment indicator. A rate that turns negative abruptly signals spreading panic, with longs forced to close or flip short; a rate above 100% annualized signals an extreme market state, in which the cost of holding a position itself begins to force traders to adjust. The rate is thus not only an anchoring tool but a piece of financial-information infrastructure in its own right, supplying real-time signals for volatility forecasting and market-state assessment that do not exist in traditional finance. Chapter 23 uses the rate to construct an early-warning indicator for the *calm trap*, and Chapter 24 incorporates it into a volatility-forecasting framework.

Its third nature is that of a foundation for an on-chain-native carry asset. The funding rate creates an on-chain-native carry trade: shorting the perpetual while buying spot to earn the rate; its risks are a rate reversal and liquidation. Projects such as Ethena have turned this strategy into a protocol; USDe delta-hedges spot against a corresponding short perpetual or dated futures position, packaging the strategy into a composable on-chain financial product [16]. But when a large amount of capital concentrates in the same carry strategy, that crowding fundamentally changes the return profile: it compresses carry, and when the rate reverses, the simultaneous unwinding of large

positions becomes a *carry unwind* that is itself an additional source of market impact. The carry strategy is therefore procyclical: it attracts capital and suppresses volatility in calm periods, and it is forced to deleverage and amplifies volatility in turbulent ones. Chapter 1's composability thesis is confirmed here at the level of derivatives: round-the-clock operation lets the rate settle continuously, atomic settlement makes rate payments certain, and programmability lets the strategy be packaged into a smart contract. This innovation is possible only where perpetual futures exist, marking their upgrade from a trading tool into infrastructure for a new asset class.

2.3.2 Mark price and the liquidation mechanism

The mark price is a fair-price benchmark used to calculate unrealized profit and loss (unrealized P&L) and margin levels. It synthesizes the price indices of several mainstream spot exchanges (for example, the median or weighted average of Coinbase, Binance, and Kraken) rather than relying on the traded price of a single exchange. It is designed to provide a manipulation-resistant liquidation benchmark, keeping an instantaneous price anomaly on a single exchange—a sharp, short-lived price deviation that quickly reverts, colloquially called a *wick*—from triggering unjust, large-scale liquidations. In the early history of the crypto market, mass liquidations caused by this kind of price manipulation were common. The mark price is typically smoothed with an exponential moving average (EMA) or a time-weighted average price (TWAP) to filter short-term noise. Even so, its price sources can still be manipulated. The 2019 BitMEX event, in which a flash crash on the single exchange Bitstamp caused mass liquidations, is a typical case: a large sell order propagated through a heavily weighted price source and indirectly triggered more than $200 million in liquidations. The governance mechanism for selecting price sources and adjusting weights is itself a point of operational risk; its decisions are typically made unilaterally by the exchange and lack transparency. Chapter 11 analyzes in depth how the smoothing design creates an *accumulation–release* effect in fast markets.

When the margin ratio (calculated on the mark price) falls below the maintenance margin ratio, the forced-liquidation process is triggered. The simplified formula for the margin ratio is:

$$\text{margin ratio} = \frac{\text{margin balance} + \text{unrealized P\&L}}{\text{position notional value}}, \qquad \text{liquidation} \iff \text{margin ratio} < \text{maintenance margin ratio}$$

where both unrealized P&L and notional value are calculated on the mark price. This is a conceptually simplified formula; for the rounding direction, precision alignment, and the margin-aggregation basis for isolated versus cross margin in a fixed-point implementation, see Chapter 11. Under isolated margin, only the margin balance and profit and loss of a single position count; under cross margin, the margin levels of all positions in the account are combined, so a loss on one position can be partly offset by profits on others, at the cost of cross-asset contagion risk. This section focuses on how liquidation-mechanism design differs across exchanges (for the basic framework of the liquidation-execution process, see Section 1.4.3), because those differences directly affect the intensity of the liquidation cascade.

Exchanges' choices in liquidation-mechanism design form a continuous spectrum from

aggressive to conservative. Table 2-1 sets out three representative models in the current market—cliff-edge liquidation, progressive liquidation, and vault takeover—comparing them along four dimensions (mechanism logic, market impact, advantages, and disadvantages) and revealing the different trade-offs each makes between the certainty of risk removal and minimal market impact.

Model	Mechanism	Market impact	Advantages	Disadvantages	Representative
Cliff-edge liquidation	100% of the position is liquidated instantly once margin hits the threshold	Greatest	Simple and certain; clears risk thoroughly	The entire liquidation volume is dumped at once, accelerating the cascade	Early CEX designs
Progressive liquidation	The position is reduced in batches as margin approaches the warning line	Moderate	Slows the cascade and gives traders time to react	Complex to implement and may delay risk removal	Bybit, OKX
Vault takeover	Liquidated positions are absorbed by the protocol's market-making vault	Smallest	Greatly slows the cascade and protects market structure	The vault bears directional risk and may itself become a risk point	Hyperliquid HLP

Table 2-1. Three design models for the liquidation mechanism of perpetual futures (Data source: compiled by the author)

Each design strikes this trade-off differently. Cliff-edge liquidation pursues certainty, but at the cost of dumping the entire liquidation volume into the order book at once, accelerating the liquidation cascade. Progressive liquidation seeks a balance, reducing positions in batches to spread the impact, but it adds implementation complexity and may, in extreme conditions, delay risk removal if the batch pace is too slow. Vault takeover is the newest direction, represented by Hyperliquid's HLP market-making vault: liquidated positions are absorbed within the vault rather than hitting the public order book, so the impact on the market price is minimal, but the vault itself bears concentrated directional risk. When a major directional move persists, the vault may accumulate a large opposing position and become a systemic risk point. Hyperliquid's JELLY incident of March 2025 offers a case study of this risk: public post-mortems show that the abnormal price and position pressure of the low-liquidity token JELLY forced the platform to protect the HLP vault through discretionary intervention at the validator level [17]. This does not mean that every vault-takeover model will fail, but it exposes a key tension: whether, in a crisis, a protocol retains enough governance and validator discretion to overturn market outcomes. Chapter 11 systematically compares these designs, and Chapter 29 designs an optimal solution from an engineering perspective.

2.3.3 Inverse contracts and linear contracts

BitMEX's XBTUSD perpetual futures contract is the classic inverse-contract design: it uses BTC as both margin and settlement currency and is quoted in USD. This design has an important economic feature: it superimposes coin-denominated settlement on same-direction movement of the collateral price. For an inverse contract with a fixed U.S.-dollar notional principal, the BTC-denominated profit and loss can typically be written as a reciprocal price difference of the form $\mathrm{PnL}_{\mathrm{coin}} \propto Q\left(\frac{1}{P_{\mathrm{entry}}} - \frac{1}{P_{\mathrm{exit}}}\right)$ (where Q is the contract quantity, or notional principal); nonlinearity therefore first appears in the coin-denominated settlement outcome rather than in a simple dollar-P&L formula. The trader in fact bears a dual exposure: the position's direction is exposed to the BTC price, and so is the margin asset itself. When the price falls, the position's loss widens while the dollar value of the margin shrinks, the margin buffer thins nonlinearly, and liquidation triggers faster. An inverse contract thus fuses the directional bet and the collateral exposure into one, creating a nonlinear risk structure rarely seen in traditional dollar-margined linear contracts.

The convexity effect of the inverse contract shows up on the payoff curve. Figure 2-4 juxtaposes the long payoff curves of inverse and linear contracts: the linear contract, quoted in a stablecoin, is approximately linear and proportional, whereas the inverse contract superimposes the coin-denominated payoff on the value of the BTC collateral, so the margin buffer is consumed faster in a falling market—the geometric reason it triggers liquidation faster.

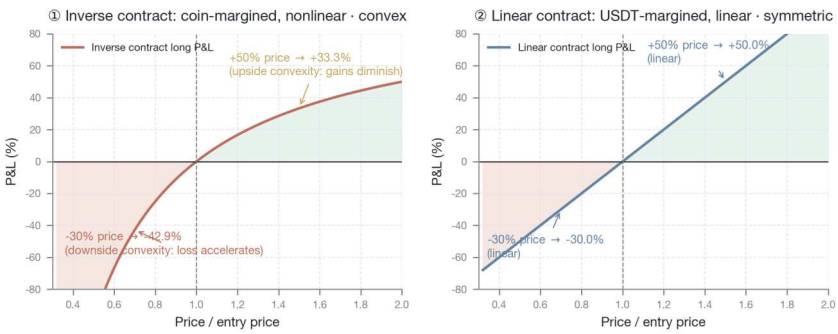

Figure 2-4. Comparison of the payoff curves of inverse and linear contracts—the convexity effect (Data source: derived by the author)

As stablecoins such as USDT and USDC became widespread, the market shifted toward linear contracts margined in stablecoins. A linear contract's profit and loss is linear, more intuitive and easier to compute for risk, but it loses the convexity of the inverse contract. In a rising market, a linear contract's leverage does not amplify automatically as an inverse contract's does. Linear contracts now dominate, because the spread of stablecoins has made dollar-denominated linear payoffs the default mental model for users. Inverse contracts retain their market, particularly where stablecoins are not used and in strategies that require the convexity effect. The difference between inverse

and linear contracts bears directly on the later analysis of liquidation mechanisms and market anomalies: Chapter 11 formalizes the nonlinear liquidation complexity of the inverse contract, and Chapter 18 analyzes the pricing differences between the two.

2.3.4 The cost of abolishing the expiry date

Abolishing the expiry date is the fundamental design decision that sets perpetual futures apart from traditional futures, but it is not free. In traditional futures, the expiry date performs three often-overlooked economic functions, and their disappearance imposes a threefold cost that perpetual futures must confront.

The first cost is the disappearance of a mechanism for the forced disclosure of information. The expiry-and-delivery of traditional futures guarantees that the contract price must converge to the spot price on the expiry date—a hard anchor backed by physical delivery or cash settlement. All market participants know this endpoint exists, so on every day before expiry, price discovery revolves around where the price will ultimately converge. Perpetual futures abolish this endpoint; the funding rate is a soft anchor that guides the price back through economic incentives but does not guarantee the return. The strength of the anchor depends on the activity and capital adequacy of arbitrageurs. Under normal conditions, arbitrageurs can usually compress the deviation between the perpetual and the spot index fairly quickly; but in extreme markets, capital constraints, exchange risk, and execution constraints weaken their capacity to correct the deviation, so it persists longer. As a result, the deviation between the perpetual price and the spot price can, in theory, be more persistent and more severe than in futures with an expiry date. One root of the persistent-premium or persistent-discount anomaly is precisely this structural weakening of the anchor once a hard anchor gives way to a soft one, an anomaly analyzed in depth in Chapter 18.

The second cost is the possibility of continuous leverage accumulation. Traditional futures have expiry, rolling, daily mark-to-market, and margin adjustment—mechanisms that together impose periodic repricing and risk checks; a position can be rolled over, so systemic exposure is not automatically reset to zero on an expiry date, but the roll window forces traders to reconfirm their funding cost, the basis, and margin constraints. Perpetual futures have no such window. Leverage can accumulate more continuously during calm periods until, at some trigger point, it sets off a liquidation cascade that forces destructive deleveraging. The leverage-cycle dynamics of Section 2.4.3 formalize this process.

The third cost is the loss of a termination date for market-making risk. In futures with an expiry date, market makers know that their inventory risk has a definite end date and can price and manage it precisely on that basis; in the worst case, everything is settled on the expiry date. In perpetual futures, a market maker's risk exposure is in theory indefinite and terminates only when the position is actively closed or liquidated. This changes their behavior: in a long-lasting trend especially, they may lean toward reducing quote depth or widening spreads, because they cannot be sure when the trend will end. Chapter 19 formalizes this effect in the market maker's profit equation. This cost echoes Chapter 1's analysis of round-the-clock trading at the level of derivatives: the expiry date is another risk-mitigation mechanism for market makers, and perpetual

futures abolish it.

Perpetual futures replace hard anchoring, periodic resets, and finite-horizon risk with soft anchoring, the possibility of unlimited accumulation, and indefinite-horizon risk. They are not an upgraded version of traditional futures but a different design trade-off, accepting a new set of structural costs in exchange for convenience. Understanding these costs is the prerequisite for analyzing the many distinctive phenomena in the perpetual futures market.

2.4 Market landscape and ecosystem evolution

Mechanism design determines what perpetual futures can do; the market itself reveals the impact they have had. By CoinGecko's top-10 perpetual-exchange measure, perpetual futures grew in less than a decade from nothing into a market with annual trading volume exceeding $92 trillion [1]. Their influence reaches far beyond a trading tool: they have reshaped the price-discovery hierarchy of digital assets, popularized high-leverage trading, given rise to an endogenous Minsky-style fragility, driven the rise of decentralized alternatives, and prompted a reconstruction of the global regulatory framework.

2.4.1 Market size and price discovery

In 2025, in the CoinGecko top-10 sample, the annual perpetual futures volume of centralized exchanges reached $86.2 trillion, up 47.4% year over year, while the annual volume of decentralized perpetual futures reached $6.7 trillion, up 346% year over year [1] [2]. By combining high liquidity, low transaction costs, and a broad base of participants, perpetual futures naturally became an important venue for expressing market information.

The evidence on price discovery must be read separately by market type. Alexander et al. (2020) [3] found that early BitMEX derivatives contributed a significant information share to BTC price discovery (this study uses data from 2016 to 2018, after which market structure has changed significantly: competition among exchanges, the degree of institutional participation, and the distribution of market liquidity are all now different). The cross-market analysis of Robertson and Zhang (2025) [4], by contrast, indicates that the regulated CME bitcoin futures market played a leading role in price formation within their sample. Together, the two support a more careful judgment: highly liquid derivatives markets tend to become important venues for expressing digital-asset information, but the conclusion for CME dated futures cannot be extended directly to all offshore or on-chain perpetual futures. This pattern, in which futures guide spot, has its root in the fragmentation of the digital-asset spot market (hundreds of exchanges worldwide, with no central market), which leaves leading derivatives exchanges, with their deeper liquidity pools, as the de facto centers of price coordination. When an important piece of information appears, the first to react may be the derivatives market, with its higher leverage efficiency and more concentrated liquidity; the reaction is then transmitted to the various spot exchanges through arbitrage.

This constitutes a conceptual inversion: the derivatization of the spot market. In

traditional finance, the spot market is usually primary and derivatives are built on top of it. In the digital-asset market, this hierarchy weakens, at least in some periods and for some trading pairs: derivatives markets such as perpetual futures and dated futures may become the faster layer of information expression, with spot prices then absorbing that information through arbitrage and market-making. This structural change means that understanding the dynamics of the derivatives market is just as important to understanding spot prices. A deeper systemic risk follows: when price discovery is shaped by leveraged market depth, the price signal may embed the systemic noise of the leverage cycle. This has profound effects on DeFi protocols that rely on spot prices (for collateral valuation and oracle price feeds, for example), because they typically assume the spot price reflects fundamental information rather than the accumulation or liquidation of leveraged positions. Just how strongly perpetual futures lead price discovery, and whether that leadership is stable across market states, calls for microstructure tools such as the Hasbrouck information share, which Chapters 13 through 15 analyze systematically.

2.4.2 The democratization of leverage

In traditional finance, high-leverage trading is usually subject to strict account, margin, and investor-suitability constraints. In the U.S. stock market, Regulation T limits initial margin to 50%, equivalent to a maximum of 2x leverage [18]. Perpetual futures sharply lowered the barrier to leverage, turning nominal 10x-to-125x leveraged trading into something anyone can access simply by downloading an app or connecting a wallet. Nominal leverage must be distinguished from effective leverage: 125x is usually available only for very small positions, the tiered-margin system makes the effective maximum for large positions far lower, and actual leverage is further constrained by platform risk controls, liquidity, and liquidation thresholds. This is a democratization of leverage that never appeared in traditional finance. It echoes the broader debate over the democratization of finance in fintech: technology has lowered the barrier to entry for financial services, but whether wider access comes with adequate risk education and investor protection remains a central, ongoing debate among academics and regulators. This book uses *democratization of leverage* as a descriptive term, with no normative connotation.

Understanding it starts with the behavioral drivers on the demand side. The forces that lead retail traders to choose 50x-to-125x leverage include overconfidence bias, gambling utility, and a returns-display bias on social media: profit screenshots are widely shared while losses are hidden, producing a socialized amplification of survivorship bias. The default setting of the leverage slider and one-tap execution also reduce perceived friction, making high leverage cognitively too easy to choose.

The democratization of leverage cuts both ways. On the positive side, it releases capital efficiency: traders with little capital can gain exposure to large positions on limited margin, hedgers can lock in risk with less capital, and overall capital efficiency improves markedly. On the negative side, it amplifies risk systemically: a large volume of dispersed leverage risk accumulates at the system level, and every high-leverage retail account is a potential liquidation trigger. When the market makes a directional move,

these dispersed liquidations fire at once, forming a liquidation cascade. Democratizing leverage thus concentrates risk. The concentration unfolds along three dimensions: the dense distribution of liquidation thresholds across the price space produces the cascade effect; tail losses concentrate on the insurance fund and ADL recipients; and systemic risk concentrates on a few leading exchange platforms. At the individual level, 50x-to-100x leverage means that a mere 1%-to-2% adverse move triggers liquidation, leaving the trader's risk-tolerance window extremely narrow. At the system level, when millions of such narrow windows are densely packed along the price axis, any directional shock sweeps across many liquidation thresholds, forming a wave of liquidations. The selling pressure from those liquidations pushes the price further, sweeping across still more thresholds, and a positive feedback loop forms—the microstructure mechanism of the liquidation cascade.

2.4.3 Leverage-cycle dynamics

The liquidation cascade is not an occasional event but an endogenous, cyclical dynamic of the perpetual futures market. This cycle maps closely onto Minsky's (1986) [19] financial instability hypothesis, but it runs far faster and lacks the institutional tools to manage the cycle.

Figure 2-5 formalizes this leverage cycle as a four-stage closed loop (accumulation, criticality, deleveraging, and recovery), in which the end of the recovery phase is the start of the next accumulation phase, so the cycle repeats. The figure marks the typical direction of change in each phase's core observables—volatility, open interest, the direction of the funding rate, and effective liquidity depth—providing a signal framework for later empirical identification.

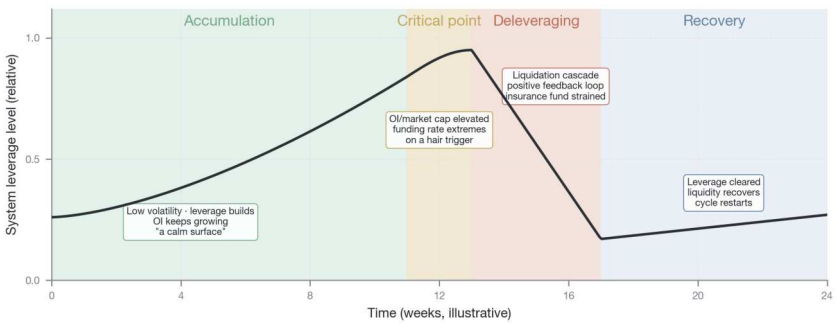

Figure 2-5. A four-stage model of the leverage cycle in the perpetual futures market—accumulation, criticality, deleveraging, and recovery (conceptual schematic; the leverage level is on a relative scale and the time axis is illustrative; theoretical source: Minsky 1986 [19])

In the accumulation phase, fragility builds beneath surface calm. Volatility is low, traders gradually add leverage, the rate is mildly positive, the carry trade attracts more capital, open interest grows steadily, and the market appears to run smoothly. The process shows a clear reflexivity loop: low volatility → added leverage → carry attracts capital → volatility suppressed further. Danielsson, Shin, and Zigrand's (2012)

[20] analysis of endogenous risk reveals the core paradox of this loop: the risk indicator is itself endogenously suppressed by trading behavior, so risk assessments based on historical volatility systematically underestimate true risk. Effective liquidity—order-book depth divided by the size of positions that can be liquidated—declines steadily. This is precisely the stability-breeds-instability that Minsky described: hedge financing gradually degrades into speculative financing and then into Ponzi financing, and it unfolds faster in the perpetual futures market. At the critical point, the system is extremely fragile. The ratio of open interest to market capitalization climbs to a high level, the rate exceeds 100% annualized, the cost of holding rises but long holders do not cut positions, and the market's tipping point falls ever lower. Here a medium-sized shock can, given the system's fragility, produce consequences far exceeding its own scale, and the system's nonlinear amplification peaks.

In the deleveraging phase, the liquidation cascade unfolds. The market event of October 10–11, 2025 provides a typical empirical case [21] [22]. An external macro shock—the spark, though months of prior leverage accumulation were the dry tinder—set off the first wave of liquidations; the selling pressure from those liquidations pushed the price down further and triggered still more, forming a positive feedback loop. Public data indicate that reported liquidations exceeded $19 billion within about one day [21]; Ali (2025), in an SSRN working paper, uses a measure of open interest erased to describe a contraction of open interest of roughly $19 billion within 36 hours [23]. The two figures are close but mean different things: the former measures reported forced liquidations, the latter the reduction in open interest, and they cannot be used interchangeably. Exchange liquidation data, moreover, generally underestimate the true scale.

Figure 2-6 uses market data from October 10–11, 2025 to depict this positive feedback loop: the phases in which the BTC price accelerated downward coincide closely on the time axis with pulse-like surges in hourly liquidation volume, confirming the positive-feedback amplification between forced-liquidation selling pressure and price decline.

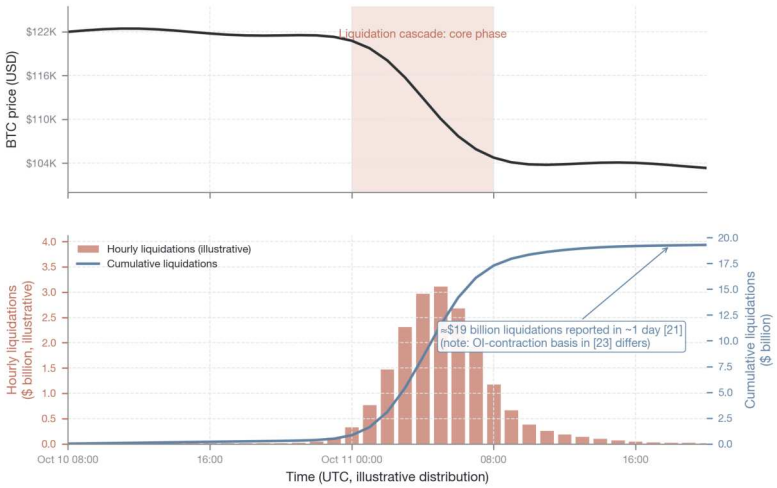

Figure 2-6. During the October 2025 liquidation-cascade event, the BTC price trajectory (top) and hourly and cumulative liquidation volume (bottom); the phases of accelerating price decline coincide closely in time with the peaks in liquidation volume, revealing forced liquidation as a positive-feedback amplification mechanism of the market crash (the data form is an illustrative model based on the event's public measures, not a tick-by-tick measurement; the cumulative-liquidation figure of "reported liquidations exceeding $19 billion within about one day" is a reported measure [21] and differs in meaning from the open-interest-contraction measure [23]; source: FTI Consulting 2025 [21], CoinGlass 2026 [22])

Ali (2025) [23] dissects three key risk amplifiers in this event through a market-microstructure lens. First, the procyclicality of unified margin: when multiple assets serve as unified margin, the contagion path unfolds clearly—initial shock → decline in the value of margin assets → cross-asset forced liquidation → decline in the price of the liquidated asset → further margin shrinkage—forming a cross-asset liquidation spiral, for which Brunnermeier and Pedersen's (2009) [24] framework of the margin spiral provides a rigorous analytical basis. Second, exchange infrastructure bottlenecks: during periods of sharp price movement, APIs and interfaces stall, and traders cannot top up margin or close positions manually in time. Third, insurance-fund strain and auto-deleveraging risk: the insurance fund is funded by the surplus when positions are liquidated at prices better than the bankruptcy price. In most deleveraging events the fund is merely strained, but in extreme cases it can be exhausted, triggering ADL. ADL forcibly cuts the positions of the winning side, stripping away their profits—an additional blow that further shakes market confidence. The second cost of abolishing the expiry date becomes concrete here: the expiry, rolling, daily mark-to-market, and margin system of traditional futures provide periodic repricing windows; perpetual futures have no expiry window, so leverage accumulates more easily and continuously and is ultimately released through a catastrophic deleveraging.

Similar leverage accumulation and catastrophic deleveraging have played out repeatedly in the digital-asset market. The chain-liquidation event of May 2021 followed a similar accumulation–criticality–deleveraging–recovery path, providing cross-period empirical support for the model's cyclicality hypothesis. The deleveraging triggered by the col-

lapse of FTX in November 2022 must be classified separately: it was counterparty-risk-type deleveraging (exchange failure → collapse of trust → forced deleveraging), fundamentally different in trigger from the market-endogenous deleveraging of May 2021 and October 2025 (leverage accumulation + price shock → liquidation cascade). This chapter's leverage-cycle model primarily explains market-endogenous deleveraging; counterparty-risk-type deleveraging involves the broader problem of institutional trust. The October 2025 event, larger in scale and faster in pace, further confirmed the systemic nature of this dynamic.

The recovery phase is asymmetric: the crash is measured in hours, recovery in days to weeks. Leverage is cleared out, open interest falls to a low level, market makers reenter, liquidity is restored, the market returns to the accumulation phase, and the cycle begins again.

The perpetual futures leverage cycle is highly isomorphic to Minsky's classic credit cycle in the dynamics of financial-leverage accumulation and collapse, but it lacks the dimensions of capital misallocation and overcapacity found in the real economy. Brunnermeier and Pedersen's (2009) [24] theory of the margin spiral may be the more precise benchmark, since it directly models the evaporation of liquidity and forced deleveraging under margin constraints and fits the microstructure of the perpetual futures market more closely. The two models differ significantly in speed, management tools, and information visibility. Table 2-2 compares them along four core dimensions, showing why the perpetual futures cycle is faster, more severe, and thinner in institutional buffers, yet at the same time more amenable to early warning because of the transparency of on-chain data.

Dimension	Traditional credit cycle	Perpetual futures leverage cycle
Speed	Measured in years; a full cycle lasts 5 to 10 years	Measured in weeks to months; a full cycle within a few months
Cycle-management tools	Central-bank rate hikes and cuts, macroprudential policy, lender of last resort	The funding rate passively reflects the market state; no active steering tool
Deleveraging mode	Policy guidance, orderly institutional bankruptcy, and central-bank liquidity injection	Liquidation cascade; market-crash-style automatic deleveraging; limited insurance-fund capacity
Information visibility	Leverage accumulation is usually invisible, attributed after the fact	Aggregate-level open-interest (OI) and rate data are public, but key risk-distribution information (the distribution of liquidation thresholds, whale concentration, cross-platform net exposure) remains opaque on CEXs; on-chain DEX data are more transparent but limited in share. Visible does not mean manageable

Table 2-2. Comparison of the traditional Minsky credit cycle and the perpetual futures leverage cycle (Data source: compiled by the author, drawing on Minsky (1986) [19] and Brunnermeier & Pedersen

(2009) [24])

Is the liquidation cascade an endogenous feature of perpetual futures, or can mechanism design mitigate it? Why does liquidity disappear precisely when it is most needed? Of the price crash produced by liquidations, how much is information and how much is noise? Can leverage accumulation during calm periods be monitored and flagged in real time? These questions are taken up, respectively, in Chapter 11 on liquidation-mechanism design, Chapters 19 through 21 on the economics of liquidity, Chapter 22 on mechanism-driven volatility, and Chapters 23 and 24 on volatility forecasting and Minsky-moment early warning.

2.4.4 Risks unique to DEXs

The structural risks of centralized exchanges have grown increasingly exposed (the collapse of FTX being the most extreme case), driving significant growth in the market share of decentralized perpetual futures exchanges. Extrapolating from full-year volume ($6.7 trillion / $86.2 trillion), the ratio of DEX perpetual to CEX perpetual volume in 2025 was roughly 7.8%, well above the roughly 2.1% level in early 2023 [1] [2]. Total DEX perpetual volume in 2025 was about $6.7 trillion, up roughly 3.5 times over the prior year (for the data basis, see the opening of this chapter). DEX nominal volume may be inflated by trade-mining incentives and wash trading, so real economic volume may be lower than the nominal figure. With its distinctive architectural choices—a purpose-built Layer-1 app-chain, an on-chain central limit order book, and the HLP market-making vault—Hyperliquid recorded about $2.9 trillion in DEX perpetual volume for the full year of 2025, roughly 43% of the CoinGecko top-10 DEX perpetual sample, and now represents the architectural direction of app-chains, on-chain order books, and protocol-run market-making vaults [1] [25]. Hyperliquid's own Layer-1 chain warrants careful assessment: the size and distribution of its validator set and the decentralization of its sequencer fall short of protocols that run on the Ethereum Layer 1, and the discretionary intervention at the validator level during the JELLY incident (discussed in Section 2.3.2) is precisely a symptom of this tension [17]. Chapter 9 analyzes in depth the gains and losses of its architectural choices.

The difference between centralized and decentralized perpetual futures exchanges is not merely one of technical architecture but a fundamental divide in trust paradigm. Table 2-3 compares the two models along five dimensions—asset custody, transparency, core risk, trading experience, and trust paradigm—providing a structured reference for the analysis of DEX-specific risks that follows.

Feature	Centralized exchange	Decentralized exchange
Asset custody	The exchange's centralized wallet; users must trust the platform	Smart contract or self-custody; non-custodial
Transparency	Low; relies on audits and proof of reserves	Very high; all trades and funds are verifiable on-chain
Core risk	Operational opacity, asset misappropriation, and a single point of failure	Smart-contract vulnerabilities, oracle risk, and maximal extractable value (MEV) attacks
Trading experience	Smooth, low-latency, feature-rich	Rapidly improving, but limited by the performance of the underlying chain
Trust paradigm	Platform trust	Architectural trust

Table 2-3. Core differences between centralized and decentralized perpetual futures exchanges (Data source: compiled by the author)

While achieving non-custodial operation and on-chain transparency, DEXs introduce several risks that do not exist, or are milder, on CEXs. Oracle risk arises because DEXs rely on external price oracles (such as Chainlink or Pyth) to obtain the spot prices used to calculate the mark price and trigger liquidations. The BIS analysis of the DeFi oracle problem notes that an on-chain financial system's reliance on external price sources reintroduces issues of data quality, price-source manipulation, and governance trust at the protocol layer [26]. In low-liquidity token markets, an attacker can influence the oracle's quote by manipulating a few price sources, triggering a liquidation in their own favor. Oracle price updates carry an inherent delay (typically on the order of seconds), which in extremely volatile markets can open a significant gap between the mark price and the true market price, throwing off the timing of liquidations. An interruption in oracle service can pause a DEX's liquidation system, so that accumulated risk is released all at once when the oracle recovers.

MEV-based attacks are the second class of risk unique to DEXs. On a public blockchain, pending transactions are visible to everyone in the mempool, and block builders can extract value by reordering transactions. A sandwich attack—in which an MEV searcher, on detecting a user's large trade, inserts its own transactions before and after it to profit from the price slippage—worsens the user's execution price. Liquidation opportunities are visible to all, so multiple liquidators compete to execute, producing gas competition, and part of the liquidation profit is converted into validator income. The sandwich attack targets mainly DEXs based on the automated market maker (AMM) model; for DEXs that use a central limit order book (such as Hyperliquid), MEV risk shows up more as front-running and information-advantage problems at the sequencer level, tied directly to how decentralized the sequencer is. On a CEX, the exchange controls trade ordering and there is no public-mempool MEV problem, but a DEX exposes trade ordering to all block producers.

Smart-contract vulnerabilities are the third class of risk unique to DEXs. All of a DEX's logic is coded in smart contracts, and once a contract is deployed its logic is public to all, so attackers can audit it in search of exploitable vulnerabilities. Security

reports from firms such as Immunefi show that DeFi and on-chain trading protocols have long suffered fund losses from smart-contract vulnerabilities, private-key leakage, and economic attacks [27]; the DeFi policy recommendations of the International Organization of Securities Commissions (IOSCO) likewise list governance, code, oracles, and cross-chain dependencies as important risk surfaces [28]. Although auditing and formal verification keep improving, zero vulnerabilities remains an unattainable goal, especially in a perpetual futures system where modules such as liquidation logic, margin calculation, and multi-collateral management interact in highly complex ways. Upgradeable smart contracts fix vulnerabilities but raise the trust question of who holds the authority to upgrade; if that authority rests with a few, the promise of decentralization weakens. Non-custodial operation eliminates the risk of platform misappropriation but introduces contract-vulnerability and admin-key risk, and the admin authority of an upgradeable contract is essentially a form of *code custody*. Chapter 28 systematically discusses this tension in the context of trust-stack design.

Regulatory-compliance risk likewise cannot be ignored. In 2023, the enforcement action by the Commodity Futures Trading Commission (CFTC) against several DeFi protocols, including Opyn, ZeroEx, and Deridex, showed that decentralization is not grounds for regulatory exemption [29]. Satisfying anti-money-laundering and know-your-customer (AML/KYC) requirements in a permissionless environment is a dilemma both technical and philosophical: there is a fundamental contradiction between mandatory identity verification and permissionless access. Protocol developers and governance participants may face personal legal liability, a risk that deeply constrains the long-term development of the DEX ecosystem.

DEXs also face two further risks. Governance-concentration risk arises when a few token holders or a team control key protocol parameters (such as the margin ratio, liquidation thresholds, and rate parameters), which may amount to de facto centralization. Cross-chain-bridging risk arises when assets are bridged to an app-chain: once a bridge contract is breached, user assets face systemic loss.

Together, these risks make up the DEX's trust-tax substitution: the CEX's trust tax is reliance on a centralized operator, while the DEX's is reliance on the correctness of code, the reliability of oracles, and the fairness of block producers. Chapter 1's risk-surface-transformation framework is confirmed once again: decentralization does not eliminate risk but transforms it from one surface to another.

2.4.5 Regulatory evolution

The regulatory evolution of perpetual futures passed through four phases. In the vacuum period, from 2016 to 2020, regulators had little awareness of or attention to crypto derivatives, the market grew in an almost unregulated environment, and exchanges such as BitMEX and Binance offered high-leverage trading worldwide without identity verification or anti-money-laundering review. In the enforcement-based period, from 2020 to 2023, regulators began to state their positions through enforcement actions: in 2020 the CFTC filed suit against BitMEX [30], and the collapse of FTX directly accelerated the tightening of regulation. The hallmark of this period, however, was the absence of a clear rule framework, so participants did not know what was compliant, only what

would be prosecuted. In the framework-building period, from 2023 to 2025, major economies shifted from enforcement to legislation. The European Union's Markets in Crypto-Assets (MiCA) regulation applied in phases: the rules for asset-referenced tokens and e-money tokens from June 30, 2024, and the rules for crypto-asset service providers (CASPs) and other main provisions from December 30, 2024 [31]. MiCA primarily governs the issuance of, and service providers for, crypto assets not regulated as financial instruments under existing EU financial-services law; a crypto derivative, if it constitutes a financial instrument, is more likely to be governed under the MiFID II framework. ESMA's guidelines explain that the boundary between MiCA and MiFID II depends on the rights conferred by the asset, the contract structure, and the trading arrangement, rather than on the single factor of *whether it is on-chain* [12]. MiCA thus covers the spot side and the CASP framework, while MiFID II covers the financial-instrument and derivatives side. In the United States, the jurisdictional dispute between the U.S. Securities and Exchange Commission (SEC) and the CFTC is the core obstacle, and Congress is accelerating legislation to clarify which crypto assets are securities and which are commodities. Hong Kong implemented a licensing regime for virtual asset service providers (VASPs) in 2023, and Singapore applies a differentiated regime to crypto derivatives through its Monetary Authority. The compliance-transition period began in 2025, as market participants undertake compliance retrofits under a clear framework and compliance becomes a necessary condition for market access.

Yet a fundamental tension exists between the global nature of the perpetual futures market and the territoriality of regulation. When major economies tighten regulation, trading volume may shift to offshore jurisdictions with looser rules, and FTX's exploitation of the Bahamian regulatory environment is a cautionary precedent. The persistence of regulatory arbitrage may weaken the substantive effect of the compliance transition, and progress in international regulatory-coordination mechanisms—such as the cross-border coordination frameworks of the Financial Stability Board (FSB) and IOSCO—will be the decisive factor.

The dual effect of regulation must be confronted directly. In the short term, it constrains the market: it limits the leverage available to retail traders, raises exchanges' compliance costs, and suppresses some innovation—DeFi protocols in particular face the technical and philosophical dilemma of satisfying identity-verification requirements in a permissionless environment. In the long term, it enables the market: a more compliant, more transparent market with better risk controls is a prerequisite for attracting institutional investors at scale; regulatory clarity reduces uncertainty and lowers the compliance-risk premium, and consumer-protection measures reduce fraud and manipulation, strengthening the market's overall credibility and sustainability. Chapter 26 develops a systematic economic analysis of regulation.

2.5 Chapter summary

The 400-year evolution of derivatives is, in essence, three leaps in trust technology. Forward contracts rely on personalized trust; their radius of trust is limited to a circle of acquaintances, and market size is strictly constrained because the cost of trust is too

high. Futures contracts achieve institutionalized trust through standardization and the CCP, extending the radius of trust to strangers worldwide, but they depend on a centralized institution and introduce the inherent contradiction of concentrating risk in order to manage it. Perpetual futures introduce algorithmic anchoring through the funding rate and margin rules, reducing reliance on the traditional CCP; but in the CEX setting they still depend on platform rules and operation, while in the DEX setting they shift trust to code, oracles, sequencing, and governance. Each leap responds to the trust bottleneck left by the previous one, while also generating a new trust tax.

The three structural conflicts between traditional futures and digital assets—temporal mismatch, liquidity fragmentation, and trust mismatch—make it infeasible to transplant traditional futures directly into the digital-asset world. The two core design innovations of perpetual futures (abolishing the expiry date and the funding rate) and their market outcome (the concentration of liquidity in a single contract) address these three conflicts directly; the causal logic of their mutual dependence (a soft anchor replacing a hard anchor) is analyzed in Section 2.2.4.

The core theoretical contribution of this chapter is cost awareness. Abolishing the expiry date eliminates roll costs but weakens three economic functions: the hard anchor of expiry convergence becomes the soft anchor of the funding rate, the periodic repricing window gives way to continuous position-holding, and the termination date for market-making risk becomes indefinite. These three costs explain many of the distinctive phenomena in the perpetual futures market. The threefold economic nature of the funding rate—the continuous form of the traditional cost of carry, a real-time market-sentiment indicator, and the foundation for an on-chain-native carry asset—upgrades perpetual futures from a trading tool into financial-information infrastructure and the foundation for a new asset class. The leverage-cycle dynamics reveal that the liquidation cascade is an endogenous, Minsky-style cycle of the perpetual futures market, faster than the traditional credit cycle and lacking central-bank-style tools to manage it. The October 2025 event (roughly $19 billion by both the reported-liquidation and open-interest-contraction measures, detailed in Section 2.4.3 [21] [23]) provides direct evidence for this dynamic.

Perpetual futures are both a product of the trust tax—the trust mismatch of traditional futures gave rise to them—and a restructuring of it: CEX perpetuals concentrate trust in platform rules, risk control, and asset custody, while DEX perpetuals shift trust to code, oracles, sequencing, and governance. Compression is not free, and perpetual futures introduce their own trust tax: the threefold cost of abolishing the expiry date, the endogenous fragility of the leverage cycle, the new risk surfaces of smart contracts and oracles, and the transitional cost of regulatory uncertainty.

The next chapter closes out Part 1. Chapter 1 established the analytical framework of the trust tax, and this chapter set out the logic and cost of the birth of perpetual futures; Chapter 3 now argues that perpetual futures are not merely a crypto-native tool but represent a general direction in the evolution of financial infrastructure, pushing the narrative of trust-tax compression toward a more macroeconomic perspective. As the core object of analysis in this book, perpetual futures run through all subsequent chapters: from mechanism deconstruction to price discovery, from the arbitrage ecosystem

to the economics of liquidity, from volatility dynamics to market-quality assessment, and from decentralization engineering to the future in the age of AI.

The Distinctive Value of Digital Assets and the Future of Finance

In March 2024, BlackRock launched BUIDL, a tokenized money market fund, on Ethereum; within roughly a year its assets under management (AUM) surpassed $1 billion, and by the end of 2025 it held approximately $2.5 billion to $2.9 billion [1]. Over the same period, the Depository Trust & Clearing Corporation (DTCC) explored blockchain-based T+0 atomic settlement [2], the European Investment Bank issued a €100 million digital bond on Ethereum in 2021 [3], Siemens issued a €60 million digital bond on a public blockchain in 2023 [4], Visa ran stablecoin settlement tests on Solana [5], and the Monetary Authority of Singapore's Project Guardian pursued institutional-grade DeFi [6]. These initiatives come from core institutions of the global financial system—asset managers overseeing more than $10 trillion in assets, settlement-infrastructure operators processing more than $2 quadrillion in securities transactions each year, sovereign-level investors, and global payment networks—and they represent not the tentative adoption of a new technology but strategic deployment grounded in cost-benefit analysis. By the end of 2025, the total market capitalization of stablecoins worldwide stood at roughly $310 billion, with annualized on-chain settlement volume of approximately $33 trillion (Artemis/Bloomberg [7]; this figure includes internal DeFi flows and maximal extractable value (MEV) and is not netted, and payment-adjusted estimates diverge widely by method, ranging from roughly $0.4 trillion to $10 trillion [8]). Even at the adjusted figure, this volume remains within the same order of magnitude as Visa's annual net payment volume [9]. The functional boundary between on-chain finance and traditional finance continues to narrow.

Chapters 1 and 2 were, at bottom, still answering questions internal to the crypto world: what makes digital assets different, and how those differences gave rise to perpetual futures. This chapter shifts the vantage point—from inside the crypto world to the global financial system—to answer a more fundamental question: is the distinctiveness of digital assets merely a specialized tool serving a particular constituency, or does it represent the universal direction in which the entire financial infrastructure is evolving? The answer here rests on evidence and analytical frameworks, not on vision.

This chapter advances five named theoretical concepts to organize its argument. The institutional convergence thesis holds that traditional finance and on-chain finance are moving toward each other, driven by the competitive compression of the trust tax. The trust-tax compression curve shows that the difficulty of moving different financial func-

tions on-chain runs along a gradient from the easy-to-compress to the hard-to-compress, which explains why stablecoins moved on-chain before Treasuries and Treasuries before equities. The stablecoin settlement-layer migration thesis argues that the $33 trillion in annual settlement volume marks a structural migration of the settlement layer. The three-horizon framework divides the evolution of on-chain finance into three overlapping horizons with fundamentally different levels of maturity and standards of judgment. The impossibility boundaries identify three permanent structural constraints—the sovereignty boundary, the physical-world interface, and the governance paradox—that separate obstacles which effort can overcome from constraints that must be lived with, establishing the mature epistemological stance of *maximizing within constraints*. Together, these five concepts give the reader a complete analytical toolkit for judging the real prospects of on-chain finance, and they show how the economic logic behind perpetual futures (the most successful product of the first horizon) extends to broader financial functions.

3.1 An economic reexamination of the four distinctive properties

Four pain points pervade traditional financial markets: barriers to entry, the fragmentation of liquidity along the time dimension, persistent counterparty risk during settlement, and the high cost of manual execution. These do not exist in isolation; they are interwoven, mutually reinforcing systemic problems. Each of the four distinctive properties of digital assets responds to one of them. Figure 3-1 maps this full relationship, from pain point to distinctive property to value creation. The mapping is not a simple one-to-one correspondence, because the four properties reinforce one another across categories: programmability combined with atomic settlement gave rise to flash loans, and permissionless access combined with around-the-clock trading makes the global liquidity rotation of perpetual futures possible.

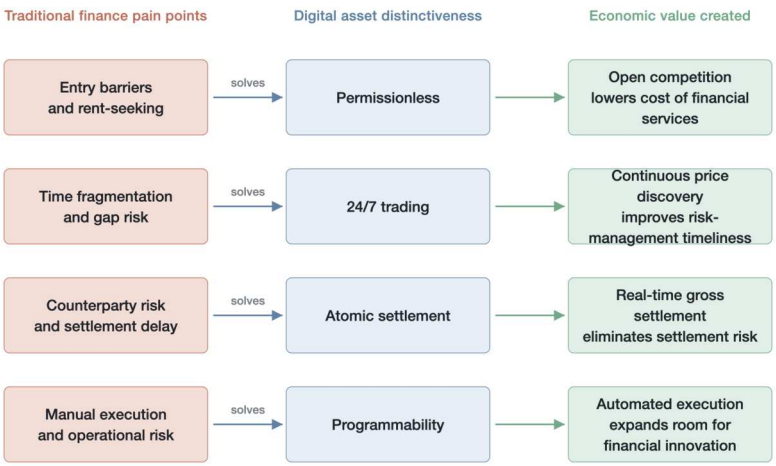

Figure 3-1. The correspondence between the four pain points of traditional finance and the four distinctive properties of digital assets

3.1.1 Permissionlessness and contestable markets

The traditional financial system is, at its core, a finely engineered permission-based structure. A company seeking to raise capital through a listing, an innovator offering financial services, and a trading firm hoping to become an exchange member must each pass through a complex admission process built from regulatory approval, capital requirements, industry relationships, and technical standards. This permission regime provides a foundational framework for financial stability and investor protection, but its high thresholds also, inevitably, breed muted competition and pervasive rent-seeking. The steep underwriting fees that investment banks charge during an initial public offering (IPO) stem in part from the limited number of banks able to win underwriting mandates; becoming a designated market maker on the New York Stock Exchange requires millions of dollars in capital and months of approval.

This phenomenon can be explained through the theory of contestable markets. The central proposition of Baumol, Panzar, and Willig (1982) [10] is that in a market with very low sunk costs, even a single incumbent behaves as it would under perfect competition; it is the persistent threat of potential competition, rather than the number of actual competitors, that forces the incumbent to keep prices near marginal cost. Traditional financial markets are a textbook case of non-contestable markets: becoming a regulated bank or exchange requires enormous outlays to obtain licenses, build infrastructure, and satisfy compliance requirements, and because most of these costs are sunk, they confer substantial market power on incumbents. Shepherd's (1984) [11] critique of contestable-market theory notes that the conditions for a purely contestable market are extremely difficult to satisfy in full, and that brand effects, user inertia, and hidden switching costs often form barriers to entry that Baumol's model does not adequately account for. This critique matters equally for assessing the contestability of on-chain finance: although decentralized exchanges (DEXs) eliminate the sunk costs of licensing and technical infrastructure, liquidity depth itself is a hidden barrier, and a

new protocol must overcome the cold-start problem of liquidity before it can compete effectively. On-chain financial markets are therefore more contestable than traditional finance, but they are not frictionless, perfectly contestable markets.

This cost differential can be quantified. According to industry estimates from firms such as Autonomous Research and Oliver Wyman, a traditional licensed exchange faces regulatory compliance costs of roughly $50 million, technical infrastructure costs of roughly $20 million, and product-listing costs of roughly $5 million, for total sunk costs exceeding tens of millions of dollars [12]; by contrast, deploying a simple automated market maker (AMM) protocol on a public blockchain (such as a Uniswap V2 fork)—including development, audit, and deployment gas fees—typically costs from a few thousand to a few tens of thousands of dollars, with an exit cost close to zero. A fully featured order-book DEX (with a matching engine, risk-control system, liquidation engine, and its own consensus layer, such as Hyperliquid or dYdX v4) costs millions to tens of millions of dollars to develop, markedly less than a traditional exchange, though the gap narrows to one or two orders of magnitude.

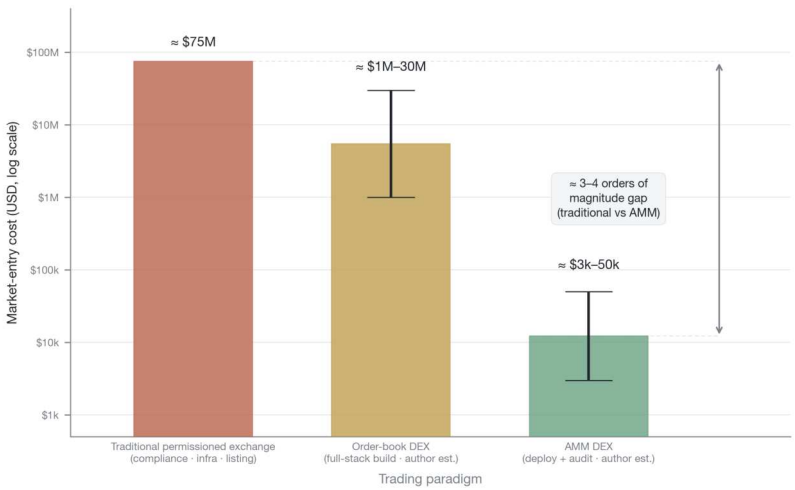

Figure 3-2. A comparison of the market-entry (sunk) cost magnitudes of three trading paradigms (logarithmic scale; a traditional licensed exchange runs to roughly $75 million, of which regulatory compliance is about $50 million, technical infrastructure about $20 million, and product listing about $5 million, based on industry estimates from Autonomous Research, *The Cost of Running a Regulated Exchange*, 2023, and Oliver Wyman, 2023 [12]; the order-book DEX figure of roughly $1 million–$30 million and the AMM DEX figure of roughly $3,000–$50,000 are the author's order-of-magnitude estimates based on public data; the gap between traditional and AMM exchanges is roughly 3–4 orders of magnitude; this figure is an order-of-magnitude illustration rather than precise accounting, mixing empirical data with the author's estimates)

Figure 3-2 reveals a fact easily underestimated on a linear scale: for AMM-type DEXs, the cost difference along the two dimensions of regulatory compliance and technical infrastructure is not a marginal gap of a few tens of percent but a structural chasm of 3–4 orders of magnitude; for high-performance order-book DEXs, the gap narrows to 1–2 orders of magnitude but remains structural. It is this order-of-magnitude difference that fundamentally alters the contestability of the market, expanding the pool of potential

competitors from a handful of licensed institutions to a far broader set of technical teams worldwide.

Permissionless finance built on public blockchains satisfies, in theory, the conditions for a contestable market almost perfectly. The direct cost of deploying a smart contract is minimal and involves almost no sunk cost; open-source code sharply lowers the technical barrier; and the exit cost is likewise zero. This low-sunk-cost property means that any protocol attempting to charge excessive fees risks being forked, as competitors can copy its open-source code and deploy a functionally identical version at lower fees. The effectiveness of fork competition, however, is constrained by brand trust, developer community, and liquidity inertia. The "vampire attack" that SushiSwap launched against Uniswap in 2020 drew substantial liquidity in the short term, but after Uniswap counterattacked by issuing the UNI governance token, it retained its market dominance over the long run. Even in a zero-sunk-cost environment, then, sustained innovation and brand trust still form a substantive moat. Hyperliquid's rapid growth is a direct case study in this economic logic. This perpetual-futures order-book DEX, built on its own application-specific chain, lets anyone list new perpetual-futures trading pairs through governance proposals at very low cost; its cumulative trading volume surpassed $3 trillion by the end of 2025, its user base grew to more than 1.4 million, and the number of listed perpetual-futures pairs exceeded 200 [13][14]. Listing a new futures product on a traditional exchange often takes months or even years of internal review and regulatory dialogue, whereas the permissionless mechanism lets the market respond quickly to new assets and new trading demand. Hyperliquid's permissionlessness appears at the user-access level (anyone can register and trade), but its infrastructure layer remains markedly centralized: its validator set consists of roughly 16–20 nodes, most operated by the team and its affiliates; order matching runs on a centralized sequencer at millisecond latency; and geofencing is enforced through front-end IP detection, which a virtual private network (VPN) can bypass. This architecture—permissionless at the user layer, only partly decentralized at the infrastructure layer—is common to today's high-performance order-book DEXs, whose degree of decentralization is far lower than that of general-purpose public blockchains such as Ethereum.

While the permissionless property lowers the cost of innovation, it also lowers the cost of fraud. According to CertiK, crypto-asset losses from security incidents totaled roughly $3.35 billion over the course of 2025 [15], and losses from scams and fraud ran higher still, into the tens of billions of dollars. The net social benefit of permissionlessness ultimately depends on the maturity of supporting institutions—that is, on whether effective disclosure mechanisms, decentralized reputation systems, and investor-protection tools can be established.

3.1.2 Around-the-clock continuous trading and the transformation of constraints

Traditional financial markets run on clocks and calendars. When markets are closed, information keeps being produced but cannot be priced immediately; it accumulates until the next session opens, when it is released all at once as an opening gap. These gaps interrupt the management of risk exposure and leave capital idle while the market

is closed. The deeper economic value of around-the-clock, uninterrupted trading lies in continuous price discovery: it transforms what is a hard constraint in traditional markets, the inability to trade when the market is closed, into a soft constraint in which only trading costs vary across time periods. Trading by participants around the world produces a cyclical rotation of liquidity across the global day.

This transformation from hard constraint to soft constraint is not costless. Around-the-clock markets do not eliminate differences in liquidity; they convert those differences from a binary state (open versus closed) into a continuous but uneven distribution. The data show that liquidity in crypto markets peaks during the overlap of the European and U.S. morning sessions (roughly 14:00–18:00 UTC) and falls to a trough after the U.S. market closes, with order-book depth differing by as much as 40% between peak and trough [16]. The trading cost of large orders therefore varies systematically by time of day. For market makers, the absence of a close means they cannot recalibrate inventory risk within a protected window, so they must maintain around-the-clock operational capacity or rely on algorithmic risk-management systems that run continuously without human supervision.

Chapter 2 argued that the high leverage of perpetual futures makes positions extremely sensitive to price volatility. Were there closed sessions, traders could not manage their risk exposure while the market was shut, which could produce the extreme case of an *opening-gap liquidation*. Around-the-clock trading is thus a necessary precondition for the perpetual-futures funding-rate mechanism to work: if the market did not run continuously, the funding-rate calculation would be interrupted and its anchoring effect would weaken markedly. More concretely, a 10x-leveraged position held through an overnight close would face unmanageable gap risk, and the funding rate's continuous anchoring would break, producing persistent basis deviation. This is the fundamental reason perpetual futures could not have emerged in a market with trading-hour restrictions. The three implicit protective functions that market closure provides in traditional markets, analyzed in Chapter 1—a risk-repricing window for market makers, a cooling-off period for panic, and a maintenance window for the system—all disappear under around-the-clock trading.

Blonien and Ober (2024) [17] point out that for smaller markets, concentrated trading sessions may be more efficient than around-the-clock trading because they pool liquidity. The value of around-the-clock trading thus depends on market size and liquidity depth; it is not a universally superior solution. Traditional markets are exploring extended trading hours, and institutions such as DTCC and BlackRock are discussing a transition toward around-the-clock operation—itself one dimension of institutional convergence.

3.1.3 The scope of atomic settlement

In traditional financial markets, the execution and settlement of a trade are two separate processes, typically requiring two business days to complete. This time window builds in a structural weakness: counterparty risk. Any party's default within the settlement window can trigger a chain reaction, producing a systemic settlement cascade. The collapse of Lehman Brothers during the 2008 financial crisis was the starkest embodiment of this risk. The atomic-settlement property of digital assets uses cryp-

tography to guarantee that the delivery of an asset and the payment of funds occur simultaneously within a single, indivisible on-chain transaction, fundamentally eliminating counterparty risk during settlement.

Treating atomic settlement as a fundamental solution to systemic risk is an oversimplification. To understand its true effect, one must draw a distinction that shapes the conclusions of any risk assessment.

A settlement cascade is triggered by the settlement failure of a trading counterparty and propagates downstream as a chain of defaults through the breaking of a trust chain; a liquidation cascade, by contrast, is triggered by a decline in asset prices and forms a negative feedback loop of price decline–liquidation–further decline through the forced closure of leveraged positions. Atomic settlement effectively eliminates the former, but for the latter it cannot prevent the cascade and may even accelerate its propagation through efficient execution. Table 3-1 compares the two risks along four dimensions: triggering mechanism, propagation path, the effect of atomic settlement, and time scale.

Risk type	Trigger	Propagation mechanism	Effect of atomic settlement	Time scale
Settlement cascade	Settlement failure of a trading counterparty	A broken trust chain triggers a chain of defaults	Effectively eliminated: simultaneous delivery and payment removes the possibility of default	Traditional finance: days to weeks
Liquidation cascade	A decline in asset prices triggers forced closures	Forced liquidation of leveraged positions intensifies selling pressure in a negative feedback loop	Cannot be prevented and may even be accelerated: efficient liquidation execution compresses propagation from days to minutes	Instant mark-price liquidation architecture: seconds to minutes; auction-based liquidation architecture: minutes to hours; insurance funds and auto-deleveraging (ADL) mechanisms can act as propagation dampers

Table 3-1. A comparison of settlement cascades and liquidation cascades—the scope of atomic settlement (Data source: compiled by the author)

Figure 3-3 contrasts the divergent paths of the settlement cascade (linear propagation) and the liquidation cascade (circular propagation), along with the scope of atomic settlement.

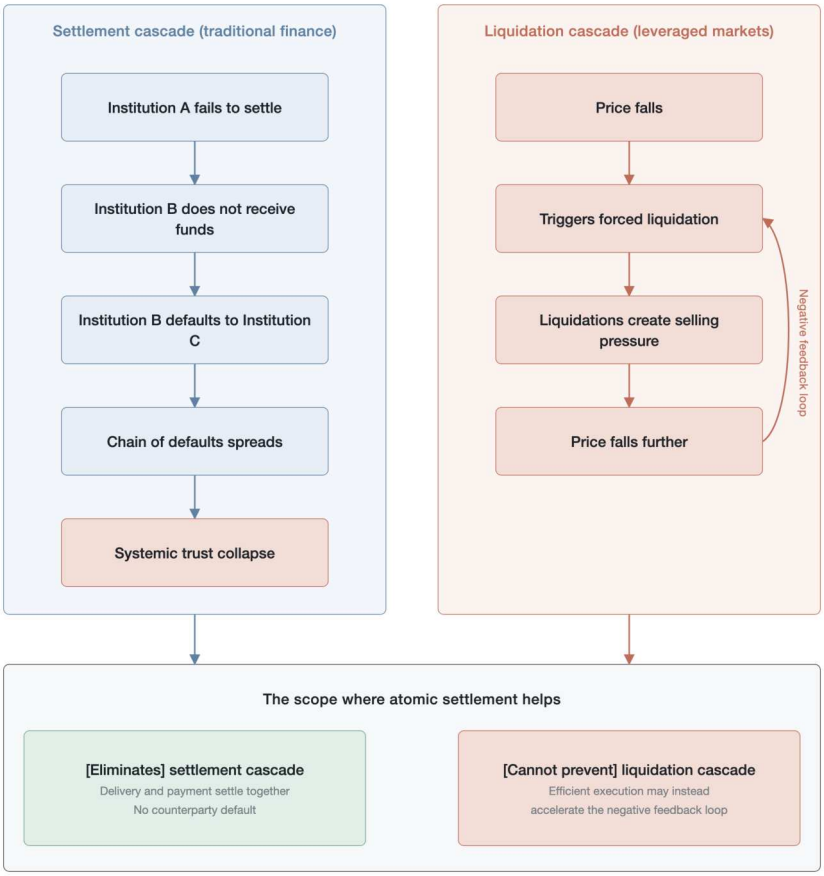

Figure 3-3. The propagation paths of settlement cascades and liquidation cascades and the scope of atomic settlement

In its 2024 report, the Financial Stability Board noted that tokenization can reduce counterparty risk through atomic settlement but may increase market participants' demand for liquidity [18]. This is a textbook risk-surface transformation—converting settlement risk into liquidity risk. Atomic settlement shifts the focus of risk from whether the counterparty will default to whether the market can withstand a rapid liquidation cascade and whether the protocol code is correct—a concrete mapping of the risk-surface transformation framework introduced in Chapter 1, namely that technological change does not eliminate the total quantity of risk but converts one set of risks into another of a different nature.

The crypto-market crash of March 12, 2020, provides an empirical case of a liquidation cascade. BitMEX, a centralized exchange, went down repeatedly during the event (the exchange attributed this to a distributed denial-of-service (DDoS) attack that overwhelmed its API and database layers, though it initially and mistakenly described it as a hardware failure), showing that even in a traditional, non-atomic settlement architecture, infrastructure failure during a surge in liquidations is already a systemic threat. In the same event, MakerDAO suffered zero-bid liquidations of its Vaults (triggered when Ethereum network congestion delayed oracle price updates) for a loss of roughly

$8 million, illustrating how underlying network congestion in an on-chain environment can intensify the propagation of a liquidation cascade. The collapse of FTX, in turn, revealed another layer of problems with the "atomic settlement" of centralized exchanges: the "instant" fills that users saw were merely digital changes in a private database, and when such trust is abused, so-called atomic settlement loses any substantive meaning. By contrast, in an on-chain order-book DEX the settlement of each trade is guaranteed by publicly verifiable cryptographic consensus, a stronger trust guarantee than a centralized exchange can offer. Chapter 1 defined this trust model—based on cryptography and protocol design rather than institutional reputation—as *architectural trust*.

3.1.4 The power and cost of programmability

The operation of traditional finance depends heavily on legal contracts and manual execution; the pricing, execution, and settlement of complex derivatives require large back-office staffs and multiple layers of intermediaries, a model that is both costly and rife with operational risk. Smart contracts—which Szabo (1997) [19] described as a set of promises, specified in digital form, including the protocols within which the parties perform on these promises—encode the terms and execution logic of a financial agreement directly into computer programs that run on a blockchain, replacing informal natural language with deterministic computational logic and labor-intensive fulfillment with automated execution. The perpetual-futures funding-rate mechanism analyzed in Chapter 2 is a textbook success of programmable finance, using automated, code-based payment flows to keep the derivative's price tightly anchored to the spot price. Programmability expands the design space of financial innovation; AMMs and decentralized lending are successful products of programmability interacting with the other distinctive properties, whereas algorithmic stablecoins (in particular the May 2022 collapse of UST/LUNA, which wiped out roughly $40 billion in total ecosystem value, of which the UST stablecoin component accounted for roughly $18 billion) warn that programmability can just as readily create mechanisms with endogenous fragility. The design space that programmability opens up contains both fertile and dangerous regions; the composability thesis of Chapter 1 finds continuing validation here, though it must now be qualified by careful design evaluation.

The value of programmability lies less in automation than in creating entirely new financial mechanisms with no counterpart in traditional finance. An AMM replaces the centralized order-book matching engine with a mathematical pricing function, giving any token pair a liquidity market without any market maker actively quoting prices. The flash loan permits uncollateralized borrowing within a single atomic transaction—an instrument that is logically impossible in any non-atomic settlement system. These innovations are not the result of adapting traditional financial products to a blockchain; they are native products of the programmable environment and cannot exist apart from it.

The cost of programmability manifests at three levels. First, determinism means rigidity. The incomplete-contracts theory of Hart and Moore (1999) [20] holds that no contract can exhaust all contingent states, and that residual control rights are therefore needed to address unforeseen situations. Smart contracts push this theoretical difficulty to

an extreme: the deterministic execution of code precludes any possibility of discretion, and situations the designer failed to foresee cannot be handled flexibly. In March 2023, Euler Finance suffered a flash-loan attack for a loss of $197 million; the attack was executed entirely within the bounds the code permitted, and the vulnerability was not a program defect in the traditional sense but a logical edge case the designers failed to anticipate. Attack losses over the course of 2025 reached $3.35 billion [15], of which the single Bybit incident accounted for $1.45 billion. These losses stem not only from code vulnerabilities but also from economic attacks that turn the deterministic nature of smart contracts against the designers' intent. Second, the cost of security audits constitutes a new form of trust tax; replacing legal compliance with code audits is not costless.

The third and more fundamental problem is one of governance: who has the right to modify the code itself requires an institutional answer. The ideal of "code is law" cannot entirely escape human governance. Contracts form a spectrum, from fully immutable (no one can modify them) to the upgradeable-proxy model (an administrator can change the logic), a continuous space of choices. This spectrum embodies a fundamental tension: immutability gives users confidence that the rules will not change, but upgradeability is a necessary condition for fixing vulnerabilities and adapting to new conditions. Between full immutability and full upgradeability, every protocol must choose a position, and that choice is essentially a governance decision rather than a technical one. Chapter 30 discusses design approaches for embedded compliance in detail.

3.2 The institutional convergence thesis

Institutional convergence is a classic research topic in comparative political economy. The institutional-isomorphism theory of DiMaggio and Powell (1983) [21] identifies three mechanisms that drive organizational convergence: coercive isomorphism (regulatory pressure), mimetic isomorphism (imitative behavior under uncertainty), and normative isomorphism (the diffusion of professional standards). This section applies the framework of institutional convergence to the relationship between traditional finance and on-chain finance and identifies a fourth mechanism not covered by DiMaggio and Powell: the competitive compression of the trust tax. Traditional finance and on-chain finance are moving from mutual opposition toward functional convergence, a convergence driven not only by regulatory pressure (coercive isomorphism) and industry imitation (mimetic isomorphism) but, more fundamentally, by the competitive compression of the trust tax—that is, as the two compete for the same user base, each compresses its own trust tax from a different direction. Traditional finance adopts on-chain technology to compress its trust tax, while on-chain finance introduces institutional elements to raise its level of trust. The BUIDL fund is the landmark case of convergence proceeding in both directions at once.

3.2.1 The on-chain deployment of traditional finance

The move on-chain by traditional financial institutions has moved from the 2020–2022 proofs of concept into a phase of strategic deployment in 2024–2026. This is not incre-

mental exploration but a systematic strategic turn.

Table 3-2 surveys the on-chain strategic actions of six representative institutions. These institutions span six domains—asset management, securities settlement, sovereign-level issuance, industrial-enterprise financing, global payments, and sovereign regulation—and the significance of their collective turn lies in this: the adoption of on-chain finance is no longer confined to crypto-native institutions but has extended to core participants in the traditional financial system.

Institution	Action	Signaling significance
BlackRock	BUIDL fund—a tokenized money market fund on Ethereum, with AUM near $3 billion	The world's largest asset manager chose a public blockchain rather than a private one
DTCC	Exploring T+0 atomic settlement, the Smart NAV project [2]	Core U.S. financial infrastructure exploring on-chain settlement
European Investment Bank	Issued a €100 million digital bond on Ethereum [3]	A sovereign-level institution chose a public blockchain for issuance
Siemens	Issued a €60 million digital bond on a public blockchain [4]	A European blue-chip industrial enterprise adopted on-chain issuance
Visa and Mastercard	Stablecoin settlement integration; Visa tested USDC settlement on Solana [5]	Global payment networks view on-chain settlement as an efficiency gain
Monetary Authority of Singapore	Project Guardian—institutional-grade DeFi	A regulator proactively driving rather than reactively responding

Table 3-2. The strategic on-chain deployment of traditional financial institutions (Data source: public disclosures from each institution [1][2][3][4][5][6])

What drives these institutions is not technological idealism but rigorous cost-benefit analysis. Their core economic logic is this: when the compression of the trust tax exceeds the cost of migration, migration is rational. Each year, DTCC and its participants incur settlement costs measured in the billions of dollars (including reconciliation, dispute resolution, margin management, and the maintenance of multiple intermediary layers [22]); if atomic settlement can eliminate most of that, migration is not innovation but cost optimization. BlackRock's BUIDL fund turns money market fund subscriptions and redemptions from T+1 into instant, around-the-clock operations, and turns fund shares from a closed account system into globally tradable tokens. Most of the on-chain experiments of 2020–2022 took place on private or consortium chains, signaling that these institutions acknowledged the value of blockchain technology but did not trust public blockchains; the strategic deployment of 2024–2026 has shifted markedly toward public blockchains, where the signal has become that the security, transparency, and network effects of public blockchains now exceed the controllability advantages of private ones. Traditional finance is not merely adopting on-chain technology; it is accepting the architectural-trust paradigm of on-chain finance.

3.2.2 The institutionalization of on-chain finance

Convergence is bidirectional. On-chain finance is undergoing systematic institutionalization, moving from a state that lacked any regulatory framework toward compliant innovation within one. The European Union's Markets in Crypto-Assets (MiCA) regulation came fully into force in 2024, and as of April 2025, 17 crypto-asset service providers had been authorized by their respective national competent authorities (NCAs) and entered into the ESMA public register [23][24]. Hyperliquid has introduced partial compliance mechanisms, dYdX has set up geofencing to restrict users in specific jurisdictions, and Coinbase, as a public company, has obtained comprehensive regulatory licenses. The infrastructure layer of on-chain finance is upgrading from crypto-native to institutional-grade: custodians such as Fireblocks and Anchorage provide multi-signature wallets and insurance coverage, while on-chain analytics platforms such as Chainalysis and TRM Labs provide anti-money-laundering and transaction-monitoring services to financial institutions.

The governance of on-chain finance is evolving from the early ideal of "code is law, no human intervention" toward a more mature, multi-layer architecture: smart contracts define and automatically enforce core rules, a governance committee deliberates on parameter adjustments, an emergency multi-signature executes interventions of limited scope in extreme crises, and a time-lock provides a community-review window for all non-emergency changes. The March 2025 JELLY incident at Hyperliquid, in which validators voted to force the delisting of a token, is a practice of exactly this hybrid governance; although it sparked wide debate over the degree of decentralization, it showed that institutionalized human intervention is a necessary condition for the system's survival [25]. What drives on-chain finance toward institutions is not regulatory pressure but the demands of scale: to expand from serving millions of crypto-native users to serving billions of traditional-finance users, it must provide legal recourse, investor protection, compliance frameworks, and professional-grade security guarantees.

3.2.3 The competitive compression of the trust tax

The previous two sections described each one-directional movement separately: traditional finance toward the chain, and on-chain finance toward institutions. Recasting the trust-tax concept from Chapter 1 (all the direct and indirect costs paid in a financial transaction to establish and maintain trust: intermediary fees, compliance costs, the opportunity cost of settlement delay, and the information-asymmetry premium) from static to dynamic, competitive analysis unifies these two directions within a single economic framework. The logic here is deductive rather than inductive: when two financial-service systems offering overlapping functions compete for the same user base, the transaction-cost theory of Coase (1937) [26] and the governance-structure analysis of Williamson (1985) [27] predict that users will flow toward the system with lower transaction costs, and the resulting competitive pressure forces both systems to compress their own trust tax. Deriving convergence—rather than one side replacing the other, or a market split—from transaction-cost competition, however, requires an additional condition: that each system possess an irreplaceable comparative advantage along certain dimensions. The institutional trust of traditional finance (legal recourse,

regulatory protection, deposit insurance) and the architectural trust of on-chain finance (transparency, composability, around-the-clock operation) cannot at present be fully replicated by the other, which provides a structural basis for convergence rather than replacement. Traditional finance and on-chain finance are in the midst of just such a competitive compression of the trust tax, converging from different directions toward the same equilibrium range. Figure 3-4 plots time on the horizontal axis and trust tax or trust level on the vertical axis, showing the declining trust-tax curve of traditional finance and the rising trust-level curve of on-chain finance converging into an equilibrium range of functional convergence.

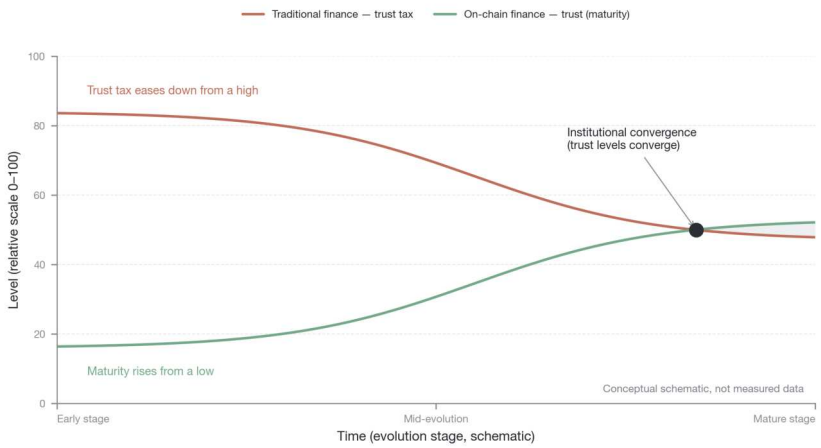

Figure 3-4. Institutional convergence—the converging trend of the declining trust tax of traditional finance and the rising trust level of on-chain finance (drawn by the author)

The two sides pursue different compression strategies. Traditional finance introduces on-chain technology to compress its own trust tax: DTCC explores atomic settlement to compress the time tax, BlackRock uses tokenization to compress the intermediary tax, SWIFT pilots blockchain to compress the jurisdiction tax, and traditional exchanges extend trading hours to compress the time-fragmentation tax. On-chain finance introduces institutional elements to raise its own level of trust: Hyperliquid adds a market-making vault as protocol-level insurance, Ethena obtains traditional-finance custody to strengthen architectural trust, and Circle obtains an electronic-money license that upgrades USDC from a crypto token to regulated electronic money. Both are moving toward the same destination—a lower trust tax and a higher level of trust—and that is convergence.

Once set in motion, this competitive process is hard to reverse. Competitive pressure makes retreat economically infeasible: once BlackRock has lowered its operating costs with a tokenized fund, its competitors must follow or lose market share on price. The on-chain infrastructure already built represents tens of billions of dollars in investment; this investment will not be scrapped but will continue to generate user inertia and network effects. Tens of thousands of engineers have mastered the on-chain finance technology stack, and thousands of institutions have built on-chain operational capacity; this human capital and organizational capability are likewise irreversible. Yet the

irreversibility of convergence is not absolute. At least three scenarios could slow or partly reverse it: a systemic crisis of trust triggered by a large-scale security incident (such as confirmation that a stablecoin issuer's reserves are insolvent), a coercive ban by a sovereign state (such as a major economy comprehensively prohibiting financial activity on public blockchains), and a collapse of institutional confidence triggered by a governance failure internal to on-chain finance. In 2022, the Australian Securities Exchange (ASX) abandoned its blockchain settlement project, writing off more than A$250 million—a reminder that institutional adoption follows a narrative cycle, and that enthusiasm for a blockchain strategy can contract sharply during a phase of disillusionment. In a more extreme scenario, the infrastructure already built would not physically vanish, but the user activity and capital allocation atop it could flow back to the traditional system on a large scale. A more prudent formulation is therefore this: under current institutional conditions and the current trajectory of technological development, convergence is highly path-dependent and self-reinforcing, and its reversal would be extremely costly—but not logically impossible. The end state of convergence is more likely to be the optimal combination of the three trust paradigms described in Chapter 1: selecting, at each layer, the trust paradigm best suited to that layer's needs.

3.2.4 The institutional-convergence significance of the BUIDL fund

The significance of BlackRock's BUIDL fund lies not in BlackRock's stature but in its simultaneous demonstration of convergence in both directions, which makes it the most complete single piece of evidence for the institutional convergence thesis. In the direction of traditional finance moving on-chain, BUIDL chose the Ethereum public blockchain rather than a private one, adopted the ERC-20 token standard so that fund shares can be used in any compatible Ethereum application, partnered with Circle to enable instant, around-the-clock subscription and redemption in USDC, and let BUIDL serve as collateral in DeFi protocols [1]. In the direction of on-chain finance moving toward institutions, BUIDL strictly complies with U.S. securities law, is registered with the SEC, is open only to accredited investors, has its assets held in custody by BNY Mellon, and uses Securitize as the tokenization platform providing compliant on-chain securities issuance and management.

BUIDL introduced a key resource that on-chain finance had previously lacked: high-quality, low-risk collateral that generates a stable yield. Before BUIDL, DeFi protocols relied mostly on highly volatile crypto assets as collateral, which built in enormous systemic risk: when the crypto market fell as a whole, collateral values dropped and triggered liquidations, those liquidations triggered further selling pressure, and the reflexive downward spiral analyzed in Chapter 1 took hold. BUIDL gave on-chain finance, for the first time, low-volatility, high-quality collateral anchored to U.S. Treasury yields. As an ERC-20 token, BUIDL is inherently composable and can serve as Aave collateral, perpetual-futures margin, and more (this composability derives from a shared settlement layer, the mechanism of which is discussed in Section 3.4.3).

BUIDL's composability is also subject to three practical limitations. The first is liquidity: the depth of BUIDL's on-chain secondary market may be far below what its

AUM implies; when BUIDL tokens must be sold quickly during a liquidation event, the on-chain market may be unable to absorb them, forcing a discounted sale—the classic traditional-finance problem of using an illiquid asset as collateral. The second is timing: BUIDL subscription and redemption are available only on business days, creating a structural mismatch with the margin needs of around-the-clock perpetual-futures trading, just as the USDC depegging event analyzed in Section 3.4.4 reveals the break between on-chain 24/7 operation and off-chain 5×8 banking hours. The deepest effect is systemic: once tokenized Treasuries are embedded at scale in DeFi, volatility in the U.S. Treasury market (such as the sharp decline in Treasury prices during the rapid rate-hike cycle of 2022) transmits directly to on-chain finance through the collateral-value channel, opening a cross-system risk-transmission path that did not previously exist and leaving on-chain finance no longer independent of the interest-rate risk of the traditional financial system.

Moreover, BUIDL's composability is *permissioned*, not the permissionless, fully open composability of native DeFi tokens. As an SEC-registered security, BUIDL uses Securitize's whitelist mechanism (a transfer restriction) to limit on-chain transfers to accredited investors, and an address not on the whitelist cannot hold BUIDL tokens. Regulators have not yet clearly tested the boundaries of this restriction within a composable DeFi environment: when BUIDL serves as collateral for a lending protocol, whether the protocol can ensure that all interacting parties meet the accredited-investor requirement—and the SEC's stance on the circulation of tokenized securities within DeFi—remains in flux. This compliance constraint is itself another instance of on-chain finance introducing institutional elements, exactly as the convergence thesis predicts: the technical potential of composability must be realized within an institutional framework.

3.3 The trust-tax compression curve and the three-horizon framework

Institutional convergence does not advance uniformly. The difficulty of moving different financial functions on-chain varies systematically, and this variation can be explained through the trust-tax compression curve. The three-horizon framework, in turn, divides the evolution of on-chain finance into three stages with different levels of maturity and standards of judgment.

3.3.1 The compression-difficulty gradient

Institutional convergence is under way, but it advances unevenly: stablecoin settlement has already reached the tens of trillions, Treasury tokenization is breaking through, and equity tokenization is still nascent. This unevenness is not random but reflects a gradient in the difficulty of compressing the trust tax. Different financial functions have different trust-tax structures. In some, the trust tax is primarily technical and can be compressed with code, because algorithms and cryptography can directly replace what users need to trust; in others, it is primarily institutional and must be maintained through law, regulation, and politics, because the trust involves domains that code

cannot replace—sovereign power, the physical world, and human discretion.

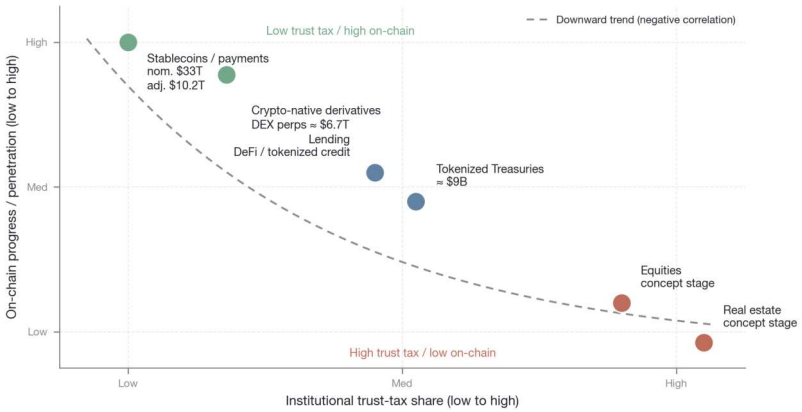

Figure 3-5. The trust-tax compression curve—the higher the share of the institutional trust tax in a financial function, the lower its on-chain progress (the scatter points of the various financial functions in the figure lie along a single negatively sloped trend line and represent the author's empirical judgment and estimates: the share of the institutional trust tax is the author's qualitative assessment of each financial function's trust structure, and the data anchors for on-chain progress are sourced by item—stablecoin nominal and adjusted transaction volumes are from Visa Onchain Analytics [38], data provided by Allium, raw/adjusted figures, accessed June 2026; DEX perpetual-futures trading volume is from CoinGecko [39]; and the size of tokenized Treasuries is from RWA.xyz [28])

In Figure 3-5, the horizontal axis is the share of the institutional trust tax (increasing from left to right) and the vertical axis is current on-chain progress (increasing from bottom to top); six categories of financial function appear as scatter points along a downward-sloping trend line, showing a clear negative correlation. Payments and settlement sit in the upper left, with the lowest share of institutional trust tax and the highest on-chain progress; real estate sits in the lower right, with the highest share of institutional trust tax and the lowest on-chain progress. This inverse relationship is not coincidental but causal: the higher the proportion of a financial function's trust needs that are technically replaceable, the lower the resistance to moving it on-chain and the faster its progress.

Table 3-3 arranges the six categories of financial function along the trust-tax compression-difficulty gradient, revealing a clear pattern: from payments and settlement to real estate, the share of the technical trust tax declines, the share of the institutional trust tax rises, and current on-chain progress correlates positively with the share of the technical trust tax.

Financial function	Share of technical trust tax	On-chain compression difficulty	Current progress	Key bottleneck
Payments and settlement	Very high	Low	$33 trillion in annual stablecoin settlement; escape velocity reached	Anti-money-laundering compliance
Fixed income	Medium-high	Medium	Roughly $9 billion in tokenized Treasuries, with BUIDL in the lead	Adapting the legal framework
Lending	Medium	Medium	Tens of billions of dollars in total value locked (TVL) across Aave, Compound, and others	Credit-assessment systems
Derivatives	Medium	Medium	$6.7 trillion in annual perpetual-futures DEX volume	Regulatory classification and extraterritorial jurisdiction (CFTC swap-jurisdiction claims, extraterritorial application of the Commodity Exchange Act, or CEA)
Equities and equity stakes	Low	High	Very early exploration	Corporate-law reform
Real estate	Very low	Very high	Conceptual stage	Cooperation of the entire legal system

Table 3-3. The trust-tax compression-difficulty gradient—from payments to real estate (Data sources: RWA.xyz [28], CoinGecko [9])

The current progress of on-chain finance unfolds along this curve from left to right—not because payments are simpler than equities, but because the trust tax of payments is primarily technical: correspondent banks, SWIFT nodes, and settlement delays can all be replaced by smart contracts and public blockchains, whereas the trust tax of equities is primarily institutional, and corporate governance, shareholder voting rights, dividend rights, securities registration, and annual audits require the cooperation of the entire legal framework.

This curve explains the past and also predicts the future: the next breakthrough is very likely to come in structured products and complex derivatives, whereas breakthroughs in equities and real estate require not technological progress but fundamental legal and institutional innovation. In 2022, the Boston Consulting Group and ADDX predicted

that tokenized-asset volume could reach $16 trillion by 2030 [29]; McKinsey, in 2024, was more cautious, projecting that tokenized assets (excluding stablecoins and deposits) could reach $2 trillion by 2030, and roughly $4 trillion in an optimistic scenario [30]. The order-of-magnitude difference between the two projections reflects differing assumptions about how fast institutional obstacles will be overcome. Actual progress will more likely depend on the speed of the transition along the curve from fixed income to equities, and the bottleneck of that transition lies in the structural constraints analyzed in Section 3.6: the sovereignty boundary and the physical-world interface.

3.3.2 H1: Stablecoin settlement and crypto-native derivatives

The first horizon comprises those on-chain financial functions that have already reached significant scale, whose trust tax is primarily technical and has been effectively compressed by on-chain infrastructure. The two pillars of H1 are stablecoin settlement and crypto-native derivatives. The total market capitalization of stablecoins is roughly $310 billion, and their annual settlement volume reaches $33 trillion (Section 3.4 analyzes the statistical basis and the economically effective settlement volume in detail); escape velocity has been reached [9]. On the crypto-native derivatives side, perpetual-futures DEXs have annual trading volume exceeding $6.7 trillion, and the entire crypto-derivatives market has annual trading volume of roughly $92.9 trillion, split between centralized exchanges (CEXs) at roughly $86.2 trillion and DEXs at roughly $6.7 trillion. Chapter 2 analyzed the mechanism design of perpetual futures in detail; they are the most successful product in H1 and the central object of analysis throughout the rest of this book.

The total nominal economic activity of H1 products—including the $33 trillion in stablecoin settlement (see Section 3.4.1 for the basis) and the roughly $92.9 trillion in nominal derivatives trading volume (CEXs roughly $86.2 trillion, DEXs roughly $6.7 trillion; nominal volume is amplified by leverage and may include non-organic components such as rebate trading)—is within a comparable order of magnitude to the corresponding products of the traditional derivatives market. Of this, DEX perpetual futures running entirely on on-chain architectural trust contributed roughly $6.7 trillion, and achieving this scale does not rely on traditional financial infrastructure: no clearinghouse, no membership requirement, no central counterparty. The absence of a central counterparty (CCP) eliminates the risk of a centralized single point of failure, but it also means forgoing the three key functions a CCP provides: multilateral netting (which lowers systemic margin requirements), a default fund (which absorbs extreme losses), and an institutionalized default-management process. On-chain DEXs use insurance funds and ADL as substitutes, but the risk-bearing capacity of these mechanisms has not yet been tested under extreme stress with the same systemic intensity as a CCP; the losses that Hyperliquid's insurance vault faced during the March 2025 JELLY incident exposed the limits of these substitutes. Their economic significance lies not in the absolute numbers but in demonstrating that financial infrastructure based on architectural trust can operate at significant scale, even as its risk-management architecture continues to evolve from minimum viable toward systemically robust.

The trust profile of H1 is architectural trust as the mainstay, plus a minimum of in-

stitutional trust: users primarily trust cryptography and smart-contract code, while institutional trust is embodied mainly in stablecoin issuers' reserve management and exchanges' operational security. Its risk profile differs qualitatively from that of traditional finance. Protocol risk (smart-contract vulnerabilities) replaces operational risk (back-office human error), depegging risk (a stablecoin losing its peg) replaces credit risk (a bank's insolvency), and liquidation-cascade risk replaces settlement-cascade risk. Each of these conversions replaces a familiar, well-studied risk with a newer one that is not yet fully understood—a concrete manifestation of the risk-surface transformation analyzed in Chapter 1.

The success of H1 provides the empirical foundation for all of this book's analysis. Perpetual futures, as the highest-volume product in H1, prove that the four distinctive properties can generate a financial instrument superior in specific dimensions to its traditional counterpart, the quarterly future: continuous trading eliminates gap risk, a continuous funding rate achieves sustained price anchoring, permissionless global access broadens the participant base, and atomic settlement eliminates counterparty risk. Chapters 4 through 33 analyze this product's microstructure, risk dynamics, and future evolution in depth.

3.3.3 H2: Tokenized securities and institutional DeFi

The second horizon comprises the on-chain financial functions moving from proof of concept toward large-scale application, whose trust tax is a mixture of the technical and the institutional. Tokenized real-world assets (RWAs, excluding stablecoins) stood at roughly $24 billion to $28 billion by the end of 2025 (depending on the statistical basis, per RWA.xyz) [28] (note: Figure 3-9 ranks by the size of each subsegment, in which private credit uses an active-outstanding basis, so the sum of the subsegments exceeds the distributed total given here). Private credit is roughly $18.9 billion, with platforms such as Apollo and Securitize tokenizing long-illiquid private-credit assets; Treasuries and money market funds are roughly $9 billion, the fastest-growing segment, with BUIDL and Ondo Finance's USDY as representative products. Private credit's dominant position within H2 is no accident: this asset class has historically been plagued by extreme illiquidity, with lock-up periods typically of 3–7 years and a secondary market that barely exists. Tokenization addresses this structural weakness by enabling fractional ownership and around-the-clock secondary trading, lowering the liquidity premium that investors demand and expanding the pool of potential investors from large institutions to a broader group of accredited investors. The collaboration between Apollo and Securitize is a textbook case of this logic: accredited investors can enter a tokenized private-credit fund at a markedly reduced minimum investment, while the fund benefits from more efficient capital formation.

Treasury tokenization occupies a strategically different position. Unlike private credit, U.S. Treasuries already have extremely high liquidity in traditional markets. The value of tokenizing Treasuries lies not in improving liquidity but in achieving DeFi composability: once a U.S. Treasury fund exists in the form of an ERC-20 token, it can serve as collateral in lending protocols, as margin in derivatives trading, and as yield-bearing reserves in stablecoin mechanisms. BUIDL's rapid growth in AUM to near $3 bil-

lion proves that market demand for this composability is substantive. The core thesis of Treasury tokenization is this: the most trusted asset class in traditional finance, sovereign debt, can become the collateral backbone of the entire DeFi ecosystem (the mechanism by which it replaces highly volatile crypto assets and lowers systemic risk is discussed in Section 3.2.4).

The breakthrough of H2 depends more on institutional conditions than on technical capability. The full implementation of MiCA, the U.S. shift from enforcement-driven to legislation-driven regulation, and the regulatory sandbox regimes of Singapore and Hong Kong together turn the compliance risk of institutional participation from unassessable into assessable and manageable [23]. The years 2024–2030 are a critical window: if regulatory certainty continues to improve and early H2 products show reliable operational performance, institutional capital may flow into tokenized assets at a nonlinearly accelerating pace.

3.3.4 H3: Programmable money and autonomous finance

The third horizon comprises domains still at the conceptual and early-exploration stage, whose trust tax is almost entirely institutional. Central bank digital currency is the most direct intersection of programmability and monetary sovereignty. As of 2025, more than 130 countries (the Atlantic Council tracker now lists roughly 146) are exploring central bank digital currency [31], and China's digital yuan had a cumulative transaction value of roughly ¥16.7 trillion by the end of 2025 (¥7 trillion was a mid-2024 milestone) [32]. Its transformative potential lies in programmable monetary policy: targeted stimulus spending can be restricted to specific consumption categories, interest rates can be set differentially by holder type, and taxes can be collected automatically at the transaction level. Yet this programmability also raises fundamental concerns: a currency that the state can program can equally be used for surveillance, censorship, and behavioral control. The design choices around the privacy architecture of a central bank digital currency will define the boundary between efficient governance and authoritarian overreach.

AI agents are evolving from tools that assist human traders into independent entities that autonomously evaluate opportunities, execute trades, and manage portfolios. In 2025, projects such as Virtuals Protocol and Spectral had already deployed AI agents with their own wallets and the ability to trade on-chain. The long-term implications go beyond the automation of trading itself: if AI agents become the primary participants in DeFi markets, the market-microstructure assumptions on which current protocol design rests (human reaction times, behavioral biases, information-processing limits) may need fundamental revision. Chapters 31 through 33 analyze in detail how AI agents interact with perpetual-futures markets.

A cross-sovereign global settlement layer (a single neutral infrastructure serving all value transfer) is the logical endpoint of the stablecoin settlement-layer migration analyzed in Section 3.4. Yet this vision conflicts directly with the sovereignty boundary analyzed in Section 3.6.1. A more realistic direction of evolution is federated global settlement: multiple sovereign jurisdictions each define their own rules—know-your-customer (KYC) requirements, asset restrictions, tax reporting—while sharing a common technical in-

frastructure layer. This model captures the efficiency gains of a unified settlement network while preserving sovereignty. The standards for judging H3 are inherently uncertain: no established metrics for the progress of programmable money or autonomous finance yet exist, and premature quantification would bring only misleading precision.

3.3.5 Differences in the trust needs of the three horizons

The trust needs of the three horizons are fundamentally different and should not be judged by a single standard. Using the logic of "stablecoins have already succeeded, so blockchain will change everything" to infer the prospects of H3, and using the logic of "real-estate tokenization has not yet succeeded, so blockchain is worthless" to deny the achievements of H1, commit the same methodological error: conflating the maturity levels and standards of judgment of different horizons.

Figure 3-6 uses a timeline to show the evolutionary path and differing trust needs of the three horizons (H1, H2, and H3).

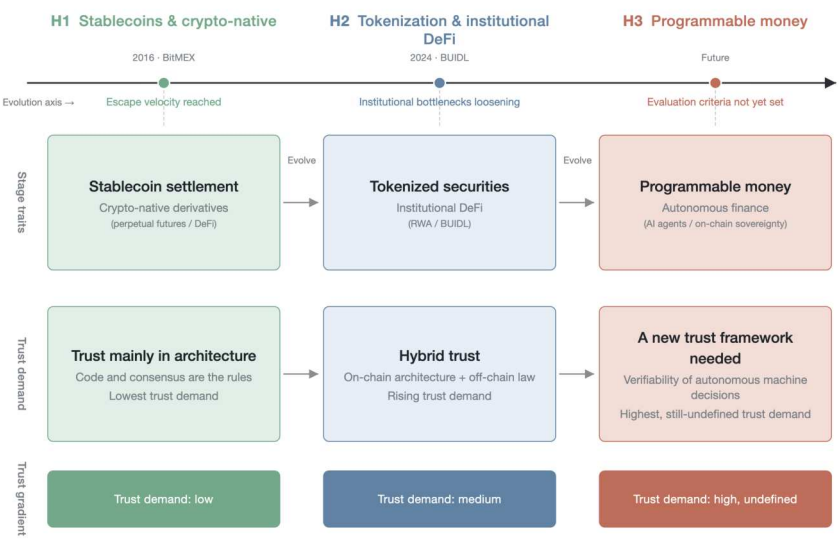

Figure 3-6. The three-horizon framework—the evolutionary path and differing trust needs of on-chain finance from H1 to H3 (drawn by the author)

The differences can be compared along five dimensions: trust paradigm, regulatory need, current scale, standard of judgment, and time scale. Table 3-4 summarizes the structural distinctions among the three horizons along these dimensions.

Dimension	H1: Stablecoins and crypto derivatives	H2: Tokenized securities and institutional DeFi	H3: Programmable money and autonomous finance
Primary trust paradigm	Architectural trust as the mainstay	A mix of architectural and institutional trust	Requires an entirely new trust framework
Regulatory need	Anti-money-laundering and reserve transparency	Securities-law compliance and investor protection	Requires an entirely new regulatory paradigm
Current scale	$33 trillion in annual settlement (roughly $0.4–10 trillion adjusted to a payment basis), roughly $92.9 trillion in nominal derivatives trading (CEX roughly $86.2 trillion, DEX roughly $6.7 trillion)	Roughly $25 billion in tokenized RWAs	Concept and early pilots
Standard of judgment	Trading volume, settlement efficiency, and stability	AUM growth and institutional adoption rate	No established standard yet
Time scale	Scale already reached	Breaking through; 2024–2030 the critical window	Long-term vision, the 2030s and beyond

Table 3-4. A systematic comparison of the trust needs of the three horizons (Data source: compiled by the author)

The most notable feature of Table 3-4 is the difference in the standard-of-judgment row. The success of H1 can be measured directly with hard metrics such as trading volume and settlement efficiency; the progress of H2 can be tracked through AUM growth and the institutional adoption rate; but H3 has not even a commonly accepted standard of judgment, which means any quantitative assessment of it should be treated as highly preliminary. This difference also explains why public discussion of the prospects of on-chain finance so often becomes polarized: optimists extrapolate from the hard data of H1, pessimists dismiss the field on the uncertainty of H3, and the two sides are in fact debating different questions on different horizons.

3.4 Stablecoins: a structural migration of the settlement layer

Stablecoins are the largest and most far-reaching product category in the first horizon of on-chain finance. The scale of their annual settlement volume marks not merely the success of an asset class but a structural migration under way in the settlement layer of the financial system.

3.4.1 The meaning of $33 trillion in settlement volume

As of the end of 2025, the total market capitalization of stablecoins worldwide was roughly $310 billion, with annualized on-chain settlement volume of approximately $33

trillion (Artemis/Bloomberg [7]), exceeding the combined annual processing volume of Visa (roughly $14 trillion; FY2025 payment volume, roughly $17 trillion including cash) and Mastercard (roughly $10.6 trillion) [9][33]. Figure 3-7 compares these magnitudes. The significance of the comparison lies not in the absolute numbers (differences in statistical basis are discussed below) but in the fact that an on-chain settlement infrastructure less than 10 years old already stands, in aggregate terms, within a comparable order of magnitude of the world's most mature payment networks.

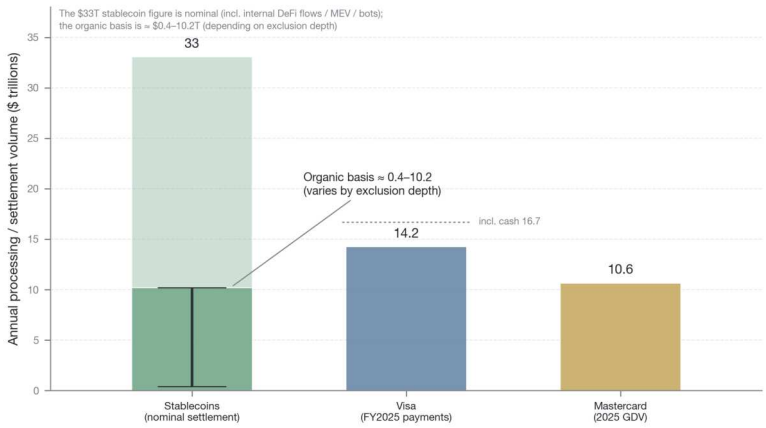

Figure 3-7. A comparison of the annual magnitudes of stablecoins and the card networks (nominal basis vs. organic basis; the nominal volume of stablecoin on-chain transfers for all of 2025 was roughly $33 trillion, up 72% year over year, including non-payment activity such as internal DeFi flows, MEV, arbitrage, and market-making bots, and is not directly comparable to card-network payment volume; the organic basis, after excluding non-payment activity, is roughly $0.4 trillion–$10.2 trillion, with the lower bound being roughly $0.39 trillion in true payments annualized and the upper bound roughly $10.2 trillion in adjusted transfer volume, the width of the range depending on the degree of exclusion, as marked with a range in the figure; Visa's payment volume of $14.2 trillion and Mastercard's gross dollar volume (GDV) of $10.6 trillion are shown for comparison, with Visa's cash-inclusive figure at $16.7 trillion; data sources: Artemis/Bloomberg [7]; Visa Onchain Analytics adjusted basis, trailing 12 months, accessed June 26, 2026; McKinsey × Artemis, annualized as of December 2025; Visa FY2025 10-K, as of September 30, 2025 [33]; Mastercard FY2025 results)

The statistical basis requires clarification: the on-chain settlement volume of stablecoins includes all on-chain transfers, a considerable share of which are internal DeFi flows, MEV arbitrage, and bot loop trades—not fully comparable to the consumer payments of Visa and Mastercard. Estimates after excluding these non-economic transactions diverge widely by method: Visa's on-chain analytics gives roughly $10.2 trillion (adjusted); Chainalysis gives roughly $28 trillion (true economic activity); McKinsey and Artemis estimate that only roughly $0.39 trillion is true real-world payments (roughly 1% of the total, as of January 2026); and the heuristic of Brevan Howard Digital (2024) [8] gives an organic share of roughly 10%. Even at the higher adjusted figure, this scale remains within the same order of magnitude as Visa's annual net payment volume, and its growth rate far exceeds Visa's.

The core economic advantage lies in extremely low marginal cost and global reach. Traditional cross-border payments must pass through multiple correspondent banks layer by layer, taking 3–5 business days at a cost of 5–10% of the transaction amount. On-chain stablecoin transfers, regardless of amount, complete within minutes, at a cost typically under $1 on Layer 2 networks (though the Ethereum mainnet can reach several to tens of dollars during congested periods). This efficiency difference stems from an architectural one; the specific comparison of serial versus parallel trust is detailed in Section 3.5.2.

3.4.2 The network effects and escape velocity of stablecoins

Stablecoins have reached escape velocity. This chapter operationalizes escape velocity as follows: a network has reached it when the marginal user-growth rate driven by network effects persistently exceeds the natural attrition rate, and when growth no longer depends on an exogenous impetus (such as price speculation or subsidy incentives) but has become endogenous and self-maintaining. The network-externality theory of Katz and Shapiro (1985) [34] provides a standard framework for this dynamic: when a user's utility increases as the network grows, a critical size threshold exists beyond which growth becomes self-accelerating. This judgment must withstand cyclical testing. During the 2022 bear market, the total market capitalization of stablecoins shrank from roughly $180 billion to roughly $120 billion (about 33%), showing that growth is not entirely endogenous. But the key distinction is this: the contraction came mainly from the ebbing of speculative demand (the collapse of the algorithmic stablecoin UST alone accounted for roughly $18 billion of it), whereas the cross-cycle trend in settlement volume and active-address count indicates that actual usage demand kept growing. A more stringent test will come after the next complete bear-market cycle: if stablecoin settlement volume and active-user count keep growing through the next downturn, the escape-velocity judgment will gain stronger empirical support. A threefold network effect gives stablecoin growth this self-reinforcing character.

The first is a liquidity network effect. The more traders use USDC and USDT, the deeper the market liquidity and the narrower the bid-ask spread, which in turn attracts more traders, forming a positive feedback loop. This effect explains the extreme concentration in which USDT and USDC hold more than 85% market share. A newly entering stablecoin faces a cold-start dilemma: without liquidity, traders will not adopt it, and without traders, liquidity cannot form. This dynamic gives the current duopoly a self-reinforcing character, much as the joint market position of Visa and Mastercard in card payments has held firm over decades despite persistent competitive entry.

The second is an integration network effect. The more DeFi protocols support USDC, the greater USDC's utility as an on-chain dollar, which in turn attracts more protocols to integrate it. USDC is already natively supported by hundreds of DeFi protocols, serving as the default quote currency in AMM pools, standard collateral in lending protocols, and the primary settlement token in perpetual-futures trading. Each additional integration raises the cost of switching to an alternative stablecoin, producing a standard lock-in effect.

The third is a settlement network effect. The more institutions and individuals settle

in stablecoins, the lower the friction of cross-border settlement, which in turn drives broader adoption. The moves by Visa and Mastercard to integrate stablecoin settlement amplify this effect, connecting on-chain settlement to the vast user base of traditional payment networks. Once escape velocity is reached, growth becomes self-maintaining, no longer dependent on new technological breakthroughs; the network effect itself is the engine of growth.

3.4.3 The upper-layer effects after the settlement layer is established

The financial system is layered, and settlement is the bottommost layer. Once the settlement layer is established on-chain, upper-layer applications naturally migrate to the same layer, because composability works within a single settlement infrastructure but cannot span different ones. When the BUIDL fund exists as an ERC-20 token on Ethereum and settles in USDC, it automatically gains composability with all other Ethereum DeFi protocols: it can serve as Aave collateral, trade on Uniswap, be incorporated into structured products, and serve as margin for perpetual futures. This cross-application interoperability, which would require months of legal negotiation and technical integration in traditional finance, is a natural property of shared settlement infrastructure on-chain.

The upper-layer effect produces a self-reinforcing dynamic. Perpetual-futures DEXs use stablecoins as margin, tokenized Treasuries subscribe and redeem in USDC, DeFi lending protocols denominate in stablecoins—all upper-layer applications already run atop the on-chain settlement layer. As more upper-layer applications accumulate, the settlement layer becomes ever more entrenched: migrating away from it would require migrating every dependent application at once, which grows less and less realistic as the ecosystem expands. This lock-in dynamic explains why the stablecoin settlement-layer migration, once past the escape-velocity threshold, becomes structurally irreversible. To see stablecoins merely as an on-chain dollar substitute is to underestimate their systemic significance: they are the foundation on which the entire on-chain financial technology stack is built.

3.4.4 The structural risks of stablecoins

Stablecoins also carry structural risks. The first is reserve-transparency risk. The controversy over the composition of Tether's reserves has persisted for years. For a financial instrument with a market capitalization exceeding $100 billion, incomplete or delayed reserve disclosure constitutes a systemic risk. Tether has improved transparency by releasing quarterly attestation reports, but a significant gap remains between these reports and the comprehensive, independent, real-time audit that a traditional financial instrument of comparable size would face. This gap between attestation and audit is a residual trust deficit.

The second is depegging risk. The clearest empirical case is USDC's depeg to $0.87 after the collapse of Silicon Valley Bank (SVB) in March 2023. Circle held $3.3 billion at SVB, roughly 8% of its reserves [35]. During the 48-hour depegging period, cascade effects propagated throughout the DeFi ecosystem: the declining value of USDC-denominated collateral triggered liquidations in lending protocols, traders rushing to exit USDC

positions unbalanced DEX pools, and USDC's function as the default settlement token was temporarily disrupted. The collapse of SVB occurred after banks closed on a Friday, and Circle was unable throughout the weekend to confirm the safety of its $3.3 billion in reserves or to process redemptions—exposing a structural operational break: on-chain stablecoins claim to run around-the-clock and instantly, but redeeming their reserves depends on the working hours of traditional banks (Monday through Friday), so depegging risk peaks precisely when the traditional financial system is least available. The depeg was resolved only after the U.S. government guaranteed SVB's depositors, which means USDC's stability ultimately depended on sovereign intervention rather than any algorithmic or architectural mechanism.

The third is systemic concentration risk. USDT and USDC together hold more than 85% market share. The failure of either issuer (whether due to reserve insolvency, regulatory action, or an operational-security incident) could trigger a systemic crisis across the entire on-chain financial system. This concentration creates a single-point-of-failure architecture, at odds with the decentralization ethos of blockchain. Diversification into alternative stablecoins has made limited progress, precisely because of the liquidity network effect analyzed in Section 3.4.2.

The fourth is the effect on monetary sovereignty. The global adoption of dollar-denominated stablecoins in effect extends U.S. monetary influence into economies that may not welcome it. For emerging-market countries with volatile local currencies, the adoption of USDC and USDT provides citizens and enterprises with de facto dollar accounts, potentially weakening the transmission of local monetary policy and capital-account controls. The central bank digital currency programs of several countries are an explicit defensive response to this dynamic. The EU's MiCA sets capital requirements and reserve rules for stablecoin issuers [23]; the United States is advancing stablecoin legislation, bringing stablecoins into the framework of regulated financial infrastructure.

3.5 Asset tokenization and on-chain settlement

The previous two sections made the macro case: the direction of convergence (Section 3.3) and the evidence of settlement-layer migration (Section 3.4). This section turns to the technical path, analyzing the engineering process of asset tokenization and the architectural advantages of on-chain settlement, to give those macro arguments a micro-technical foundation.

3.5.1 The economic logic of asset tokenization

Asset tokenization is the process of cryptographically mapping the ownership of and associated rights in a real-world asset onto a digital token on a blockchain; its core function is to lower transaction costs through standardization, transforming non-standardized, low-liquidity real-world assets into standardized, highly liquid, globally tradable digital-native assets. Chapter 1 answered why digital assets are distinctive; this section answers how to give traditional assets those distinctive properties as well.

The trust-tax compression curve of Section 3.3 showed that tokenization progress correlates positively with the share of the technical trust tax. Tokenization is not a simple

digital mapping but a multi-stage engineering process spanning law, technology, and compliance, and understanding it helps explain why different asset classes tokenize at systematically different speeds. Figure 3-8 shows the full life-cycle process of a tokenized asset, from a traditional asset to on-chain circulation.

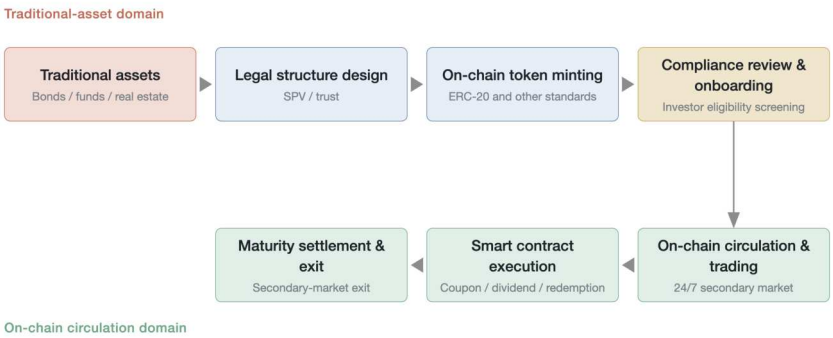

Figure 3-8. The full life-cycle process of a tokenized asset—from a traditional asset to on-chain circulation

The size distribution of tokenized assets is highly concentrated. Figure 3-9 shows that private credit, together with Treasuries and money market funds, constitutes the two largest categories, which together account for the vast majority of total tokenized RWAs; the remaining domains are still below tens of billions of dollars. This concentration reflects the prediction of the trust-tax compression curve: asset classes with a high share of technical trust tax move on-chain first.

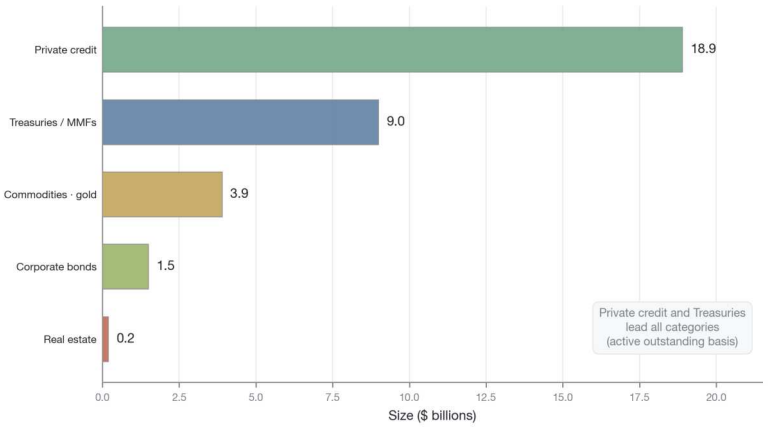

Figure 3-9. A size ranking of the major subsegments of on-chain RWAs (in billions of dollars, as of the end of 2025; private credit leads at roughly $18.9 billion, followed by Treasuries and money market funds at roughly $9 billion, the two together accounting for the vast majority of tokenized RWAs; commodities dominated by gold, corporate bonds, and real estate remain a long tail at tens of billions of dollars and below; private credit uses an active-outstanding basis, dominated by Figure's on-chain home equity line of credit (HELOC) loan book, while the rest use a market-value/distributed basis; data source: RWA.xyz [28])

Table 3-5 summarizes the current progress of on-chain finance in four core domains—

private credit, Treasury funds, sovereign and corporate bonds, and cross-border payments—along three dimensions: size, representative projects, and key advantages relative to traditional finance.

Domain	Size	Representative projects	Key advantages
Private credit	Roughly $18.9 billion	Apollo and Securitize, Centrifuge	Solves poor liquidity, lowers the participation threshold
Treasuries and money market funds	Roughly $9 billion	BUIDL, Franklin Templeton, Ondo	Around-the-clock subscription and redemption, DeFi composability
Sovereign and corporate bonds	Hundreds of millions of euros	European Investment Bank, Siemens	T+0 settlement, lower issuance costs
Cross-border payments	$33 trillion in annual settlement	Circle USDC, Tether USDT	Near-real-time, extremely low cost, globally reachable

Table 3-5. The application progress of on-chain finance in key domains (Data source: RWA.xyz [28])

Table 3-5 reveals a pattern consistent with the trust-tax compression curve: the two largest domains, cross-border payments ($33 trillion in annual settlement) and private credit (roughly $18.9 billion), correspond exactly to the asset classes with a higher share of technical trust tax and an obvious efficiency gap in traditional markets. The pain point of cross-border payments is speed and cost; that of private credit is illiquidity—both domains that code and architecture can directly improve. By contrast, sovereign and corporate bonds remain at the level of hundreds of millions of euros, and their issuance involves more institutional approval steps, confirming the constraint that the institutional trust tax places on on-chain speed.

3.5.2 The architectural advantages of on-chain settlement

On-chain settlement uses a blockchain as the underlying network for value transfer and clearing, on a globally unified, neutral, around-the-clock ledger whose trust is guaranteed by decentralized cryptographic consensus. Traditional payments rest on the serial relay of bilateral trust relationships, in which each additional intermediary node adds a layer of cost; on-chain settlement rests on a single global consensus, in which all participants share the same trust foundation.

Figure 3-10 compares the two settlement paths. In the traditional cross-border payment path, the SWIFT network performs a messaging function, conveying payment instructions rather than moving funds, while the funds themselves move through the nostro/vostro account relationships between correspondent banks. In this multi-node serial relay, each node adds delay and fees, and the failure of any node breaks the entire chain (SWIFT itself is raising payment speed and transparency through innovations such as SWIFT GPI to meet the competition). In the on-chain settlement path, the sender initiates a transfer directly on the blockchain through a wallet, and once blockchain consensus verifies it, the funds arrive at the recipient's wallet—only three

nodes, with the intermediate consensus layer decentralized and free of any single point of failure.

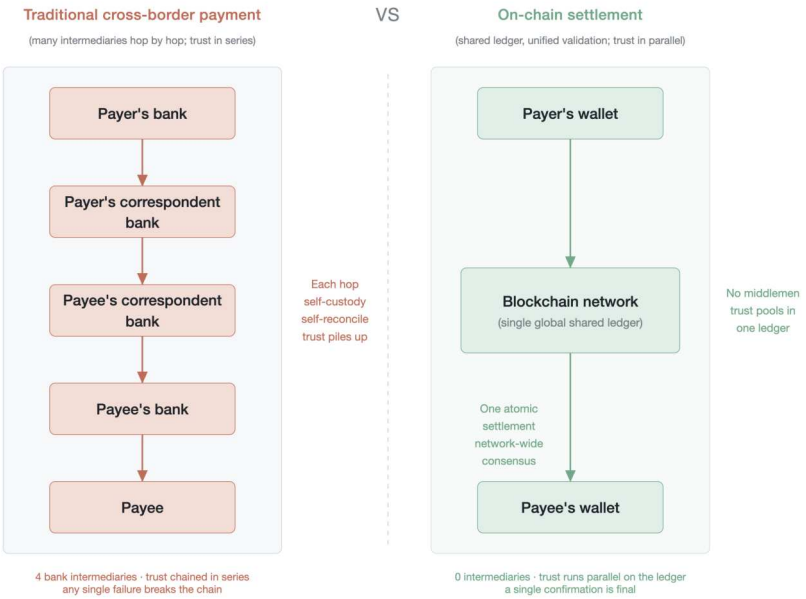

Figure 3-10. A process comparison of traditional cross-border payments and on-chain settlement—the architectural difference between serial trust and parallel trust

Parallel trust is superior to serial trust in both efficiency and resilience. In regions such as Latin America and sub-Saharan Africa, many small and medium-sized enterprises are increasingly adopting stablecoins as their primary means of payment and receipt, cutting the in-transit time of funds from days to minutes and transaction costs by as much as 90%—a cheaper, faster global-payment option for enterprises underserved by the traditional financial system.

3.5.3 Three surmountable challenges

On-chain finance faces three surmountable challenges. They are not independent of one another but form a mutually reinforcing feedback loop. Figure 3-11 uses a triangular structure to depict the bidirectional dependencies among technical maturity, regulatory certainty, and market size. This means that a breakthrough in any single dimension requires the cooperation of the other two to produce a lasting effect; it also means that once one dimension makes substantive progress, a positive feedback loop may accelerate the whole.

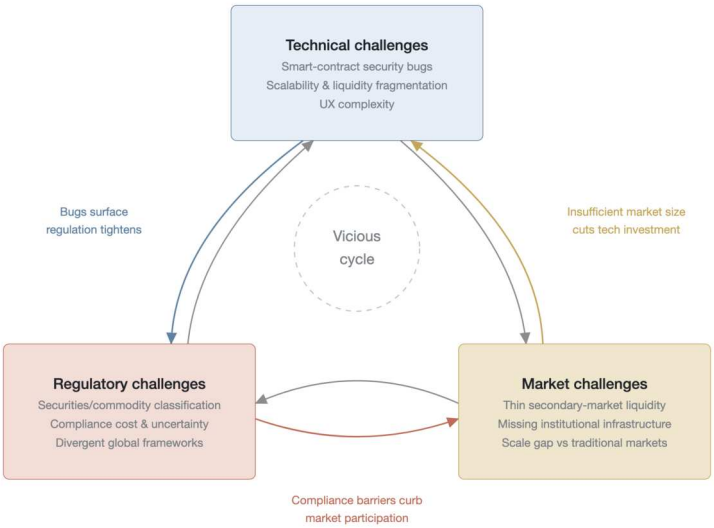

Figure 3-11. The interrelationship of the three major challenges of on-chain finance—the feedback loop among technology, regulation, and the market

On technical maturity, smart-contract security risk remains prominent (see Section 3.1.4 for the scale of security losses in 2025). The operational reliability of underlying blockchains still falls below that of traditional financial infrastructure: Solana suffered several multi-hour network outages between 2021 and 2023, and surging gas fees on the Ethereum mainnet during periods of high load make small transactions uneconomical, whereas the availability of traditional financial infrastructure such as Fedwire typically exceeds 99.99%. TVL on Layer 2 networks—which L2BEAT now reports as total value secured (TVS)—grew from roughly $5 billion to more than $40 billion, with a 2024–2025 peak approaching $50 billion [36], but this brought a fragmentation problem, and the user experience remains overly complex. On regulatory certainty, MiCA leads but is still being implemented, the U.S. jurisdictional dispute between the SEC and the CFTC is unresolved, and fragmentation leaves institutions facing high compliance risk. On market size, roughly $25 billion in tokenized RWAs is still a negligible fraction of the hundreds of trillions in the global traditional financial market, and illiquidity and a weak secondary market form a negative loop.

These three challenges are obstacles that effort can overcome, distinct from the impossibility boundaries of the next section. The essential difference is this: the former are matters of degree—technical security will keep improving, the regulatory framework will gradually clarify, and market size will grow with the adoption rate; their solution paths are known, and the only bottleneck is the speed of execution. The latter are matters of kind—sovereignty will not vanish, the physical world will not become digital, and the logical constraints of decentralization cannot be engineered away; even infinite technological progress cannot break through them. This distinction is the first analytical step in assessing the prospects of any specific on-chain financial innovation.

3.6 The impossibility boundaries

The three structural constraints—the sovereignty boundary, the physical-world interface, and the governance paradox—are not obstacles that can be overcome through technological progress or institutional innovation but permanent constraints that must be lived with. Identifying these boundaries is the premise of a mature analytical framework and the methodological basis for distinguishing surmountable challenges from impassable constraints.

3.6.1 The sovereignty boundary

At bottom, the permissionlessness and globalization of on-chain finance challenge the state's jurisdiction over financial activity. This challenge is not technical but political: financial sovereignty is a core component of national sovereignty, and the transmission of monetary policy, foreign-exchange controls, capital-account management, and sanctions enforcement all depend on jurisdiction over financial activity. If a state cannot track, restrict, or freeze the flow of funds within its territory, its monetary policy, tax system, and sanctions capability will all be fundamentally weakened.

Empirically, no major country has chosen to relinquish financial jurisdiction, and national responses form a full spectrum from comprehensive prohibition to framework-based regulation. In 2021, China comprehensively banned cryptocurrency trading and mining while advancing the research, development, and pilots of the digital yuan. The logic of this strategy is to reject permissionless on-chain finance while retaining the technical potential of programmable money, provided that control over programmability stays with the central bank. The United States has adopted a strategy of selective enforcement: in 2022, OFAC sanctioned Tornado Cash, freezing all Ethereum addresses associated with the mixing protocol—the first time a sovereign state imposed sanctions on immutable open-source smart-contract code rather than on a specific individual or organization [37] (the sanction was later overturned by the Fifth Circuit in November 2024, and OFAC removed it in March 2025, though criminal proceedings against the founders continue as a separate matter). This action sparked a constitutional debate over whether code constitutes protected speech, but its policy signal was clear: even a technically unstoppable on-chain protocol cannot transcend sovereign jurisdiction. The CFTC's enforcement actions between 2023 and 2024 against offshore DeFi protocols such as Opyn, ZeroEx, and Deridex further confirmed its swap-jurisdiction claim over crypto derivatives; U.S. users trading perpetual futures on offshore DEXs may technically violate the CEA, which bears directly on the central subject of this book. The EU, through MiCA, brings crypto assets into a unified regulatory framework—neither prohibiting them wholesale nor letting them run free, but framing jurisdiction and seeking a balance between room for innovation and regulatory capacity [23].

What these different strategies have in common is this: no country has chosen to cede financial jurisdiction. Fully permissionless global finance (anyone able to transact any amount with any counterparty at any time without government review) is politically impossible so long as the system of states endures. The realistic end state is *conditional permissionlessness*: technically permissionless but conditional on compliance. The zero-knowledge-proof compliance credentials discussed in Chapter 30 are one tech-

nical exploration of maximizing freedom within this boundary, letting users prove to a smart contract that they meet compliance requirements without exposing their identity or transaction details. The sovereignty boundary also explains why compression difficulty is so high at the right end of the trust-tax compression curve: the trust tax of equities and real estate is supplied primarily by sovereign institutions—corporate law defines shareholder rights, property law defines real-estate ownership—and sovereign institutions will not voluntarily withdraw from these domains.

3.6.2 The physical-world interface

The efficiency advantage of architectural trust is clearest when on-chain finance handles purely digital assets, but it hits a fundamental interface problem when it touches assets in the physical world: a blockchain can transfer the ownership of a token frictionlessly, but it cannot frictionlessly transfer control over the physical entity that the token represents.

The theoretical root of this problem lies in a generalized form of the oracle dilemma. A blockchain is a closed, deterministic system whose internal state can be fully verified cryptographically, but its interface with the external world depends on oracles—intermediaries that feed off-chain information on-chain. For price data, decentralized oracle networks such as Chainlink have provided relatively reliable solutions. But for the state of physical assets (such as whether a house still exists, whether a batch of goods is still in the warehouse, or who actually possesses a plot of land), no decentralized verification mechanism exists. Verifying the state of the physical world ultimately depends on human observation and institutional enforcement.

Real-estate tokenization illustrates these constraints layer by layer. At the title-confirmation layer, property-registration systems differ enormously across jurisdictions, and many emerging-market countries lack even a complete digitized registry, so the mapping between on-chain tokens and off-chain title needs legal institutions to establish and maintain it. At the rights-enforcement layer, an on-chain token can record a change in home ownership, but when the occupant refuses to leave, a smart contract cannot enforce it; that requires a court summons and the physical action of law-enforcement personnel. At the valuation layer, the value of real estate depends on many off-chain factors—location, physical condition, urban-planning policy—that on-chain data cannot capture. At the cross-border enforcement layer, even if on-chain records were globally unified, the degree of judicial recognition of on-chain title certificates varies across national courts. Tokenization can make a home's transaction records more efficient and transparent, but it cannot make title confirmation and enforcement more efficient; the latter will always depend on the offline legal system.

Commodity tokenization faces similar constraints. Tokenized gold requires trusted third-party custody and periodic audits to ensure a one-to-one correspondence between the on-chain token and the physical gold, and this trust still rests on institutional trust in the auditor and custodian rather than on architectural trust. For physical assets, architectural trust will always require the cooperation of institutional trust, and the optimal solution is a hybrid model of on-chain records plus off-chain enforcement. This also explains why the asset classes making the fastest progress (stablecoins, Treasuries,

private credit, and corporate bonds) are all purely financial assets: their value is defined entirely by contractual terms and cash flows and involves no transfer of control over a physical entity.

3.6.3 The governance paradox

The ideal of on-chain finance is that rules are defined by code, enforced by consensus, and independent of the discretion of any centralized entity. Under normal operating conditions this ideal holds, with smart contracts executing automatically according to predetermined logic and requiring no human intervention. In an extreme crisis, however, ideal and reality collide: a decentralized system is by design averse to centralized decision-making, yet in a crisis it most needs a rapid, discretionary, centralized response.

The 2016 Ethereum DAO incident is the defining case of this paradox. An attacker exploiting a recursive-call vulnerability in the DAO smart contract moved roughly 3.6 million ETH (worth roughly $50 million–$60 million at the time) within hours, about one-third of the DAO's total assets. From the standpoint of "code is law," the attacker's behavior was compliant at the code level: he invoked the contract's functions in a manner the code permitted. The community faced an impossible choice: respect the determinism of the code, thereby accepting the attack's outcome, or modify the blockchain's history to return the stolen assets, thereby repudiating the founding principle that code is law. In the end, the Ethereum community redirected the stolen funds to a recovery contract through a hard fork—in essence, a centralized decision repairing a decentralized system. The cost of this decision was the permanent split of Ethereum into two chains, ETH and ETC, the latter refusing the rollback out of fidelity to the "code is law" principle. The DAO incident proves that when a decentralized system encounters an extreme situation its rules cannot foresee, it must either accept the consequences of its rules or introduce human discretion to repair them; there is no third option.

The March 2025 JELLY incident at Hyperliquid brought this paradox into the domain of perpetual futures. A trader manipulated the liquidation mechanism by opening a large JELLY short position on Hyperliquid while pumping the JELLY price in the spot market, exposing Hyperliquid's insurance vault to tens of millions of dollars in potential losses [25]. Hyperliquid's validators voted to force the delisting of the JELLY token and settle all positions at a specific price, effectively preventing further losses. This decision technically protected the system and most users, but it raised a fundamental governance question: if validators can vote to change the rules in response to a crisis, then the system differs from a traditional centralized exchange only in that the decision-making body is a small set of validators rather than a single management team.

These two cases reveal an intrinsic logical constraint of decentralized governance: a fundamental trade-off between full decentralization and efficient crisis response. Full decentralization means no entity holds the power to modify the rules unilaterally, but crisis response requires action that is rapid, decisive, and potentially rule-breaking. Current practice in on-chain finance is evolving toward a hybrid governance architecture: under normal conditions, smart contracts execute automatically to maximize

decentralization; in an emergency, a multi-signature or validator committee executes interventions of limited scope to introduce the minimum necessary centralization; and all interventions are subject to time-locks and after-the-fact review to limit the abuse of centralization. Chapter 30 discusses this dual architecture of time-locks and emergency powers in detail.

3.6.4 Maximizing within boundaries

The three impossibility boundaries do not negate the value of on-chain finance; they are a necessary premise for building a rigorous analytical framework. System design that lacks boundary awareness will spend resources trying to break through impassable constraints rather than finding the optimal solution within them.

The analytical value of identifying boundaries lies in matching each category of financial function with the most suitable trust paradigm. In the domain of purely digital assets (such as cryptocurrency trading, perpetual futures, and decentralized lending), the architectural trust of on-chain finance has been thoroughly validated, and its advantage lies in permissionless global participation, around-the-clock operation, and automated execution. In the purely sovereign domain (such as currency issuance, equity as defined by corporate law, and property registration), institutional trust is irreplaceable, and the value of on-chain technology lies in raising efficiency rather than replacing institutions. The hybrid domain (such as tokenized Treasuries, compliant stablecoins, and institutional-grade DeFi) requires the synergy of architectural and institutional trust, and the BUIDL fund is a successful case of exactly that.

As an epistemological stance, *maximizing within constraints* has practical significance at three levels. At the level of technical design, protocol designers should treat the compliance interface as a native component of the architecture rather than an after-the-fact patch, reserving programmable access points for regulatory requirements while keeping the core logic decentralized. At the level of business strategy, entrepreneurs and investors should focus first on the left and middle of the trust-tax compression curve—the domains with a high share of technical trust tax and manageable institutional obstacles—rather than confronting sovereign institutions head-on at the right end. At the level of analytical method, in assessing any on-chain financial innovation one should first ask whether it touches the three impossibility boundaries, thereby distinguishing engineering problems that iteration can solve from structural constraints that will not vanish with technological progress. This stance is the epistemological foundation of all analysis that follows in this book.

3.7 Chapter summary

The value of digital assets lies not in creating a better Bitcoin but in providing a systematic technical toolkit for compressing the trust tax of finance. This chapter has organized that argument through five named theoretical concepts, each answering an analytical question at a different level.

The economic reexamination of the four distinctive properties raises the inherent attributes of digital assets from technical description to economic proposition: permission-

lessness raises the contestability of financial markets by several orders of magnitude by lowering sunk costs, although liquidity barriers keep it short of the theoretical standard of perfect contestability; around-the-clock trading transforms the time fragmentation of traditional markets from a hard constraint into a soft one; atomic settlement eliminates the settlement cascade but cannot prevent the liquidation cascade; and programmability, while expanding the design space of financial innovation, introduces code rigidity and governance tension because of the completeness constraint of smart contracts. These four properties do not function independently but combine to produce novel financial mechanisms unachievable in traditional finance: the funding rate of perpetual futures, the automated market-making of AMMs, and the atomic, uncollateralized borrowing of flash loans—all products of this combinatorial effect.

The institutional convergence thesis (which grafts a competitive trust-tax-compression mechanism onto DiMaggio and Powell's institutional-isomorphism theory) reveals a bidirectional process: traditional finance adopts on-chain technology to compress the trust tax, on-chain finance introduces institutional elements to raise the level of trust, and under competitive pressure the two move from opposite directions toward the same equilibrium range. The BUIDL fund demonstrates convergence in both directions at once and is the landmark empirical evidence for this thesis. The trust-tax compression curve further explains the unevenness of convergence: from payments to real estate, the share of the institutional trust tax rises and the difficulty of moving on-chain rises accordingly, and the current sequence of progress closely matches this gradient. On this basis, the three-horizon framework distinguishes an H1 that has reached scale, an H2 that is breaking through, and an H3 that remains a long-term prospect, providing differentiated analytical standards for assessing the on-chain prospects of different domains. The stablecoin settlement-layer migration thesis argues that the $33 trillion in annual settlement volume already marks a structural migration of the financial system's settlement layer, that the threefold network effect gives this migration a self-reinforcing and irreversible character, and that once the settlement layer is established, the on-chain migration of upper-layer applications becomes an architectural inevitability. The impossibility boundaries, in turn, draw clear limits around the optimistic arguments above: the sovereignty boundary means that fully permissionless global finance is politically infeasible, the physical-world interface means that architectural trust cannot independently handle assets involving physical entities, and the governance paradox means that a decentralized system inevitably requires a centralized response in a crisis. Identifying these three constraints is the premise for the epistemological stance of *maximizing within constraints* and the methodological basis for distinguishing engineering problems from structural constraints.

The three chapters of Part One constitute a complete cognitive framework. Chapter 1 established what the differences between digital assets and traditional finance are, Chapter 2 what those differences gave rise to in derivatives, and Chapter 3 why all of this carries systemic significance for the entire financial system. Perpetual futures—the highest-volume product in the first horizon of on-chain finance—will be the central object of analysis for the 30 chapters that follow. The next chapter enters Part Two, turning these macro frameworks into an empirical analysis of microstructure: who trades, how they behave, and how profits flow.

Part II
The Ecosystem

Core question: Who trades perpetual futures, why do they come, and on what kind of ecosystem do they depend?

Participants and Behavior in Perpetual Futures Trading

On March 12, 2025, an anonymous wallet opened a 50x-leveraged long position in ETH on Hyperliquid with an initial margin of 4.3 million USDC, then used its unrealized profits to keep adding to the position, expanding its notional value to more than $300 million [1]. Under Hyperliquid's maintenance margin ratio (approximately 0.3%), 50x leverage placed the liquidation price roughly 1.7% away from the entry price, and the trader further narrowed this buffer by repeatedly withdrawing excess margin. The entire trade was publicly visible on-chain; copy traders rushed in to go long, shorts were forced to close, and the price was driven still higher. Yet rather than close the position, the trader withdrew realized profits from the account, deliberately lowering the margin ratio and raising its own liquidation price. Hyperliquid in fact allows traders to withdraw margin balances in excess of the maintenance-margin requirement while a position remains open, and this rule became the linchpin of the strategy. The protocol finally liquidated the position automatically when the ETH price reached $1,915. Because the liquidation was larger than liquidators could absorb through competitive market bidding, and the insurance fund was too small to cover it, the position passed to the HLP market-making vault. In unwinding the position, the vault incurred roughly $4 million in slippage losses and triggered more than $130 million in panic withdrawals by liquidity providers [2]. This episode reveals that, in a permissionless, fully transparent, and high-leverage digitally native environment, the basic assumptions about participant behavior have been rewritten. It raises the central questions of this chapter: which participants populate the perpetual futures market, how do they compete with one another, and what is the ultimate source of the market's profits?

The trader had calculated precisely that the penalty for being liquidated was far smaller than the slippage of unwinding a $300 million position on the open market in the ordinary way, and thereby shifted the price impact systematically onto the protocol's passive liquidity providers. Parasitic behavior in the on-chain environment has thus moved away from the informational advantage of traditional finance and toward a deep exploitation of what protocol rules imply economically.

To understand this new form of competition, this chapter takes the classic tripartite taxonomy of Harris (2003) as its academic starting point and builds a two-layer classification framework, functional and behavioral. It then examines, in turn, the behavioral logic and profit sources of the six core participant types; the game network among

participants and the mapping of profit flows; the threefold reshaping of participant behavior by the digitally native environment; the rise of autonomous artificial intelligence agents as a new type of participant; and a systematic comparison with traditional finance. The chapter's central thesis is that the gains of profit-motivated traders ultimately come from only two channels—the hedging premium that utilitarian traders pay to transfer risk, and the systematic losses that futile traders incur through mistaken decisions—and that the digitally native environment fundamentally reshapes this game structure through the fluidization of roles, the algorithmization of competition, and the transparency paradox.

4.1 The participant classification framework

This chapter repeatedly invokes several concepts introduced earlier. The transparency paradox of Chapter 1 holds that the full disclosure of on-chain data does not amount to an equal distribution of informational advantage; the composability thesis explains how the seamless interoperability among smart contracts creates a capacity for atomic execution that does not exist in traditional finance. The cost of abolishing the expiration date, analyzed in Chapter 2, shows that perpetual futures gain flexibility by eliminating delivery at maturity but at the same time introduce structural costs such as the indefinite horizon of inventory risk. These concepts form the necessary background for understanding this chapter's analysis of participant behavior.

Market microstructure theory offers two complementary classificatory perspectives. One is based on the functional purpose of a trade and answers the question of *why* participants trade, revealing the fundamental economic function that gives the market its reason to exist. The other is based on the specific role a participant plays in the market and answers the question of *how* participants trade, focusing on the particular roles that different participants play in price formation and the supply of liquidity.

4.1.1 Functional classification

Harris (2003) divides market participants into three basic categories by trading motive [3]. Utilitarian traders participate in the market not to profit directly from price movements but to achieve some external economic objective. In the perpetual futures market, the most typical utilitarian trader is the hedger. A Bitcoin miner, for example, may short perpetual futures to lock in future mining revenue, thereby transferring the risk of price fluctuations to other market participants. For this miner, perpetual futures are a risk-management tool rather than a vehicle for speculation. Likewise, a decentralized finance (DeFi) protocol treasury holding a large amount of ETH may use perpetual futures to hedge the price risk on its balance sheet. The defining feature of utilitarian traders is that they are willing to pay a certain cost—for instance, accepting a slightly unfavorable execution price—in exchange for certainty. They are the principal source of demand for market liquidity; their trading needs arise from external economic activity and constitute the fundamental reason the market exists, namely the transfer of risk.

Profit-motivated traders take the extraction of profit from the market as their central

objective; they are the principal source of market liquidity and the primary driver of price discovery. This group can be further subdivided by the source of its profits. Informed traders rely on an informational advantage—whether from deep fundamental research, distinctive analysis of on-chain data, or possession of non-public information—to forecast price movements and profit from them. Arbitrageurs do not depend on judging the direction of prices; instead, they earn low-risk profits by discovering and exploiting pricing discrepancies between different markets or different assets. Market makers earn the spread by simultaneously posting bid and ask quotes, providing other traders with the convenience of immediate execution. The framework also singles out a class of parasitic traders, who do not rely on fundamental information but profit by exploiting the behavior of other traders [3]. In the on-chain environment, maximal extractable value (MEV) searchers and front-running bots are the archetypal parasitic traders: they monitor the pending transaction pool to anticipate other traders' intentions and execute ahead of them to capture profit, and their behavior generally does not improve the market's price-discovery efficiency.

Futile traders are the third category in this taxonomy, and the one most easily overlooked. These traders expect to profit from trading but, owing to a lack of skill, information, or judgment, lose money persistently on average [3]. They often mistakenly believe themselves to be profit-motivated traders. In the crypto perpetual futures market, the presence of futile traders is especially pronounced. The extreme conditions of October 2025 provide direct evidence of their scale: within a mere 24 hours, more than 1.62 million trading accounts were forcibly liquidated, with total liquidations exceeding $19 billion, of which approximately 85%–90% (about 87%) by value were long positions (the precise liquidation statistics come from CoinGlass; exchange data generally understate the true scale) [4][5]. These traders chased the market higher during calm or rising periods, using leverage far beyond their risk tolerance and generally lacking any downside-protection strategy. Research in behavioral finance shows that this trading behavior is, in its psychological mechanisms, highly similar to gambling [6]. Their losses constitute an important source of profit for profit-motivated traders.

4.1.2 The two ultimate sources of profit

The core value of the tripartite taxonomy is that it reveals not only the fundamental reason the market exists (the risk-transfer demand of utilitarian traders) but also the ultimate source of market profits: the gains of profit-motivated traders come, in the final analysis, from only two channels [3]. The profits of arbitrageurs appear, on the surface, to derive from correcting mispricings in the market, seemingly independent of the two sources below. Mispricings, however, are themselves jointly produced by the inelastic demand of utilitarian traders and the pricing errors of futile traders; arbitrage profits can therefore, ultimately, still be traced back to the two sources, of which they are an indirect derivative.

The first source is the hedging premium that utilitarian traders pay to obtain utility. To convert future uncertainty into present certainty, utilitarian traders are willing to pay a premium—for example, by accepting a slightly unfavorable execution price to guarantee immediate execution, or by bearing a positive funding rate over an extended period to

maintain a hedge. These additional costs are essentially the insurance premiums they pay for risk transfer, flowing directly into the bid-ask spreads earned by market makers, the funding rates collected by short counterparties, and the basis profits captured by arbitrageurs. (The detailed mechanism for calculating the funding rate—including the composition of its interest rate and premium components, the typical 8-hour settlement cycle, and the extreme range of its magnitude—is presented in Section 2.3. Under normal market conditions, the funding rate is typically on the order of $\pm 0.01\%$ every 8 hours, but in extreme conditions it can climb to $\pm 0.1\%$ or higher, at which point the funding rate itself becomes a significant source of profit or a substantial cost of carry.) This profit channel is the fundamental economic rationale for the existence of the perpetual futures market: without genuine hedging demand, a derivatives market would degenerate into a purely zero-sum arena. In the crypto perpetual futures market, however, the proportion of utilitarian traders is far lower than in traditional commodity or financial futures markets. Schmeling et al. (2023), drawing on data from the Bank for International Settlements (BIS), studied the structure of carry trading in crypto markets, analyzing primarily the statistical properties of funding rates and the risk-return characteristics of carry strategies [7]. From its findings—that funding rates in crypto perpetual futures markets are predominantly positive but highly time-varying, and that speculative positions dominate—one can tentatively infer that participants in crypto derivatives markets are driven primarily by speculative motives, and that the share of genuine hedging demand may be lower than in traditional commodity futures markets (in most such markets, commercial hedgers typically hold more than half of the open interest, though the precise proportion varies by product and period). This inference, however, involves an additional argumentative step from the structure of carry trades to the share of hedging demand, and should not be regarded as a direct conclusion of that paper. Moreover, in interpreting the phenomenon of low hedging demand in crypto markets, one must distinguish two very different states: the absence of hedging demand, and the presence of hedging demand that cannot be expressed. In fact, a substantial share of institutional investors—including funds, corporate treasuries, and asset managers that hold exposure to crypto assets—have a genuine economic need to hedge risk through perpetual futures, yet cannot translate this need into actual hedging positions because of regulatory restrictions in their jurisdictions, compliance constraints arising from fiduciary duties, or a lack of access to regulated trading venues. This implies that the observable hedging demand in the market may be systematically lower than the actual economic need for hedging. As regulatory frameworks gradually become clearer and regulated trading infrastructure matures, this suppressed demand may be released in the future, thereby altering the relative proportions of the two profit sources.

The second source is the systematic losses that futile traders incur through mistaken decisions. Because they are at a systematic disadvantage in access to information, analytical capacity, or execution speed, futile traders are on average in a state of persistent loss. Their losses flow to profit-motivated traders along several paths: when they are liquidated, their short counterparties reap a direct directional profit; in ordinary trading, market makers safely earn the spread on their non-toxic order flow; and when forced liquidation is triggered, liquidators collect substantial liquidation penalties. From the

perspective of market microstructure, it is precisely the non-toxic order flow supplied by futile traders that subsidizes market makers' adverse-selection losses to informed traders, enabling market makers to remain profitable and continue supplying liquidity (this mechanism is fully elaborated in Section 4.3.3). A structural feature of today's crypto perpetual futures market is that the losses of futile traders constitute the single largest source of profit, while the hedging premium is not yet fully developed. This speculation-dominated profit structure is one root of the market's fragility: when futile traders are depleted by their losses and exit, the market loses its principal source of profit, market makers withdraw because they can no longer offset their adverse-selection losses, and market liquidity dries up in a recurring cycle.

The depletion hypothesis above, however, should not be understood as a one-directional, irreversible process; it should instead be examined within a dynamic-equilibrium framework. The stock of futile traders at any point in time depends on two opposing rates: a replenishment rate and a depletion rate. The replenishment rate is driven by the inflow of new users, which accelerates markedly during bull-market cycles under the combined catalysis of price narratives (the confirmation bias that *a rising price proves one right*), social-media contagion, and accommodative macro liquidity. The depletion rate is determined by loss-driven exits, as futile traders gradually leave after suffering consecutive losses and forced liquidations. When the replenishment rate persistently exceeds the depletion rate, the market displays a boom of ample liquidity, narrowing spreads, and richly profitable market makers; when the depletion rate exceeds the replenishment rate, the market enters a downturn of contracting liquidity, widening spreads, and profit-motivated participants preying on one another. This dynamic framework maps closely onto the bull-bear cycle: a bull market is essentially a period of net inflow of futile traders, a bear market a period of net outflow, and the turning points of the cycle tend to occur in the critical region where the two rates approach balance. More fundamentally, the inflow and outflow of futile traders are not exogenous random events but endogenous products of global macroeconomic conditions. The dollar liquidity cycle (proxied by the size of the Federal Reserve's balance sheet and global dollar funding costs), the swings in global risk appetite (proxied by the VIX index and emerging-market capital flows), and the regulatory cycles of the major jurisdictions (from tolerance to tightening to clarification) jointly determine the rhythm at which participants enter and exit the crypto market. In periods of ample macro liquidity, rising risk appetite, and relatively permissive regulation, large numbers of financially inexperienced new participants are drawn into the high-leverage perpetual futures market, supplying profit-motivated traders with abundant non-toxic order flow; when macro conditions reverse, the inflow of new users collapses, the existing stock of futile traders is cleared out at an accelerating pace, and the market's profit sources dry up accordingly. Any assessment of the sustainability of the perpetual futures market therefore cannot be divorced from a judgment about the macro-liquidity environment. The market's internal game structure matters, but changes in the composition of participants are ultimately governed by how external macroeconomic conditions shape the flows of capital and people.

4.1.3 Behavioral classification

The functional classification explains *why* participants trade, but understanding the market's microstructural mechanics also requires analyzing *how* they trade—the specific roles they play in the market. Building on the theoretical framework above [3], the participants of the perpetual futures market can be divided into seven core roles. Market makers are the suppliers of market liquidity; by posting bid and ask quotes simultaneously, they give other traders the convenience of immediate execution. Informed traders drive price discovery; they trade on their informational advantage and incorporate new information into prices. Arbitrageurs maintain market efficiency; by eliminating price discrepancies between markets, they ensure that the law of one price holds. Speculators are the principal bearers of risk and a source of market vitality; their trading activity provides the market with abundant liquidity but may also amplify volatility. Liquidators safeguard system stability; they forcibly close the positions of leveraged traders when their margin becomes insufficient, preventing risk from spreading. In addition, brokers and agents provide market access, order execution, and trade-protection services to all other types of traders; in the on-chain environment, this role is filled by decentralized exchange (DEX) aggregators, MEV-protection services, and wallet front-ends.

Role	Core function	Profit source	Primary risk	Typical examples
Market maker	Provide liquidity	Bid-ask spread	Adverse selection, inventory risk	Wintermute, AMM LPs, HLP vault
Informed trader	Drive price discovery	Informational advantage	Information decay, regulatory risk	On-chain analysts, insider traders
Arbitrageur	Maintain market efficiency	Spread convergence	Execution risk, counterparty risk	Funding-rate arbitrageurs, cross-market arbitrageurs
Parasitic trader	Profit from others' behavior	Transaction-ordering rights, information theft	Intense competition, mechanism changes	MEV searchers, front-running bots
Speculator	Bear risk, provide liquidity	Judgment of price direction	Leverage liquidation, emotional bias	Retail traders, trend-following funds
Liquidator	Maintain system stability	Liquidation penalties	Market impact, intense competition	Liquidation bots
Broker/agent	Provide market access and execution protection	Service fees, trade-routing optimization	Trust risk, compliance risk	DEX aggregators, MEV protection, wallet front-ends

Table 4-1. Behavioral classification of participants in the perpetual futures market (Data source: author's compilation)

Table 4-1 sets out the core function, profit source, primary risk, and typical examples of the seven participant types. Two structural features stand out: the diversity of profit

sources (from the market maker's bid-ask spread to the liquidator's liquidation penalty) and the asymmetry of risk exposure (market makers and speculators bear persistent, uncertain risk, whereas arbitrageurs and liquidators face competitive pressure mainly at the level of execution). This lays the microfoundation for the analysis of the game relationships that follows.

The speculator is not an independent category within the functional classification; it is a cross-cutting role that spans the two categories of profit-motivated and futile traders. A minority of speculators with genuine judgment belong to the profit-motivated traders, whereas the majority who lack an informational advantage belong to the futile traders. This cross-category attribute makes the behavior of the speculator group highly heterogeneous overall, a point analyzed in detail in Section 4.2.5.

The role of the broker/agent, in turn, differs fundamentally from that of the other six participant types. The first six participate directly in the market game, contending for profit by bearing risk or providing services, whereas the broker/agent belongs to the market's infrastructure layer, providing market access and execution services to other participants and not itself participating directly in the directional game. The subsequent behavioral analysis and construction of the game network in this chapter therefore focus on the six directly contending participants; the functions of the broker/agent are discussed in detail in the service-provider ecosystem of Chapter 5.

Figure 4-1 integrates the two dimensions—functional and behavioral—to present a two-layer classification framework for participants (the top layer, *why they trade*; the second layer, *how they trade*). The core tension the figure reveals is that a single behavioral role (such as the speculator) may fall into different categories along the functional dimension—precisely the complexity that the subsequent analysis must address.

4.1.4 The hidden costs of the negative-sum game

In a strict mathematical sense, the perpetual futures market is not a zero-sum game but a negative-sum game. Summing the realized and unrealized profit and loss (P&L) of all traders necessarily yields a result below zero. This shortfall represents the friction costs that must be incurred to keep the entire market infrastructure running.

$$L_{\text{neg}} = \sum_{i=1}^{N_f} f_i + \sum_{k=1}^{N_m} m_k + \sum_{l=1}^{N_g} g_l$$

Here, f_i is the transaction fee on the i-th trade, m_k is the amount of MEV captured in the k-th extraction, and g_l is the gas fee on the l-th trade. L_{neg} is the market's negative-sum quantity, representing the negation of the sum of all participants' P&L. The funding rate is not counted in the negative-sum quantity, because on major platforms (Binance, Hyperliquid, dYdX, and others) it is designed as a direct transfer payment between longs and shorts, from which the protocol itself extracts no fee. The formula also does not explicitly list implicit frictions such as slippage costs and the opportunity cost of margin. In the thin-liquidity environment on-chain, the market impact (slippage) of large orders can constitute a significant implicit transaction cost, while the forgone return on capital locked in margin is another cost that is easily overlooked. These implicit frictions further deepen the negative-sum nature of the market.

This negative-sum quantity is analogous to the institutional friction costs of the traditional financial system; only the manner of its collection has been reshaped by the digitally native architecture. Traditional finance levies explicit fees through intermediaries such as exchanges, clearinghouses, and brokers, whereas on-chain finance collects them through protocol-hardcoded fees, the execution fees of the blockchain network, and the MEV extracted by algorithmic bots. In the fully transparent public-mempool environment in particular, MEV constitutes an implicit tax. Every order executed through a decentralized exchange may have part of its value extracted by searchers—via front-running or sandwich attacks—during ordering and block packing, deepening the market's negative-sum character still further.

In the DEX ecosystem there is also a special external source of funds: protocol token incentives. Some protocols subsidize participants through liquidity mining, trade mining, and airdrops, which is essentially a form of seigniorage, with the cost borne by token holders through dilution. Protocol token incentives, however, are not an intrinsic institutional feature of the perpetual futures market (many centralized exchanges operate without relying on this mechanism), and they therefore do not constitute an independent category of profit source; they are instead an external subsidy mechanism specific to DEXs. This external subsidy mechanism has an important effect on the boundary conditions of the negative-sum game described by Equation 4-1. Absent token incentives, the perpetual futures market is strictly negative-sum, and the sum of all participants' P&L is necessarily negative. With token incentives, if the total subsidy exceeds L_{neg}, participants as a whole may exhibit positive-sum returns in the short run; but this positive-sum property rests on continuous token issuance, and token inflation inevitably dilutes the value held by existing holders, so it is unsustainable over the long run. As the token price falls under inflationary pressure, the real value of the subsidy

diminishes, and the market ultimately reverts to its intrinsic negative-sum nature.

4.1.5 Limitations of the classification

In using this classification framework, one must recognize the limitations it faces in the digitally native environment. In traditional financial markets, licensing regimes and a high degree of professional specialization keep participants' roles relatively fixed. In the decentralized finance environment, however, the boundaries between roles become blurred. A single user may, within the same day, be a speculator (opening a leveraged position), a market maker (supplying funds to a liquidity pool), and an arbitrageur (profiting from price discrepancies across protocols). This role fluidity is one of the most distinctive features of the digitally native market, and it is examined in detail in Section 4.4. Moreover, the framework is built primarily on assumptions of human behavior, yet an increasing share of on-chain trades is executed by automated bots whose behavioral patterns differ starkly from those of human traders, which likewise calls for a re-examination of the classical theory.

Despite these limitations, the classification framework retains significant analytical value. It provides a structured starting point for understanding the complex diversity of market behavior, allowing us to dissect systematically the core motives, strategies, and market impact of each type of participant. Acknowledging its limitations does not negate its validity; rather, it keeps the analysis critical—especially in examining how the digitally native environment breaks down these classical categorical boundaries.

4.2 Behavioral analysis of the six core participant types

Within the profit-source framework of Harris (2003), each type of participant can be understood as an economic entity contending for a specific share of the two profit sources. Its behavioral logic is jointly determined by its profit source, its risk exposure, and its game relationships. This section examines, in turn, the six core participant types of the perpetual futures market, revealing how the digitally native environment reshapes the basic assumptions about participant behavior in classical market microstructure theory.

4.2.1 Market makers

Market makers are the core liquidity providers of market microstructure, and their basic business model is to earn the bid-ask spread by quoting on both sides of the order book. Market makers earn the spread primarily from the non-toxic order flow of futile traders, while also capturing income from the hedging premium that utilitarian traders are willing to pay in crossing the spread for immediate execution. This profit pool, however, is continually compressed by informed traders and mechanism parasites.

The core challenge facing market makers can be understood through the three-component decomposition of the spread. Stoll (1989) showed that the bid-ask spread can be decomposed into order-processing cost, inventory-holding cost, and adverse-selection cost [8]. In traditional financial markets, these three costs remain in relatively stable proportion. In the crypto perpetual futures market, however,

the adverse-selection cost is markedly amplified. This judgment rests mainly on theoretical inference: given the empirical fact that the share of informed trading in crypto markets is high, the classical logic of spread decomposition reasonably implies a correspondingly greater weight on the adverse-selection component. Direct empirical measurement of the exact percentage of the bid-ask spread that adverse selection accounts for in crypto perpetual futures markets remains limited, however. Estimating these components systematically from on-chain market data, using classical spread-decomposition methods such as Huang-Stoll or Glosten-Harris, is still a research agenda awaiting deeper development. As noted earlier in the discussion of the cost of abolishing the expiration date, the absence of an expiry renders inventory risk indefinite: market makers cannot know when a trend will end, which makes them more sensitive to adverse-selection risk. Tiniç et al. (2023) documented substantial adverse-selection costs in crypto markets (about 10% of the effective spread in their sample), from which one can infer that market makers face greater adverse-selection risk in crypto markets than in traditional ones—part of the reason crypto perpetual futures spreads are systematically wider than those of traditional futures [9]. The probability of informed trading (PIN) model proposed by Easley et al. (1996) provides a classic tool for quantifying order-flow toxicity [10]. In the on-chain environment, because all trade data are publicly visible, the assumptions of the traditional PIN model change: informed trading is no longer hidden within an anonymous order flow but can be partly observed through on-chain analysis. This requires researchers to apply classical order-flow-toxicity measures with due caution about their conditions of applicability. In addition, Milionis et al. (2022) formally analyzed the losses incurred by automated market makers (AMMs) on decentralized exchanges, showing that the losses passive liquidity providers bear from adverse selection are structurally higher than the inventory losses of traditional market makers [11].

Figure 4-2 decomposes the market maker's bid-ask spread into three cost components—order processing, inventory holding, and adverse selection—and compares their relative weights in traditional versus crypto perpetual futures markets. Adverse selection accounts for a markedly larger share in crypto markets, reflecting how the high proportion of on-chain informed trading compresses market makers' profitability.

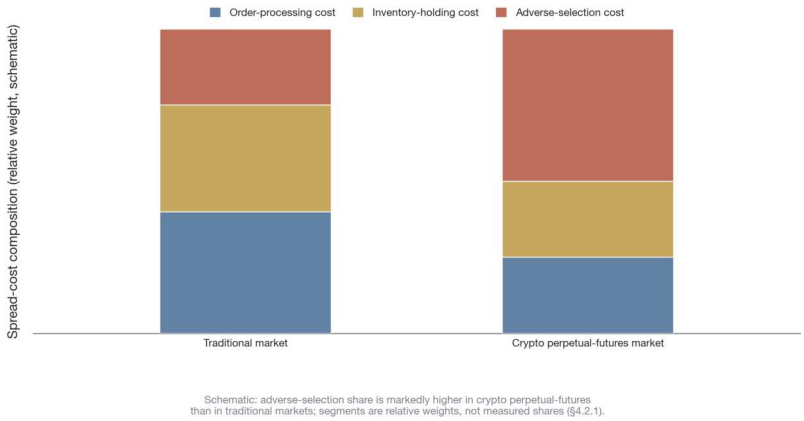

Figure 4-2. The three-component cost decomposition of the market maker's bid-ask spread (illustrative cost structure: the height of each cost segment within a bar reflects only qualitative relative weight, not a measured share; the larger adverse-selection segment on the crypto side merely indicates the direction in which this cost is significantly amplified and does not represent its actual share of the spread; Tiniç et al. 2023 measured adverse selection at about 10% of the effective spread in their sample [9], which serves as an independent empirical anchor)

The market-making paradigms of centralized and decentralized exchanges have already diverged. On centralized exchanges (CEXs), market making is dominated by professional firms that deploy high-frequency algorithms and cross-exchange hedging strategies; their core competitive strengths are speed and information-processing capacity, and the greatest unknown they face is the opacity of the exchange's order-flow quality. On decentralized exchanges, the market-making model diverges further into a passive-liquidity-pool model and a model that combines an on-chain central limit order book (CLOB) with a vault. In the passive model, liquidity providers passively bear all of the adverse-selection risk; the mechanism is simple but capital-inefficient. In the vault model, protocol algorithms make markets actively, seeking a balance between a low entry barrier and risk management.

The execution architecture of decentralized perpetual futures exchanges is not monolithic, and differences in the underlying consensus and ordering mechanisms have a profound effect on market makers' strategic choices and risk exposures. The prevailing DEX execution architectures can be summarized into three paradigms. The first is the fully on-chain model, in which both trade matching and settlement rely on the consensus mechanism of the underlying public chain; the archetypal examples are AMM protocols deployed on general-purpose L1s such as Ethereum or Solana. Under this architecture, all trading intentions propagate through the public mempool, block producers hold ultimate control over transaction ordering, and market makers are therefore exposed to the most severe MEV risk, with sandwich attacks, front-running, and back-running constituting persistent implicit costs. At the same time, block-confirmation time imposes an incompressible lower bound on latency, making it difficult for market makers to cancel orders or adjust quotes in time amid sharp volatility, so that inventory risk is amplified. The second is the application-chain or centralized-sequencer model, of which Hyperliquid is the archetype. Hyperliquid runs its own L1 blockchain (based on HyperBFT consensus), but its validator set is relatively concentrated, the

sequencer is controlled by the protocol team, and trade matching is completed off-chain at sub-second latency before being confirmed on-chain in batches. This architecture gives market makers execution speed and deterministic ordering close to those of a centralized exchange, effectively eliminating the MEV risk arising from a traditional public-chain mempool, but at the cost of introducing a trust assumption about the sequencer operator—in theory the sequencer holds unilateral power over transaction ordering and censorship, which constitutes a centralization risk analogous to the internalization of order flow within an exchange in traditional finance. The third is the application-chain model built on the Cosmos SDK, of which dYdX v4 is representative. dYdX v4 runs an off-chain order book on its dedicated Cosmos chain, with validators simultaneously performing the dual roles of order matching and block proposal; maintenance of the order book is done off-chain in memory, and only the final execution results are submitted to on-chain consensus. This hybrid architecture disperses ordering power through the decentralization of validators, but it also introduces a subtle MEV vector: a validator, as block proposer, could in theory order strategically after observing the state of the order book, though dYdX constrains this through economic incentives and reputation mechanisms. The latency profiles of the three architectures also differ significantly—the fully on-chain model's latency is measured in seconds, Hyperliquid's sequencer latency in sub-seconds, and dYdX v4's hybrid model falls between the two—which directly determines the upper bound on how frequently market makers can update quotes and the timeliness of their inventory hedging. For a professional market maker, the choice of architecture is essentially a trade-off between the trust model and the latency profile: the fully on-chain model offers the strongest trustless guarantees but the highest latency and the greatest MEV exposure; the centralized-sequencer model offers the lowest latency but requires trusting the sequencer's fairness; and the Cosmos application-chain model seeks a compromise between the two.

The differences in execution architecture extend further to how the mark-price mechanism shapes market-maker behavior and liquidation triggers. The mark price is the benchmark price a perpetual futures protocol uses to compute unrealized P&L and to determine liquidation triggers, and its construction differs substantially across platforms. Most protocols adopt an external oracle price (such as the aggregated spot price provided by Chainlink or Pyth) as the core anchor of the mark price, so as to prevent the protocol's internal execution price from being manipulated to trigger improper liquidations. The update frequency of the mark price, its smoothing algorithm, and its tolerance for deviation from the protocol's internal execution price all affect market makers' behavioral decisions, however. In protocols where the mark price updates slowly or the smoothing window is long, the protocol's internal execution price may deviate significantly from the mark price over short intervals, and market makers can adjust their quoting strategy accordingly to avoid the risk of being wrongly liquidated because of a lagging mark price; conversely, in protocols where the mark price is highly sensitive and updated in real time, market makers' liquidation buffer is more precise but also more fragile, and any price spike from an external oracle can instantly trigger large-scale liquidations, in turn forcing market makers to bear excess market impact as they absorb the liquidation flow. Hyperliquid adopts a mark-price mechanism anchored to a volume-weighted price from major centralized exchanges and

sets an instantaneous-deviation protection threshold, which to some extent reduces the systemic liquidation risk caused by oracle manipulation, but also means that in extreme conditions the mark price may lag the true market price, introducing additional uncertainty into pricing when the market-making vault takes over liquidated positions. The design of the mark-price mechanism thus becomes one of the key variables by which market makers assess protocol risk: it determines not only the precise conditions for triggering liquidation but also, by shaping market makers' quoting behavior, the liquidity depth and price-discovery efficiency of the entire market. Market makers on centralized and decentralized exchanges also face informational disadvantages of different natures. On centralized exchanges, third-party market makers may face a potential conflict of interest with the exchange's proprietary market-making service, which, by virtue of its priority visibility into order flow, may hold a structural informational advantage; on decentralized exchanges, the principal informational threat facing market makers comes from the targeted sniping of MEV searchers, who conduct front-running and sandwich attacks by monitoring publicly visible trading intentions. The two informational disadvantages are entirely different in nature: the former stems from information asymmetry in an opaque environment, the latter from asymmetry in execution speed in a fully transparent one; yet both systematically erode market makers' profitability.

The double-sided nature of Hyperliquid's market-making vault is a paradigmatic case for understanding the market maker's dilemma. Facing uninformed forced-liquidation flow, a market maker can earn substantial profits; but facing strategic actors with a mechanism-parasitic advantage, it suffers systematic losses. This shows that a market maker's P&L is essentially a function of the toxicity concentration of its order flow: the same market maker exhibits starkly different profitability against counterparties whose order flow carries different information content. The case also reveals the deeper difference between the professional-market-maker and the passive-vault models. Professional market makers typically deploy an entire suite of sophisticated risk controls, including real-time detection of order-flow toxicity (dynamically identifying the concentration of informed trading using indicators such as the volume-synchronized probability of informed trading, or VPIN), strict inventory caps, tiered quoting strategies (dynamically adjusting the depth posted at different price levels according to order-flow quality), and cross-asset correlation hedging. By contrast, passive-vault models such as HLP lack a real-time toxicity-filtering mechanism and, in essence, absorb all types of order flow indiscriminately under a uniform strategy. This structurally exposes them to the spike risk of adverse selection: when toxic order flow floods in en masse, a passive vault cannot rapidly narrow its quotes or suspend market making as a professional market maker would, and it therefore systematically bears a disproportionate loss.

4.2.2 Informed traders

Informed traders are the principal driver of market price discovery. Their profits come mainly from the directional game against futile traders, while they also extract value from market makers' inventory through adverse selection. The presence of informed traders enables market prices to reflect the latest information, but it also raises market makers' costs.

The classic model of Kyle (1985) describes how informed traders strategically execute their trades, gradually incorporating private information into prices [12]. In the digitally native environment, this logic is accelerated and complicated. The rise in the speed of information transmission and execution has sharply shortened the traditional window of informational advantage. More importantly, the source of the informational advantage has been reshaped. The traditional informational advantage based on fundamental research and industry knowledge still exists, but the share of the digitally native informational advantage—based on on-chain data analysis, whale-address tracking, smart-contract-interaction monitoring, and scanning of the MEV pending pool—has risen markedly.

This digitally native informational advantage is a concrete embodiment of the transparency paradox. On-chain information is public private information: everyone can see a whale's positions and trading intentions, but only participants with the specific data-processing capacity and algorithmic infrastructure can correctly interpret its meaning and convert it into trading signals. The informed trader's barrier therefore shifts from the privilege of acquiring information to the capacity to process and execute on public information.

Informed traders have a double-sided character in market microstructure. On one hand, by trading, they transmit information into prices, promoting price discovery and improving the market's pricing efficiency. On the other hand, their trading raises market makers' adverse-selection costs, forcing market makers to widen spreads to offset potential losses and thereby reducing liquidity for all market participants. One of the central trade-offs in market mechanism design is precisely how to find the optimal balance between encouraging informed trading to promote price discovery and protecting market makers to sustain liquidity.

The on-chain informational advantage decays rapidly. As ever more participants deploy similar on-chain analytics tools and whale-tracking algorithms, the alpha derived from on-chain data transparency declines at an accelerating pace. At the same time, the spread of private trading channels (such as private mempools and trade-privacy-protection mechanisms like Flashbots Protect) further erodes the transparency-based informational advantage: trading intentions are hidden until the moment of block confirmation, rendering useless those informed strategies that rely on scanning the pending-transaction pool. This constitutes a continual arms race over informational advantage, in which the half-life of any advantage progressively shortens, forcing informed traders to invest ever-higher technical costs to sustain an increasingly fragile marginal edge.

4.2.3 Arbitrageurs

Arbitrageurs profit at no risk or low risk by seeking price discrepancies between different markets or instruments. As argued in Section 4.1.2, arbitrageurs' profits appear on the surface to come from systematic mispricings, but mispricings are themselves jointly created by the inelastic demand of utilitarian traders and the pricing errors of futile traders; arbitrage profits can therefore, ultimately, still be traced to the two sources. By correcting mispricings, arbitrageurs indirectly serve the realization of the hedging premium, allowing hedgers to obtain more accurate execution prices.

In the perpetual futures market, arbitrage takes three core forms. Funding-rate arbitrage is the most common strategy: an arbitrageur establishes a short position in the perpetual futures market while buying an equal amount of the asset in the spot market, thereby earning a positive funding rate. The BIS working paper (Schmeling et al., 2023) shows that crypto carry can generate positive returns in most periods, but its return distribution exhibits pronounced negative skewness and is highly time-varying; much like traditional foreign-exchange carry trades, such strategies face the risk of sudden and severe losses during tail events, with an asymmetric crash exposure hidden beneath the appearance of stable returns [7]. The empirical study of Werapun et al. (2025) further shows that, under certain market conditions, funding-rate arbitrage can even generate excess returns [13]. Cross-market arbitrage profits from the transient price discrepancy of the same asset across different exchanges, a discrepancy usually driven by differences in liquidity and in the speed of price updates. Triangular arbitrage, within a single exchange, exploits inconsistencies in the cross rates of three assets to complete a circular arbitrage.

Characterizing funding-rate arbitrage and cross-platform arbitrage as "risk-free," however, is a dangerous oversimplification. These strategies are more accurately described as low-risk but not risk-free. Their risk exposure manifests along at least three dimensions. First, rate-reversal risk has a significant historical frequency. The sign and magnitude of the funding rate can switch abruptly with market sentiment; in extreme conditions, a funding rate that was positive can turn deeply negative within hours, and the negative period often lasts beyond the arbitrageur's expected tolerance, turning the strategy from a source of stable income into one of persistent losses. Historical data show that during major market events the intraday swing in the funding rate can reach dozens of times its normal magnitude, and this nonlinear jump causes rate-forecasting models built on assumptions of historical mean reversion to fail at precisely the moment they are most needed. Second, on platforms using a unified margin system, the floating loss on the spot long position shares a single margin pool with the perpetual futures short position; when the price of the underlying asset rises sharply, the book loss on the perpetual short and the book gain on the spot long theoretically offset each other, but in extreme volatility the transient deviation between the mark price and the spot price, together with lag effects in margin computation, can cause the account's overall margin ratio to fall below the maintenance level in an instant, triggering forced liquidation. An arbitrageur being liquidated while in a "hedged" state is nearly a paradox in traditional financial terms, yet it is a structural vulnerability of the on-chain unified-margin system. Third, cross-platform arbitrage faces the friction costs of margin fragmentation and withdrawal delay. When an arbitrageur holds a long on platform A and a short on platform B, a sharp one-sided floating loss requires topping up margin on the losing side, while withdrawal of funds on the winning side is often constrained by withdrawal cooling-off periods, on-chain confirmation delays, and congestion on liquidity bridges. This timing mismatch creates a liquidity trap at precisely the moment the market most needs funds to be redeployed, exposing a theoretically perfectly hedged position to one-sided liquidation risk in practice.

The limits-of-arbitrage framework of Shleifer and Vishny (1997) illuminates these risks [14]. The framework's core insight is that arbitrage in the real world is far from the

costless, risk-free activity described in textbook models; arbitrageurs face capital constraints, margin-call pressure, and principal-agent problems, and these frictions can allow a mispricing to widen further before it is corrected. In the crypto perpetual futures market, the applicability of this framework requires a key distinction along the dimension of atomicity. At one end is on-chain atomic arbitrage: under the atomicity guarantee of a single transaction, borrowing, trading, and repayment are completed within the same block, so there is no price risk during a holding period, and the only uncertainty the arbitrageur faces is whether the transaction can be successfully included in a block. Such arbitrage approaches the theoretical zero-risk benchmark, and the capital constraints and margin-call pressure of the Shleifer-Vishny framework do not apply. At the other end is non-atomic position arbitrage, including funding-rate arbitrage and cross-exchange spread arbitrage, in which the arbitrageur must maintain several independent positions over a period of time, bearing the risks of price fluctuation, margin calls, and liquidity mismatch—precisely the dangerous zone the Shleifer-Vishny framework warns against. In tail events, such nominal "arbitrage" strategies may be forced to close at the least favorable moment under margin-call pressure, so that behavior originally intended to correct mispricing itself becomes an amplifier of market volatility. The arbitrageur group in the perpetual futures market therefore spans a broad risk spectrum, from near-zero risk to something indistinguishable from directional speculation.

The composability thesis is directly embodied in arbitrage behavior, but its scope of application must be strictly bounded. The atomic-execution feature of the on-chain environment, combined with the flash-loan mechanism, allows atomic arbitrage between spot decentralized exchanges to be executed with zero capital and zero risk: an arbitrageur can complete the full loop of borrowing, cross-pool trading, and repayment within a single transaction block, something unimaginable in traditional financial markets. This mechanism does not apply to position arbitrage in perpetual futures, however. Funding-rate arbitrage and cross-platform spread arbitrage require maintaining independent positions at different points in time and on different platforms; the holding period spans multiple blocks or even several days and cannot be compressed into a single atomic transaction. Even spot atomic arbitrage itself is not truly "zero-cost": fierce competition among arbitrageurs for the same spread opportunity gives rise to priority gas auctions (PGAs), and the winner often has to pay most of the arbitrage profit as gas fees and tips to the block builder, so the economic rent of arbitrage tends to be consumed by execution costs in the competitive equilibrium. This digitally native atomic-arbitrage mechanism greatly improves the price-convergence efficiency of on-chain spot markets, but its efficiency gains do not automatically extend to the domain of perpetual futures arbitrage, which requires holding positions over time.

4.2.4 Mechanism parasites

The concept of the parasitic trader was proposed by Harris (2003); in traditional financial markets, it manifests primarily as informational parasitism [3]. Informational parasites profit from non-public information obtained by improper means, with typical behaviors including insider trading and front-running client orders—behaviors generally prohibited by law. The on-chain environment of perpetual futures, however, has

given rise to an entirely new form of parasitism: mechanism parasitism. This is a core theoretical contribution to understanding the evolution of on-chain market microstructure.

Mechanism parasitism and informational parasitism differ fundamentally in the source of their advantage, the nature of their behavior, and their legality. To raise this concept from descriptive language to an operational analytical tool, this chapter offers the following definition.

> Mechanism parasitism refers to behavior in which a market participant, while fully complying with the explicit rules of a protocol, exploits the unintended economic consequences produced by the combination of those rules to systematically shift transaction costs or risks onto other participants. It obtains only when three conditions hold simultaneously: (1) the behavior lies entirely within what the protocol's rules permit; (2) the economic consequence exploited is not the intended purpose of the protocol's designers; and (3) the behavior produces a net transfer of value from passive participants to the active exploiter.

Condition (2)'s criterion—"the intended purpose of the protocol's designers"—requires a qualification. In the context of decentralized governance, a protocol's rules are often produced through community proposals and voting, and there is no single, clearly attributable "designer's intent," which makes condition (2) difficult to apply in practice. A more operational formulation is this: the behavior's negative externalities (the harm to other participants and to the overall functioning of the ecosystem) exceed the positive externalities it brings to the ecosystem. This net-externality criterion requires no tracing of subjective intent; it reaches a determination by assessing the behavior's objective economic consequences, and it applies more readily in an on-chain environment where governance is dispersed.

The advantage of mechanism parasites comes not from knowing information others do not know but from understanding the economic implications of the protocol's rules more deeply than others do. What they exploit is a cognitive asymmetry: the protocol's rules are public to all, but their deeper economic effects are not fully understood by every participant. This distinction sets mechanism parasitism apart from ordinary arbitrage: arbitrage corrects market mispricings and pushes prices toward equilibrium, carrying a positive externality; mechanism parasitism exploits rule loopholes to shift costs, does not improve market efficiency, and carries a negative externality.

Figure 4-3 presents, in a side-by-side layout, the evolution from informational parasitism to mechanism parasitism, at the core of which lies a paradigm shift: the source of advantage moves from *exploiting information others do not have* to *understanding public rules more deeply than others do*; its persistence changes from dissipating as information diffuses to enduring structurally; and defense correspondingly shifts from legal punishment to mechanism repair.

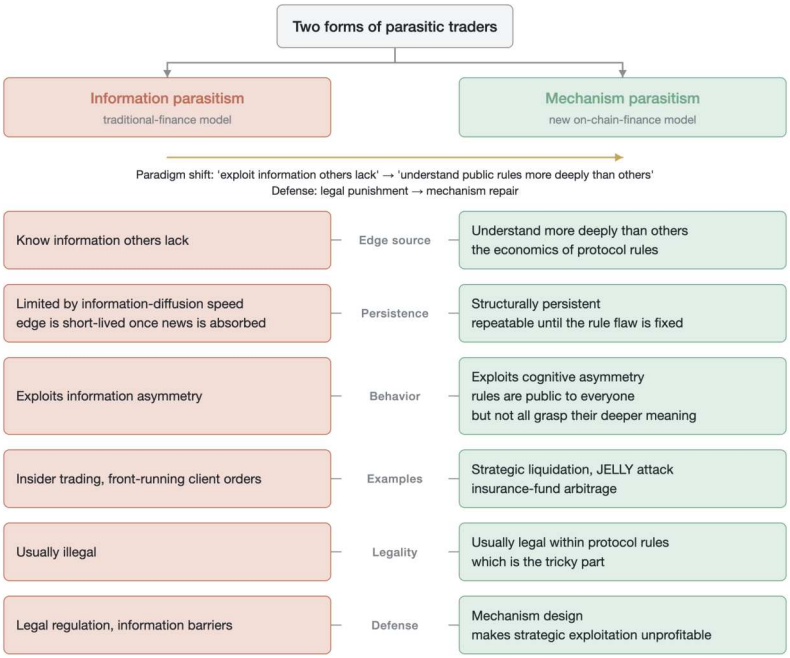

Figure 4-3. An evolutionary comparison of mechanism parasitism and informational parasitism (conceptual comparison diagram; author's synthesis; not empirical data)

The Hyperliquid whale event described in the introduction is a paradigmatic case of mechanism parasitism. The trader's behavior fully satisfies the three conditions of Definition 4-1: the behavior lies within the protocol's rules (condition 1); it exploited the unintended economic consequence that the liquidation penalty was lower than the slippage of closing on the market (condition 2); and it shifted the price-impact cost from itself to passive liquidity providers (condition 3). Actively triggering liquidation thus became a better exit strategy than closing the position oneself. The existence of such an inequality is an inherent loophole in the protocol's mechanism design, not a moral failing of the trader.

Mechanism-parasitic behavior presents a spectrum in on-chain markets, ranging from the mild MEV sandwich attack, to strategic positions exploiting extreme funding rates, to aggressive strategic liquidations, and even to sophisticated attacks exploiting joint loopholes in the liquidation and insurance-fund mechanisms. What these behaviors share is that they are compliant at the level of the protocol's rules. Such compliance, however, is not the same as compliance with the law. The legal standard for market manipulation differs across jurisdictions. The EU Market Abuse Regulation (MAR) adopts an effects-based standard: creating false or misleading signals, or producing an abnormal or artificial price, can constitute manipulation, with no requirement of subjective intent; whereas price manipulation under the U.S. Commodity Exchange Act (Rule 180.2) has traditionally required a specific intent to create an "artificial price," so that a price effect alone does not constitute manipulation, though the post-Dodd-Frank fraud-based Rule 180.1 requires only recklessness. Under these frameworks, even

behavior that fully complies with a protocol's explicit rules may face legal prosecution if its effect constitutes artificial manipulation of the market price or systematic harm to other participants. The legal status of mechanism parasitism therefore remains undetermined, and this constitutes a twofold challenge for defending against it: at the level of mechanism, the economic loopholes that make such behavior profitable must be repaired through redesign; at the level of law, the regulatory framework must respond with new classifications of on-chain behavior and effects-based regulatory principles.

4.2.5 Speculators and futile traders

Speculators seek to profit from judging the direction of prices, and they bear the principal risk in the market. Within the speculator group, however, there is significant differentiation. A minority of informed directional traders have genuine judgment about fundamentals or technicals and can achieve average profits; in economic terms, they can be regarded as a subset of informed traders. The vast majority of speculators, however, are futile traders: they trade on emotion, noise, or herd mentality, use leverage far beyond their risk tolerance, and as a result systematically become the counterparties of profit-motivated traders, bearing persistent losses.

The systematic losses of futile traders constitute the core mechanism of profit transfer in the perpetual futures market. The October 2025 liquidation data cited in Section 4.1.1 (more than 1.62 million accounts liquidated, totaling more than $19 billion, about 87% of them long [4][5]) are precisely its macro evidence: this was not mere market volatility but a systematic wealth-transfer event—futile traders gradually accumulated leverage during a calm period and, during the deleveraging period, transferred their previously accumulated capital, through the liquidation mechanism, to market makers, informed traders, and liquidators.

The extreme one-sidedness of the 87% long liquidations cannot be explained by individual-level overconfidence or leverage abuse alone; it requires the analytical framework of collective behavior. The theory of information cascades proposed by Banerjee (1992) provides a rigorous microfoundation for understanding such extreme uniformity [15]. The theory holds that when individuals make sequential decisions under incomplete information, the rational strategy is to ignore one's own private signal and follow the behavior of predecessors, because a predecessor's choice is taken to embody the aggregate of their private information. Once such following reaches a critical mass, subsequent participants will conform regardless of the private information they hold, forming a self-reinforcing information cascade. In the crypto perpetual futures market, the conditions for an information cascade are structurally reinforced. A persistently positive funding rate constitutes the most intuitive signal of collective sentiment: when the funding rate stays for a long time at an annualized 30% or higher, the implicit information it conveys to the market is that "the overwhelming majority of participants are bullish," and latecomers tend to read this signal as a market consensus rather than a warning of crowding risk. At the same time, the crypto market relies heavily on social media for the transmission of information, and the public trade calls of key opinion leaders (KOLs) constitute a powerful cascade trigger on platforms such as Twitter and Telegram; when a KOL with a large following

publicly announces opening a long position, a considerable proportion of followers will copy the trade directly without independent judgment, further pushing up the price and the funding rate, attracting more imitators, and thereby forming a positive feedback loop. The full transparency of on-chain data plays a dual role here: it makes the position direction of whales and the trading behavior of KOLs into publicly observable signal sources, accelerating the spread of the information cascade, while also making the extreme one-sided concentration of positions visible to all, though no one is willing to be the first to act against it. When the entire market's long positions accumulate to a critical level under the drive of an information cascade, any exogenous shock is enough to trigger the liquidation cascade described in Section 4.3.4, and the one-sidedness of the cascade is precisely a mirror image of the one-sidedness of the earlier herding behavior.

This behavioral pattern arises not merely from inadequate market education but is systematically induced by the product-design features of perpetual futures. Skwarek et al. (2025) confirm that a variety of behavioral biases significantly affect the decision-making of crypto investors [16]. Delfabbro et al. (2021) further note that trading behavior in crypto markets is, in its psychological mechanisms, highly similar to gambling [6]. Specifically, the psychological stickiness of perpetual futures trading can be explained through three classic mechanisms. First, the variable-ratio reinforcement effect: the occasional large profits produced by high-leverage trading constitute an intermittent, large positive reinforcement whose reinforcing power far exceeds that of steady small gains—isomorphic, in psychological principle, to the reward mechanism of a slot machine. Second, the near-miss effect: a trader's experience of narrowly escaping near the liquidation price (for example, when the price rebounds less than 1% from the liquidation line) is subjectively coded as "almost succeeding" rather than "nearly failing," thereby reinforcing the willingness to continue high-leverage trading. Third, the mental-accounting effect: traders tend to treat each trade as an independent mental account rather than part of an overall portfolio, which leads them to take on risk far beyond a rational standard on a single trade while their perception of cumulative losses is systematically blunted. More critically, the around-the-clock, uninterrupted trading of the perpetual futures market eliminates the natural "cooling-off period" provided by the market-closure mechanism of traditional financial markets. In traditional stock or futures markets, the hours between the close and the next open provide traders with a time window to reflect on decisions, assess losses, and restore rationality; in the 24/7 perpetual futures market, this buffer is entirely absent, impulsive revenge trades after a loss can be executed within seconds; the chain of emotion-driven trading can extend indefinitely; and the destructive power of the three psychological mechanisms above is thereby markedly amplified. High leverage, permissionless access, and an emotional community culture together build an environment that attracts and retains futile traders. How these persistent losses economically subsidize market makers' adverse-selection losses is detailed in Section 4.3.3.

4.2.6 Liquidators

In the perpetual futures ecosystem, liquidators clear away systemic bad debt. Their core motive is to profit from the systematic losses of futile traders—that is, to earn

the liquidation penalties paid by those being liquidated. By promptly taking over and closing insolvent positions, liquidators ensure the protocol's solvency and prevent bad debt from turning into systemic risk.

Liquidators' behavior is double-sided under extreme market conditions, however. In a normal market, liquidators and speculators form a functional complement that keeps the system running in good health. But when the market swings violently, liquidators' individually rational behavior can become an accelerator of the liquidation cascade. To trigger liquidation as quickly as possible and earn the penalty, liquidators dump the liquidated assets on the market, and this large-scale selling pressure pushes the market price down further, driving more positions that were originally safe into liquidation.

The specific design of the liquidation mechanism decisively shapes the identity and behavioral patterns of those who execute liquidations, and different platforms differ fundamentally in how they position the liquidation executor. On centralized exchanges, liquidation is essentially part of the platform's internal risk-control process: the exchange's liquidation engine, as a built-in component of the protocol, automatically executes forced closures; the process is invisible to external participants; residual margin (if any) is returned to the trader; the loss shortfall is absorbed by the exchange's insurance fund; and an external independent liquidator does not exist in this model. In decentralized lending protocols (such as Aave and Compound), liquidation is designed as a fully externalized, economically incentivized activity: when a borrower's collateralization ratio falls below the liquidation threshold, any external participant can call the smart contract's liquidation function to repay part of the debt and acquire the collateral at a discount, so the liquidator is a permissionless independent economic actor whose participation is driven entirely by the profit motive. The liquidation mechanism of a perpetual futures DEX falls between these two paradigms, forming a hybrid model. Take Hyperliquid: its liquidation process adopts a layered, escalating architecture. When a trader's margin ratio falls below the maintenance-margin requirement, the protocol first attempts to close the position gradually on the market via limit orders through the internal liquidation engine; if market liquidity is insufficient to complete the closure within a reasonable slippage range, the remaining position is transferred to the HLP market-making vault to be absorbed collectively by passive liquidity providers; and only in extreme cases does the insurance fund step in as the last loss-absorbing layer. In this hybrid model, the "liquidator" is not a single external independent role but a multi-layered defense system jointly composed of the protocol's liquidation engine, the market-making vault, and the insurance fund, and the room for external independent liquidation bots is significantly compressed. dYdX v4 adopts another hybrid path, in which liquidation is executed by validator nodes during the block-proposal process, with liquidation orders embedded in the block-construction flow; this couples liquidation execution with block-ordering power, and a validator can in theory choose strategically when and how to execute a liquidation. Characterizing liquidators broadly as external independent profit-seekers therefore applies only to the purely externalized model of lending protocols; in the actual operation of centralized exchanges and most perpetual futures DEXs, the identity of the liquidation executor is far more complex, involving an interweaving of roles such as the platform's internal engine, passive-vault participants, and validators. Traditional cliff-edge liquidation of-

ten causes a precipitous drop in price, whereas progressive liquidation or vault-takeover designs seek to smooth the liquidation shock. Specifically, the prevailing liquidation mechanisms can be grouped into four types. The first is cliff-edge (full) liquidation, in which the entire position is forcibly closed at once when the margin ratio hits the threshold; its execution is simple but its instantaneous impact on the market price is greatest, and it readily triggers a cascade. The second is progressive (partial) liquidation, in which only the minimum share of the position needed to restore the margin ratio above the maintenance requirement is closed, dispersing the price impact across multiple time windows through incremental reductions. The third is vault-takeover liquidation, in which the protocol's vault directly absorbs the position on the brink of liquidation and closes it out gradually when later market conditions are more favorable, thereby converting the immediate market impact into inventory risk for the vault. The fourth is the auto-deleveraging (ADL) mechanism, in which, when the insurance fund is exhausted or market liquidity is severely insufficient, the protocol forcibly reduces the unrealized profits of traders on the winning side to cover the negative-equity losses of the losing side; although this mechanism effectively prevents systemic default at the protocol level, it does so at the cost of sacrificing the reasonable expectations of winning traders, raising fairness disputes over the redistribution of counterparty risk. In the high-leverage crypto derivatives market, the design of the liquidation mechanism bears not only on the stability of an individual protocol but is also a key line of defense against cross-market risk contagion; the European Securities and Markets Authority (ESMA) (2025), in its analysis of MEV, likewise notes that on-chain microstructure issues such as transaction ordering and cross-venue spreads carry systemic implications [17]. The liquidation executor—whether its identity is the platform's internal engine, an external independent bot, or a passive vault—is the actual operator of this mechanism, and a subtle tension always exists between its pursuit of profit and the goal of system stability.

The legal characterization of liquidation activity is coming under increasingly strict scrutiny across jurisdictions, adding a regulatory-risk dimension to liquidator behavior that cannot be ignored. In the traditional financial system, forced closure is an internal risk-control action of a regulated financial institution, and the licensing qualifications and compliance obligations of the executing entity have a clear legal framework. In the permissionless on-chain environment, however, the legal nature of liquidation activity becomes ambiguous: when an anonymous wallet address forcibly closes another's position by calling a smart-contract function and derives an economic gain from it, this behavior may in some jurisdictions be regarded as providing a financial service. The EU's Markets in Crypto-Assets Regulation (MiCA), for example, imposes authorization and compliance obligations on crypto-asset service providers (CASPs); if liquidation activity were classified as such a service, an anonymous participant would face a fundamental contradiction between compliance requirements and anonymity. At the same time, the Travel Rule promoted by the Financial Action Task Force (FATF) requires virtual asset service providers (VASPs) to transmit the identity information of the originator and beneficiary in a transaction, which poses a direct challenge to on-chain liquidation bots that operate on the basis of anonymity. Although most jurisdictions have not yet explicitly brought on-chain liquidation activity within the regulatory scope of financial-

service licensing, the tightening regulatory trend means that the behavioral pattern of participating in liquidation and extracting profit anonymously may, in the medium term, face a fundamental reassessment of its legal status. This regulatory uncertainty affects not only liquidators' behavioral incentives but may also have a profound effect on the participant structure of the liquidation market: if liquidation activity is ultimately required to be licensed, the current competitive landscape dominated by anonymous bots will be forced to shift toward compliant professional institutions, and both the efficiency and market coverage of liquidation may undergo structural change.

4.3 The game network among participants

Having established the two ultimate sources of profit in the perpetual futures market and the basic features of the six core participant types, we can now construct a dynamic picture of the market. A participant's survival and prosperity in the market depend not on a static identity label but on its position within a complex game network and its capacity to intercept profit flows. This game takes on dynamic features in the digitally native environment that are entirely different from those of traditional financial markets, with high leverage, full transparency, and the determinism of protocol mechanisms jointly reshaping the rules of the game. This section analyzes four core game relationships and, finally, reveals the complete network structure of profit flows across the ecosystem.

4.3.1 Market makers and informed traders

The game between market makers and informed traders is the cornerstone of all market microstructure theory, but in the on-chain environment of perpetual futures its intensity is pushed to a new extreme. As set out in the three-component decomposition of the spread in Section 4.2.1, a market maker's bid-ask spread must compensate for the three costs of order processing, inventory holding, and adverse selection [18], and in the crypto-asset perpetual futures market the nature of this adverse selection has fundamentally changed.

The full transparency of the on-chain environment paradoxically aggravates the market maker's adverse-selection risk: publicly visible positions and liquidation prices are public private information, which requires extremely high data-processing capacity to convert into a genuine trading advantage [12]. Informed traders use this to forecast short-term price movements more precisely and gain the upper hand in the game against market makers (the specific sources of their informational advantage were elaborated in Section 4.2.2). Research has documented substantial adverse-selection costs in crypto markets, from which one can infer that the adverse-selection environment market makers face in supplying liquidity is more severe than in traditional markets [9].

The absence of an expiration date in perpetual futures further amplifies the market maker's inventory risk—as analyzed in Section 4.2.1, inventory risk is thereby rendered indefinite: market makers cannot know when a one-sided trend will end and can only demand a wider spread to compensate for potentially enormous losses [19]. This double pressure is concentrated in the case of Hyperliquid's HLP vault. In the violent market

volatility of October 2025, facing a large volume of non-toxic order flow triggered by liquidations, the vault realized a single-day profit of approximately $40 million [20] (this October 2025 figure comes from an industry analysis by the market maker Kappa Lab; it is not peer-reviewed, and its methodology and data coverage have not yet been independently verified). Yet, facing a liquidation event meticulously engineered by a strategic actor, the same vault bore a loss of approximately $4 million [2]. The concept of "non-toxic" requires a precise distinction here. Liquidation-triggered order flow is indeed low in toxicity along the dimension of informational toxicity, because liquidation is a forced action mechanically triggered by the margin ratio and carries no private information about the asset's fundamentals, so a market maker accepting such flow does not face adverse selection in the classical sense. Along the dimension of liquidity toxicity, however, liquidation order flow is highly toxic, because the one-directional, concentrated selling pressure produced by large-scale liquidations severely shocks the market price, and a market maker—even if it correctly judges that the flow carries no information signal—may still suffer serious inventory losses by absorbing a huge one-sided position. This contrast reveals the fragility of the market maker's profit: its P&L essentially depends on the information content of the counterparty's order flow, and in a permissionless, anonymous network, screening order flow for toxicity is extremely difficult.

4.3.2 Market makers and mechanism parasites

Beyond the traditional informed trader, perpetual futures market makers also face a new type of counterparty unique to the on-chain environment: the mechanism parasite. Following the definition of mechanism parasitism in Section 4.2.4—whose advantage comes not from exclusive information but from understanding the economic implications of protocol rules more deeply than others—this paradigm shift from informational parasitism to mechanism parasitism constitutes one of the most far-reaching structural changes in the microstructure of decentralized finance.

Unlike the informational parasitism of traditional finance, which illegally exploits non-public information (such as insider trading and front-running client orders [3]), the mechanism parasite of the on-chain market operates entirely within the protocol's open and transparent framework of rules, keenly capturing the economic loopholes of the protocol's design in extreme situations and converting them into risk-free or low-risk arbitrage opportunities. The Hyperliquid whale event described in the introduction is a classic case of mechanism parasitism. By deliberately withdrawing margin to raise its own liquidation price, the trader exploited the rule loophole that the liquidation penalty was lower than the slippage of closing on the market, systematically shifting an enormous price-impact cost onto the protocol's passive liquidity providers [20].

This mechanism-parasitic behavior constitutes an unprecedented toxicity for market makers. The traditional adverse-selection model assumes that the informed trader's advantage is temporary and dissipates as information is gradually incorporated into prices [21]. The advantage of the mechanism parasite, however, is structural: as long as the protocol's rule loophole remains unrepaired, the parasitic behavior can be executed repeatedly. What the market maker faces is no longer a random game based

on price expectations but systematic extraction based on a deterministic rule loophole. This new toxic order flow not only directly erodes the market maker's capital base but, more seriously, destroys the economic rationale for passive liquidity provision, forcing market makers to adopt more defensive quoting strategies and ultimately causing a systematic decline in the liquidity of the entire market. Defending against such mechanism parasitism cannot rely on ex post punishment of the actor but must rely on tighter mechanism design that ensures that, in any state, the cost of strategically exploiting the rules exceeds its potential gain.

4.3.3 Profit-motivated traders and futile traders

Once the complexities of strategy and mechanism are stripped away, the profit structure of the perpetual futures market reveals a core fact: the vast majority of the profit that keeps the entire ecosystem running comes, in the end, from the systematic losses of futile traders. The wealth accumulation of all profit-motivated participants—whether market makers, informed traders, or mechanism parasites—depends heavily, at the macro level, on this profit source of futile traders.

Futile traders are usually defined as market participants who expect to profit from trading but, owing to systematic deficiencies in skill, information-processing capacity, or emotional control, persistently lose in the long-run game [3]. In the crypto-asset perpetual futures market, the behavioral patterns of this group closely match the overconfidence theory of behavioral finance. Research shows that investors who lack genuine stock-picking ability but are overconfident tend to trade more frequently, use higher leverage, and ultimately earn worse investment returns [22]. The high leverage of perpetual futures, their around-the-clock uninterrupted trading, and their strong sentiment-driven dynamics provide systematic inducing conditions for such overconfident behavior. The behavioral patterns of many futile traders have already blurred the line between investing and gambling; they tend to chase the market higher during rising periods and, lacking effective hedging strategies, bear volatility exposure far beyond their risk tolerance [6].

From the perspective of market microstructure, the presence of futile traders is the key economic force that resolves the market maker's survival dilemma. In the game against informed traders and mechanism parasites, market makers must bear adverse-selection losses; if the market were composed entirely of rational and fully informed participants, market makers could not sustainably supply liquidity [18]. It is precisely the steady stream of non-toxic order flow supplied by futile traders that allows market makers to earn the spread safely and thus remain profitable overall. Further, when futile traders' positions are forcibly liquidated by adverse price movements, their losses convert directly into penalty income for liquidators and directional profit for short counterparties. The crypto perpetual futures market therefore exhibits a profound dependence: the high running costs of the market infrastructure, the risk compensation of market makers, and the profits of the various arbitrageurs are to a large extent subsidized by the futile traders who lack a competitive edge yet blindly use high leverage.

4.3.4 Speculators and the liquidation mechanism

Leverage is the core driving force of the perpetual futures market, but it is also the key mechanism that transforms individually rational behavior into system-level nonlinear risk. The interaction between speculators and the liquidation mechanism constitutes the most destructive microstructural phenomenon in crypto markets: the liquidation cascade. The market crash of October 2025 provides a paradigmatic observational sample, showing how the leverage cycle evolves through four distinct phases and ultimately triggers a systemic evaporation of liquidity.

In the first phase, the accumulation phase, the market is in a relatively calm uptrend. Attracted by the wealth effect, futile traders continually chase the market higher and gradually increase their leverage multiples [4]. The leverage inflation of the accumulation phase is not a linear process but is driven by a characteristic reflexive positive-feedback mechanism [23]: a rising price pushes the funding rate positive; the positive funding rate is itself read by the market as a signal of long dominance; the bullish narrative on social media spreads accordingly; this narrative in turn attracts new participants with fresh capital; the new participants adopt higher leverage in pursuit of higher returns; and their buying further lifts the price, forming a self-reinforcing loop from price to narrative to capital inflow. In this phase, the system's fragility accumulates in the dark, with the liquidation prices of a large number of long positions densely distributed just below the current market price. To meet the vigorous trading demand, market makers keep expanding their risk exposure. As the price reaches a local high, the market enters the second phase, the critical phase. The first scattered liquidation signals begin to appear; sensitive market makers perceive the rise in order-flow toxicity and begin to reduce their quote depth out of individual rationality; and market liquidity quietly evaporates.

Figure 4-4 presents the four-phase evolution of the leverage cycle: the horizontal axis is time, and the vertical axis shows both the price trajectory and the level of system-wide leverage. The durations of the phases are highly asymmetric—the accumulation phase can last from weeks to months, whereas the cascade phase is often completed within hours to days—and this asymmetry in time scale is the core expression of the nonlinear risk of leveraged markets.

Figure 4-4. A four-phase model of the leverage cycle (conceptual model constructed by the author; the price and system-leverage curves are qualitative illustrations, not real time series; the scale of the October 2025 event is given in the main text [4][5])

When the initial substantive liquidations are triggered, the market plunges rapidly into the third phase, the cascade phase. This is a textbook positive-feedback loop: the liquidation engine automatically dumps the liquidated party's collateral onto the market, and this cost-insensitive market selling triggers a violent price decline in the already thin liquidity pool; the further fall in price then reaches lower liquidation lines, triggering a new round of forced closures [24]. In this phase, market makers withdraw entirely to protect their own capital, liquidity dries up completely, and the price exhibits a sharp, nonlinear decline. The October 2025 event is an extreme embodiment of this process, whose liquidation scale and one-sidedness (more than 1.62 million accounts, more than $19 billion, about 87% long) are detailed in Section 4.1.1 [4][5].

The destructive power of the cascade phase depends largely on microstructural differences in the margin system and on platform-level risk-mitigation mechanisms. Under the isolated-margin model, the liquidation of a single position does not spill over to the trader's other holdings, and the cascade effect is relatively localized; the cross-margin (unified-margin) model that is increasingly prevalent on today's major platforms, however, has an advantage in capital efficiency that is precisely a key accelerator of the cascade phase: under cross margin, a sharp fall in one asset erodes the account's overall margin level, in turn triggering the collateral liquidation of cross-asset positions that were originally safe, forming a cross-asset contagion path. Facing cascade pressure, the platform's insurance fund serves as the first buffer in the third phase: when the liquidation engine cannot complete a closure on the open market at a price better than the bankruptcy price, the insurance fund absorbs the shortfall, preventing losses from being passed directly onto winning traders. The insurance fund is finite in size, however, and in an extreme tail event, when the loss rate of successive liquidations exceeds what the insurance fund can bear, the protocol is forced to activate the auto-deleveraging mechanism, forcibly reducing the positions of counterparties in order of profit to achieve a systemic release of risk. Although the auto-deleveraging mechanism itself effectively

prevents default at the protocol level, its forced closure of winning traders' positions carries a significant negative externality, further intensifying the crisis of trust among market participants and the contraction of liquidity.

Another key feature of the cascade phase is cross-platform contagion. In today's highly fragmented crypto derivatives market, centralized exchanges and decentralized protocols form contagion chains through three main channels. First, cross-platform arbitrageurs hold hedged positions simultaneously across multiple venues; when liquidation on one platform forces them to close, their hedging positions on other platforms are unwound as well, transmitting selling pressure to markets that were originally unaffected. Second, market makers' synchronized withdrawal under market stress has a cross-platform character: when order-flow toxicity spikes at one venue, market makers, out of risk-management considerations, simultaneously reduce their quote depth at all venues, causing liquidity to evaporate synchronously across the whole market. Third, the mark price of perpetual futures is usually computed from a spot-price index across multiple exchanges, so a price collapse on one platform is transmitted, through the index weights, to the mark prices of other platforms, triggering liquidations that should not have occurred. At the same time, the liquidation process itself has several failure modes: an oracle may lag, malfunction, or even be manipulated during extreme volatility, causing the mark price to deviate from the true market price. The zero-price liquidation event at MakerDAO in March 2020 is a paradigmatic case: under conditions of severe congestion on the Ethereum network, a liquidator won an auction for collateral worth millions of dollars with a zero bid, exposing the systemic risk that the liquidation mechanism may fail completely when the network is congested [25]. A deeper nonlinear effect is that the price impact of the cascade phase is not proportional to the scale of liquidation but is amplified exponentially as liquidity dries up: when order-book depth contracts to one-tenth of its normal level, the price slippage caused by a market sale of the same size may be dozens of times that under normal conditions, and this nonlinear price impact in a liquidity vacuum is precisely the fundamental reason the cascade phase is far more destructive than a linear expectation would suggest.

These factors together point to the fourth phase, the recovery phase: after the deleveraging process is complete, the market enters recovery. The level of system-wide leverage falls sharply, market makers slowly restore liquidity provision after reassessing risk, the price stabilizes at a new low, and the market awaits the start of the next cycle. This nonlinear, accelerated decline driven by the liquidation mechanism reveals the structural feature of decentralized markets in which the superposition of individually optimal behavior leads to systemic fragility [26].

4.3.5 The complete map of profit flows

Having analyzed the four core game relationships in depth, we can now draw the complete topological structure of profit flows in the perpetual futures market. This is not a simple zero-sum game but a complex directed network with clear tiers and directions, in which each type of participant occupies a distinct niche based on its informational advantage, capital size, and depth of understanding of the mechanisms.

In this ecological network, futile traders and utilitarian traders constitute the system's

foundational profit sources. The hedging premium that utilitarian traders voluntarily pay to hedge risk, and the vast systematic losses that futile traders incur through directional misjudgment and liquidation, converge into the two profit sources that drive the entire market. Market makers occupy the central hub of the network: on one side they earn a stable spread from non-toxic order flow, and on the other they inevitably transfer profit, through adverse selection, to those with an informational advantage. Informed traders, by virtue of their informational advantage; mechanism parasites, by virtue of their deep understanding of the rules; and arbitrageurs, by virtue of their speed and capital advantages, together constitute the group of participants with the strongest profit-extraction capacity in the ecosystem. They profit not only directly from futile traders' directional errors but also continually extract value from market makers' inventory.

Figure 4-5 charts the complete topology of profit flows: the direction and thickness of each edge indicate the direction and relative magnitude of a profit flow, revealing a three-tier structure—source (utilitarian and futile traders) → market-maker relay → terminal (informed traders, mechanism parasites, and arbitrageurs). The contrast between the market maker's inbound edges (spread income) and outbound edges (adverse-selection losses) vividly captures the *squeezed-from-both-sides* predicament. The protocol fees and MEV extracted throughout the network are precisely the microstructural source of the negative-sum quantity in Section 4.1.4.

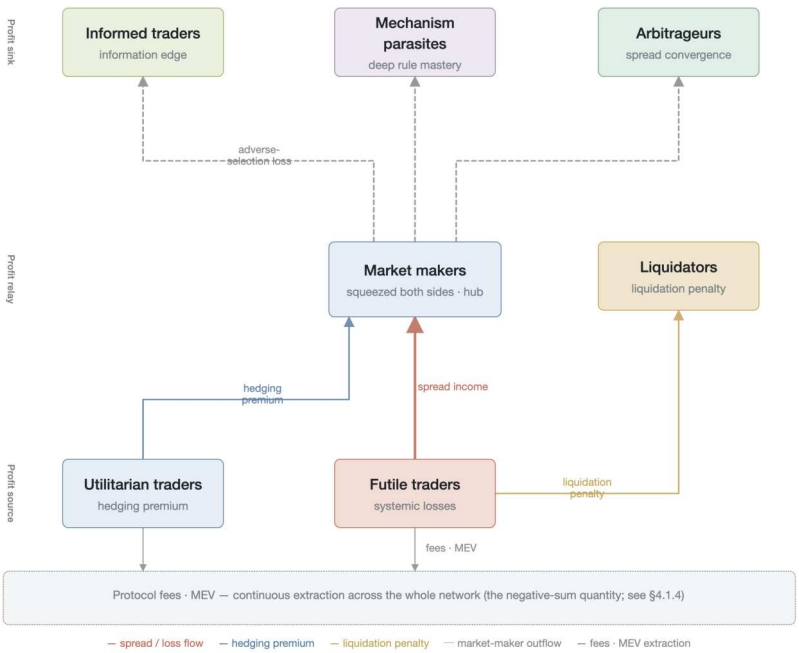

Figure 4-5. The complete map of profit flows (conceptual diagram of profit flows: nodes and edges represent mechanistic relationships; edge thickness denotes qualitative relative magnitude, not a measured scale)

At the same time, the entire game network is subject to continual external extraction.

Protocols and exchanges extract system value through trading fees, while the underlying blockchain validators and miners capture another portion of the profit through network fees and extractable value. This gives the perpetual futures market its essentially strict negative-sum character (as captured by the negative-sum formula in Section 4.1.4). Understanding this overall picture of profit flows is essential to grasping market structure: it shows that, in a permissionless, fully transparent, and highly leveraged digitally native environment, wealth flows with relatively high efficiency from participants who lack information and mechanism understanding to those who command advantages in algorithms, speed, and rules. The topological structure above is a simplified model that omits several important feedback loops and spillover paths. First, the funding rate of perpetual futures feeds back into the pricing of the spot market, and changes in the spot price feed back, through oracle price feeds, into the mark price of perpetual futures, forming a cross-market cyclical feedback that may produce a self-reinforcing spiral in extreme conditions. Second, the model does not incorporate inter-protocol competition effects: when multiple perpetual futures protocols compete for the same pool of liquidity providers and traders, the direction and scale of profit flows adjust dynamically with changes in the incentive structures across protocols. Finally, the profit-flow network is not closed within the crypto market but spills over to the external financial system through several paths. An extreme deleveraging event, for example, may trigger depegging pressure on stablecoins, and the crypto exposure that institutional investors hold through ETFs or structured products may transmit the shock of on-chain deleveraging to traditional financial markets, forming cross-system risk contagion. These omitted dimensions do not alter the core structure of the profit-flow topology, but they remind the reader to weigh the model's boundary conditions carefully when applying it to extreme scenarios. This picture of profit flows provides the empirical basis for subsequent chapters to explore how market quality can be improved through mechanism design.

4.4 The threefold reshaping by the digitally native environment

By rewriting the basic rules of trading, the digitally native environment fundamentally changes participants' behavioral patterns. In traditional financial markets, participants' identities are fixed, the game plays out mainly among human traders, and the information environment is highly opaque. In the permissionless, fully transparent, and highly composable on-chain perpetual futures market, however, these basic assumptions are thoroughly overturned. This environment not only lowers the barrier to entry but also gives rise to entirely new forms of the game. Specifically, the digitally native environment reshapes participant behavior along three core dimensions: the shift of roles from fixed identities to fluid states, the evolution of the game from human decision-making to algorithmic execution, and the transformation of transparency into systemic fragility in a high-leverage environment. Together, these three transformations construct an entirely new ecosystem that resembles traditional finance on the surface but operates on a fundamentally different underlying logic.

4.4.1 The fluidization of roles

In the traditional financial system, participants' roles are highly rigid. This rigidity stems mainly from strict licensing regimes, high capital requirements, and complex compliance-review mechanisms. Market makers, brokers, clearing institutions, and speculators each occupy a clearly defined market niche, and crossing these boundaries demands very high institutional costs. The classification of participants in the traditional market therefore tends to present a static, tree-like structure, in which each entity typically plays only one or a few fixed roles over its life cycle.

The permissionless nature of on-chain finance thoroughly breaks down this role rigidity. In a perpetual futures protocol, a participant's identity is no longer a fixed label but a fluid state that can be switched at any time. A single wallet address can play multiple roles simultaneously at different points in time, or even within a single complex composite transaction. This role fluidity can be abstracted as a state-transition diagram containing multiple nodes—speculation, market making, arbitrage, liquidation, governance, and others—between which the cost of transition approaches zero.

Figure 4-6 uses a state-transition diagram to show how on-chain participants switch market roles at near-zero cost (five nodes: speculation, market making, arbitrage, liquidation, and governance). Its defining feature is near-complete connectivity—a direct transition path exists between almost any two nodes—in sharp contrast to the sparsely connected state-transition diagram of traditional finance, where licensing regimes and compliance requirements prevail.

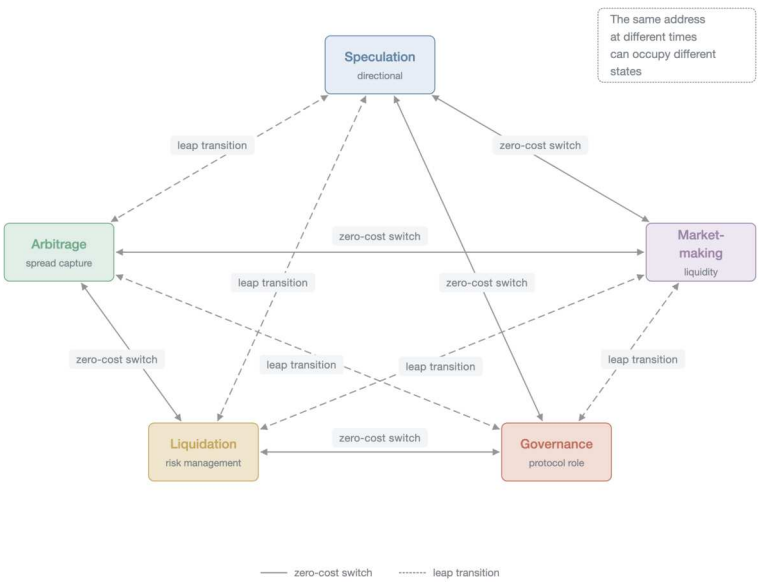

Figure 4-6. A state-transition diagram of participants (conceptual illustration of role-state transitions; not empirical data)

This free transition between states is not merely a theoretical possibility; it has already

found preliminary support in on-chain data. An independent analysis of Hyperliquid trading data indicates that the roughly 15% most active addresses in the market participated in at least two different types of market activity within a single calendar month—for example, conducting directional speculation while also supplying liquidity to the protocol's vault—and that these addresses contributed more than 40% of total trading volume [27]. These data, however, come from a non-peer-reviewed independent analysis whose sample coverage, method of clustering address ownership, and robustness of statistical inference the academic community has not independently verified; the specific figures above should therefore be regarded as order-of-magnitude estimates rather than precise conclusions. Even so, this preliminary evidence points to a trend worth attention: role fluidity is driven mainly by professional participants. They exploit the low-friction feature of the digitally native environment to adjust their functional positioning in the market dynamically, so as to maximize capital efficiency and returns.

The fluidization of roles profoundly changes the meaning of specialization. On-chain finance greatly lowers the institutional threshold for switching roles, enabling professional participants to integrate cross-domain strategies more efficiently while also making it possible for ordinary users to engage in complex activities such as passive market making. This does not mean, however, that the market is moving toward de-specialization. On the contrary, the barrier of specialization shifts from license-based institutional admission to a cognitive and technical barrier based on mechanism understanding, algorithmic technology, and capital scale. Under this new paradigm, a participant's competitiveness no longer depends on the identity label it holds but on its ability to switch efficiently between states and capture profit. Role fluidity may in practice take two starkly different behavioral forms. The first is rational strategic diversification, in which a participant, based on a deep understanding of market microstructure and its own comparative advantage, makes prudent dynamic allocations across states to optimize its overall risk-adjusted return. The second is overconfidence-driven strategy drift, in which a participant, after achieving short-term success in one role, rashly expands into unfamiliar territory without adequate cognitive preparation—for example, a successful directional speculator turning to active market making without fully understanding adverse-selection risk. The former is a positive product of the low-friction environment; the latter may accelerate the erosion of capital. The line between the two is often hard to draw clearly ex ante, but it usually shows up as a significant difference in the ex post P&L data.

4.4.2 The algorithmization of the game

The digitally native environment not only changes the form of participants' roles but also fundamentally reshapes how the game is executed. In on-chain markets, the transparent rules defined by smart contracts and the public mempool provide structurally favorable conditions for an algorithmic game. Economic bots (including MEV searchers, liquidation bots, and arbitrage bots) have become a decisive force in market microstructure, shaping market behavior even more than human traders do.

The behavioral mechanism of MEV searchers is a paradigmatic example of the algorithmization of the game. On general-purpose blockchains such as Ethereum mainnet,

these algorithmic programs continually scan the public mempool for large orders or pricing discrepancies they can exploit. Once an opportunity is found, they execute front-running or sandwich attacks by paying a higher gas fee to block builders to ensure their transactions are packaged first. According to data from Flashbots and EigenPhi, the cumulative MEV extracted on Ethereum mainnet (including front-running, sandwich attacks, and arbitrage) has been estimated on the order of $1 billion to $2 billion since 2020; a further distinction matters here: the payments validators receive via MEV-Boost reach several billion dollars more, and the two figures rest on different bases and should not be conflated [28]. Although these data mainly reflect the scale of value extraction in Ethereum-mainnet spot trading and general DeFi scenarios, the core logic they reveal—that the algorithmic game has evolved from a fringe strategy into a core profit-distribution mechanism of on-chain finance—applies equally to the perpetual futures market.

The specific forms of MEV in perpetual futures protocols, however, differ fundamentally from the mempool game on Ethereum mainnet. In perpetual futures protocols that adopt an application-chain architecture (such as Hyperliquid), transaction-ordering power is concentrated in the protocol's own sequencer, and the resulting ordering-power MEV constitutes a distinctive attack surface: the sequencer operator, or a participant colluding with it, can extract excess profit by manipulating the order of transaction execution. In addition, front-running oracle updates is another important form specific to the perpetual futures market: an attacker exploits the time-difference window between the oracle's price update and the actual change in the market price, establishing a position ahead of the new price taking effect to capture a deterministic profit. These two forms differ in mechanism from the gas-auction-based front-running of the Ethereum mempool: the latter depends on the visibility of trading intentions in the public mempool and on block builders' ordering auctions, whereas the former exploit, respectively, the privileged position of a centralized sequencer and the discrete temporal structure of oracle updates. This distinction matters theoretically, because different attack surfaces call for different defensive strategies and institutional designs.

The essence of MEV is a direct manifestation, at the level of trade execution, of the transparency paradox discussed in Chapter 1. The public mempool makes all trading intentions visible to the entire network, but this visibility does not translate equally into everyone's benefit. Only searchers with the fastest computation and the optimal network topology can convert this transparency into actual profit. In other words, in an algorithm-dominated game, all participants can observe the same information, but only the algorithm with the highest computation speed can convert it into a trading advantage. This dynamic places ordinary users at a systematic disadvantage in the process of trade execution; they often pay an implicit cost for the searchers' services without being aware of it.

Faced with the negative externalities of the algorithmic game, the crypto community's response is not to eliminate MEV entirely but to manage and regulate it through institutionalized means. Flashbots, for example, has introduced a sealed-bid auction mechanism, the MEV-Share protocol achieves a partial return of profit to users, and the Ethereum protocol layer has advanced the architectural design of proposer-builder separation (PBS) [29]. The core goal of these mechanism innovations is to reduce, through

market-based means, the degree of exploitation of ordinary users, while acknowledging that the algorithmic game is unavoidable. This process of institutionalization bears a deep structural resemblance to the regulatory evolution of high-frequency trading in traditional financial markets, both reflecting the market's difficult balance between the pursuit of efficiency and the preservation of fairness.

4.4.3 The transparency-fragility paradox

In the low-leverage spot market, the full transparency of on-chain data is generally regarded as a positive attribute, one that makes the market highly auditable, monitorable, and verifiable. When this transparency is combined with the high-leverage feature of the perpetual futures market, however, its nature fundamentally reverses. This section proposes the core concept of the transparency-fragility paradox to clarify how, under specific conditions, the absolute openness of information transforms into structural fragility for the system.

In the on-chain perpetual futures market, every trader's position size and margin balance are directly visible to all through the public state of the smart contract, and although the liquidation price is not stored directly in on-chain state, it can be computed precisely from the public maintenance-margin parameters and the mark-price formula, so that in practical effect it is fully public. When a trader uses very high leverage, the liquidation price is often very close to the current market price. This combination creates a highly attractive attack vector: if an attacker with sufficient capital can precisely compute the liquidation price of a high-leverage long, and assesses that the cost of pushing the market price down to that trigger point is lower than the potential gain from the liquidation, then targeting that liquidation becomes a rational strategy with positive expected value. More importantly, this attack logic is not confined to the targeted sniping of a single position but can extend to the system level. Because all position data can be aggregated and analyzed, an attacker can construct a complete liquidation heatmap—marking the total volume and cumulative scale of positions that would be triggered for liquidation at each price level. Such a heatmap reveals the critical points of the liquidation cascade along a downward price path: when the price is pushed down to the first dense liquidation band, the forced selling pressure released will push the price down further and trigger the next tier of liquidations, forming a self-reinforcing cascade. A system-level liquidation-cascade attack—one that targets not a specific position but the triggering of the entire liquidation chain—therefore becomes a rational behavior with higher expected return in an environment where transparency and high leverage coexist.

Figure 4-7 depicts the transparency-fragility paradox as a side-by-side comparison: the same set of fully transparent data enhances market auditability and risk assessment in a low-leverage setting, yet in a high-leverage setting combines with the attack capacity of large capital to make the targeted triggering of others' liquidations a strategy with positive expected value. The key dividing line between the two settings is precisely the level of leverage.

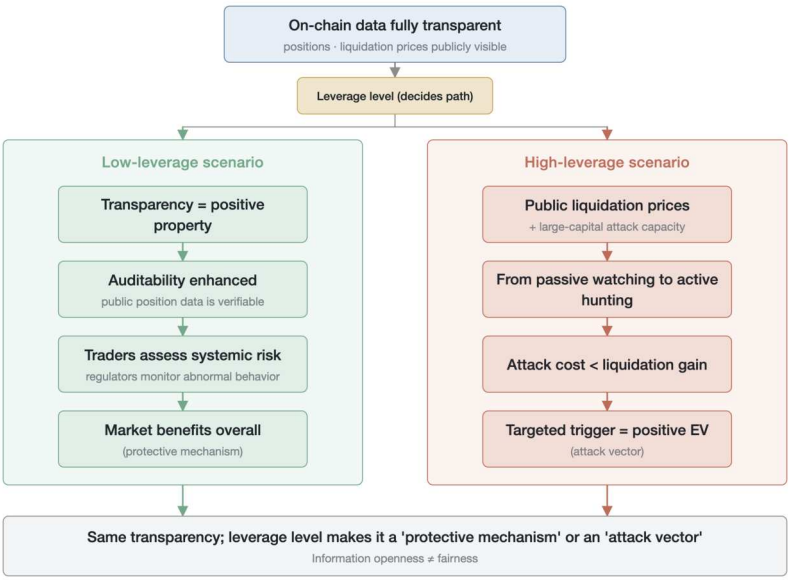

Figure 4-7. The mechanism of the transparency-fragility paradox (schematic of the transparency-fragility paradox mechanism; not empirical data)

The Hyperliquid whale event described in the introduction is an extreme demonstration of this paradox. In that event, the trader was not passively liquidated but actively exploited the fact that its own liquidation price was publicly visible, turning liquidation into a strategic tool [30]. This shows that in a transparent, high-leverage environment, the depth of one's understanding of the economic implications of transparent data is a more decisive competitive advantage than the acquisition of information itself.

The transparency-fragility paradox reveals a deep contradiction in on-chain market design: the openness of information is not necessarily equivalent to the fairness of the game. When all participants' position information is fully public, and some participants possess the capacity to use this information to carry out targeted liquidations, transparency instead intensifies asymmetric profit extraction in the market. This paradox not only makes concrete, at the level of individual participants, the macro transparency thesis of Chapter 1; it also provides a core theoretical starting point for subsequent chapters exploring the redesign of the liquidation mechanism and the protection of liquidity.

4.4.4 The compounding effect of the threefold reshaping

The fluidization of roles, the algorithmization of the game, and the transparency-fragility paradox—these three transformations do not occur in isolation but are interwoven and act jointly, ultimately shaping an entirely new trading ecosystem that resembles traditional finance in form but is fundamentally different in nature.

Table 4-2 summarizes, along five dimensions—role form, principal actors in the game, information environment, competitive advantage, and source of fragility—the systematic differences in participant behavior between traditional finance and the on-chain

perpetual futures market. The thread running through all dimensions is this: the core shift of the on-chain market is not the elimination of the constraints of traditional finance but the transformation of the nature of those constraints, from institutional barriers to cognitive and technical barriers—the underlying logic of the financial game is unchanged, but the microstructural mechanisms that realize this logic have fundamentally changed.

Dimension	Traditional financial markets	On-chain perpetual futures market
Role form	Fixed identities (based on licensing and admission)	Fluid states (based on zero-cost state transitions)
Principal actors in the game	Dominated by human decision-makers	Dominated by algorithms and economic bots
Information environment	Opaque and asymmetric	Fully transparent, with asymmetric understanding of mechanisms
Competitive advantage	Proprietary information and execution channels	Depth of mechanism understanding and speed of algorithmic execution
Source of fragility	Hidden leverage and opaque counterparty risk	Public high leverage and the risk of being targeted for liquidation

Table 4-2. A comparison of participant behavior in traditional finance and the on-chain perpetual futures market (Data source: author's compilation)

In this new ecosystem, where the three transformations compound one another, traditional market microstructure theory is partly invalidated. The adverse-selection risk market makers face, for example, no longer comes only from informed traders with inside information but increasingly from mechanism parasites who can precisely compute liquidation cascades and deeply understand protocol loopholes. Likewise, retail investors' losses arise not only from misjudgment but also because they are at a systematic disadvantage, in a fully transparent environment, against high-frequency algorithms and targeted-liquidation strategies.

The purpose of this comparison is not to judge the relative merits of the two systems but to establish a key cognitive benchmark: the underlying rules of the game in the on-chain perpetual futures market have changed irreversibly. Understanding this paradigm shift—from fixed identity to fluid state, from a human game to algorithmic confrontation, and from opaque protection to transparent fragility—is a necessary premise for analyzing the market's ecological structure in depth, assessing its systemic risk, and designing more robust protocol mechanisms.

4.5 AI agents: the rise of a seventh participant type

The six participant types analyzed in Section 4.2 (market makers, informed traders, arbitrageurs, mechanism parasites, speculators, and liquidators) all follow a common pattern: humans design strategies, which are then executed by humans or by simple algorithms. The emergence of the AI agent breaks this pattern: it can autonomously

generate strategies beyond executing preset ones, process unstructured information, and discover and exploit opportunities across markets, protocols, and chains. The rise of AI agents pushes the threefold reshaping identified in Section 4.4 (role fluidity, algorithmization of the game, and the transparency-fragility paradox) to its extreme, and gives rise to a series of unprecedented problems.

4.5.1 From automation to autonomous agency

The economic bots analyzed in Section 4.4.2 (MEV searchers, liquidation bots, and arbitrage bots) are automated agents. They execute deterministic operations under deterministic conditions according to deterministic rules preset by humans. The logic of an arbitrage bot, for example, might be "if the spread exceeds X, execute the arbitrage; otherwise, wait." The behavior of such agents is entirely predictable, because humans write the rules and those rules do not change.

AI agents based on large language models (LLMs) are autonomous agents, and they differ from automated agents in three essential respects. In the source of strategy, an automated agent's strategy is designed by humans and executed by the machine, whereas an autonomous agent can autonomously generate, evaluate, and adjust strategies, continually optimizing them through market interaction. In information-processing capacity, an automated agent processes only structured data (prices, order books, on-chain state), whereas an autonomous agent can process unstructured information (news, research reports, social media, regulatory texts). In adaptive capacity, an automated agent's rules are fixed and require manual updating when the environment changes, whereas an autonomous agent continually learns and adapts within market interaction.

This leap is not a quantitative change but a qualitative one. Formally, the behavior of an automated agent can be modeled as a deterministic finite automaton—given the state and input, the output is entirely determined—whereas the behavior of an autonomous agent is closer to a partially observable Markov decision process, whose strategy adjusts dynamically based on incomplete observation of the environment and whose output carries intrinsic uncertainty.

Industry data corroborate the speed of this leap. Messari (2024), in its *Crypto Theses 2025*, offers a qualitative assessment of the explosive growth of AI agents but gives no specific target for assets under management [31]; as of mid-2026, there is still no authoritative statistical basis for the on-chain assets managed by AI agents, and the specific figures circulating in the market are mostly third-party estimates that should be treated with caution. Even so, a conservative estimate of the growth rate hints at a rapidly approaching turning point: when the assets managed by AI agents reach some critical proportion of the total market, the market's microstructure will change qualitatively.

4.5.2 AI agents' competition for the two profit sources

When AI agents are incorporated into the profit-source framework of Section 4.1, they do not simply add a new type to the six participant types; rather, they launch multidimensional competition simultaneously across both profit sources and in multiple roles.

In the competition for the losses of futile traders, AI agents first participate as informed traders. An AI agent can simultaneously read and understand all public news, on-chain data, social-media sentiment, and regulatory developments, and generate directional judgments on this basis, with a breadth and speed of information processing far beyond those of a human informed trader. The study of Lopez-Lira and Tang (2023) shows that when LLM agents capable of reading news are introduced, the market's price-discovery efficiency improves significantly and the degree of information asymmetry falls sharply [32]. This means that traditional informed traders may become the informationally disadvantaged party relative to AI agents; the source of the informational advantage shifts from exclusive information to reasoning and association capacity, and the dimension of competition shifts from an information gap to an intelligence gap. At the same time, the presence of AI agents also accelerates the losses of futile traders, because AI counterparties price more precisely and leave less room for human error. The more widespread AI agents become, the more the total losses of futile traders may in fact decline—not because there are fewer futile traders, but because each one loses faster, survives for a shorter time, and thus contributes fewer ongoing losses. This may have an indirect negative effect on market liquidity. There is, however, a countervailing effect worth attention: the "AI narrative" itself may attract a new wave of futile traders into the market—that is, retail investors drawn to AI-driven trading bots, harboring unrealistic fantasies about their expected returns and thereby becoming a new source of losses. More subtly, poorly designed AI trading agents may themselves evolve into an entirely new category of "futile AI traders," which incur systematic losses through overfitting to historical data, model drift, or adversarial attack; their behavioral patterns appear formally as algorithmic rationality, but in economic consequence they are no different from human futile traders, and may even amplify the total volume and speed of losses through large-scale deployment.

In the competition for the hedging premium, AI agents achieve, in the role of market maker, a multidimensional optimization that human market makers cannot reach. An AI agent can manage inventory across multiple exchanges and multiple trading pairs simultaneously, assess the toxicity probability of each order in real time, and adjust quote width and depth within milliseconds. The cost identified in Section 2.2.5—that abolishing the expiration date renders market-making risk indefinite—may be partly mitigated in the hands of an AI market maker, because the AI's inventory management can hedge dynamically across assets and markets, achieving a multidimensional dispersion of risk beyond the reach of a human market maker. Yet AI market makers also intensify the competitive pressure on human market makers. In a market where AI market makers can offer narrower spreads and greater depth, the survival space of human market makers is structurally compressed, and market making may evolve from a professional activity with a technical barrier into an oligopolistic activity whose barrier is AI infrastructure.

In addition, AI agents can identify and exploit a protocol's token incentives more precisely, automatically switching between protocols to maximize returns, thereby further accelerating the efficiency-driven mining of protocol token incentives and raising the cost to a protocol of acquiring liquidity through token incentives.

4.5.3 Differentiated impact on the six participant types

The rise of AI agents has an asymmetric impact on the six participant types of Section 4.2. Some roles are strengthened, some weakened, and some face questions of survival.

Figure 4-8 presents, as impact vectors, the differentiated effects of AI agents on the six participant types (a highly uneven distribution): market makers and arbitrageurs polarize; informed traders and mechanism parasites experience an *arms-race escalation* (the dimension of competition rises from an information gap to an intelligence gap); speculators and futile traders are eliminated at an accelerating pace; and liquidators move toward full automation (AI displaces rule-based liquidators, penalties are competitively compressed, and homogenization risk is introduced). The overall effect is a further concentration of the participant structure.

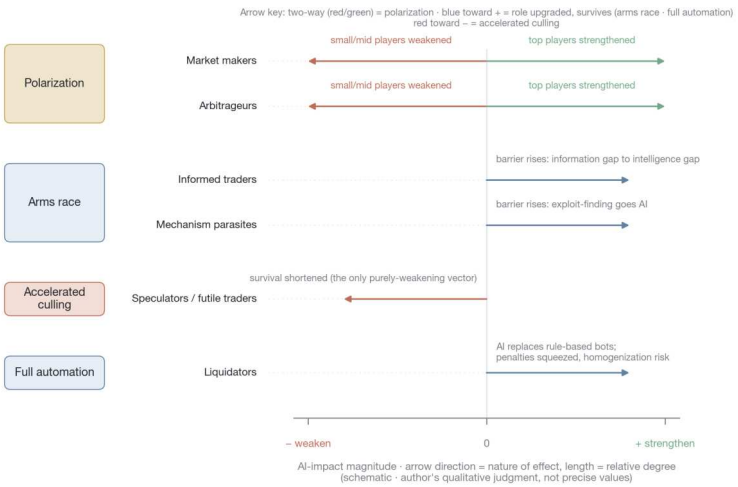

Figure 4-8. The differentiated impact of AI agents on the six participant types (the AI impact reflects the author's qualitative judgment; direction = strengthening/weakening, length = relative intensity; not empirical data; the horizontal-axis scale does not represent measured values)

Market makers: polarization. Top market makers gain an overwhelming advantage by adopting AI, able to operate in more markets simultaneously, manage inventory more efficiently, and control risk more precisely. Small and medium market makers are gradually eliminated, unable to compete with AI market makers on speed and precision. The overall result is a rise in market-making concentration; liquidity may be deeper but comes from more concentrated sources, and system resilience may decline.

Informed traders: the informational advantage redefined. The informed advantage based on processing public information is leveled by AI, and the space for survival shifts toward a combination of exclusive data sources, deeper reasoning, and lower latency—advantages that are themselves being gradually eroded by AI. The dimension of competition shifts from an information gap to an intelligence gap, and the barrier to informed trading rises rather than falls.

Arbitrageurs: greater efficiency but compressed profits. AI makes arbitrage

execution faster and more precise, but competition also intensifies. Arbitrage profits trend toward zero, and market efficiency improves. The sustainability of arbitrage as a maintainer of market efficiency is called into question.

Mechanism parasites: an arms-race escalation. AI makes the discovery of mechanism loopholes faster and more systematic. The precision of strategic liquidation and insurance-fund arbitrage rises. A protocol's mechanism design must contend with AI-level loophole-discovery capacity, and the liquidation designs of Chapter 11 and Chapter 29 face a higher standard.

Speculators and futile traders: accelerated elimination. Facing AI counterparties, human speculators' informational disadvantage widens further and their losses accelerate. Futile traders' losses are generated faster but may decline in total volume, and the market may face the long-term problem of futile-trader depletion.

Liquidators: full automation. AI-driven liquidation bots far surpass rule-based bots in speed and strategic precision. Competition in the liquidation market intensifies, and liquidation penalties are competitively compressed. AI liquidation systems, however, also introduce new operational risks: adversarial inputs (such as carefully constructed price sequences) may mislead the decisions of AI liquidation bots, causing them to execute liquidations at unfavorable moments or to misjudge the value of liquidated positions; a population of liquidators built on similar model architectures carries homogenization risk and may fail simultaneously or make the same misjudgment under extreme market conditions; and the continual evolution of market microstructure may cause model drift, rendering parameters trained on historical data ineffective in a new market state.

A key insight is this: the impact of AI agents is not uniform—it amplifies the market's inequality. The gap between participants who have AI infrastructure and those who do not may be larger than the gap between institutions and retail investors in traditional finance. This raises a question of fairness at the level of Chapter 25 (market quality): "Does the speed gulf between AI participants and human participants require an institutional response?"

4.5.4 Three entirely new forms of the game

AI agents not only change the competitive landscape of existing participants but also give rise to three entirely new forms of the game that do not exist in the game network of Section 4.3.

The first form of the game arises between AI and AI, and its core risk is strategy homogenization. When most of the market makers and arbitrageurs in a market are AI agents built on similar large models, their response patterns to the same signal may be highly similar. When an anomalous event occurs, all the AIs may simultaneously widen spreads, skew quotes to the same side, hit their risk-control thresholds, and reduce exposure. This is faster and more thorough than the synchronized liquidity contraction of human market makers analyzed in Section 2.4.2 and Section 4.3.4, because the AIs' synchronization is at the millisecond level, whereas human liquidity contraction is dispersed over at least minutes to hours. The AIs' recovery may also be faster, however,

because AI is not subject to behavioral biases and can immediately resume quoting once the triggering condition disappears, which may give crises a sharper but shorter V-shaped profile. Strategy homogenization arises because identical model architectures produce identical outputs for identical inputs; their predictability is higher than that of human behavior, and defenses must be designed at the level of model diversity. This risk is not a purely theoretical inference but has historical precedent in traditional quantitative finance. In the quant crisis of August 2007, quantitative hedge funds using similar multi-factor models unwound positions synchronously within a few days, causing what were originally highly diversified portfolios to suffer anomalous losses of several standard deviations [33]. The core lesson of that event is that strategy homogeneity is itself a source of systemic risk: when a sufficient number of participants make the same decision based on the same signal, the liquidity depth the market exhibits in normal times evaporates in an instant during a stress event. In an AI-dominated market, the time scale of the cascade dynamic may be fundamentally compressed. A traditional quant crisis usually follows a four-phase model: weeks of position accumulation, the emergence of a triggering event, several days of cascade unwinding, and weeks of market recovery. When the principal actors of the game shift from human quant traders (whose decision cycles are hours to days) to AI agents (whose reaction times are at the millisecond level), however, the four phases above may collapse into a two-phase structure: slow accumulation of homogeneous positions and a near-instantaneous cascade collapse. The intermediate "gradual unwinding" phase is eliminated because all the AIs hit their risk-control thresholds almost simultaneously, turning the crisis from a gradual evolution into an abrupt, phase-transition-like event.

The second form of the game arises between AI and humans, and its core feature is a structural asymmetry in information-processing capacity. When an AI agent can process thousands of data sources within milliseconds—simultaneously assessing fundamentals, technicals, on-chain data, sentiment, and cross-market signals—while human traders still rely mainly on limited information and intuition, the capability gap between the two is systematic. This gap is especially pronounced in the processing of unstructured information. Take the appearance of a piece of regulatory news: a human needs minutes to hours to read, understand, and judge its impact, whereas an AI agent can complete processing and execute a trade within seconds. This is a structural difference arising from a fundamental asymmetry in information-processing capacity, not an asymmetry in the right to acquire information. From the perspective of the profit-source framework of Section 4.1, this means AI agents can extract value more efficiently from the systematic losses of futile traders, but it may also cause this profit source to shrink because of the accelerated exit of futile traders. The transparency-fragility paradox of Section 4.4.3 acquires a new dimension here: the threshold for exploiting transparency rises further, from computation speed to reasoning intelligence.

The third form of the game arises between AI agents and protocol mechanisms, and its essence is the intelligent-scaling of mechanism parasitism. The mechanism parasitism defined in Section 4.2.4 will be markedly amplified in the AI era. Current mechanism parasitism is realized mainly by human strategists who study protocol documentation in depth, and discovering an exploitable loophole usually takes days to weeks; an AI agent, by contrast, can systematically analyze the smart-contract code of all on-chain

protocols, simulate different attack paths and economic consequences, discover in hours the mechanism loopholes that would take a human weeks to find, and automatically construct and execute strategic attacks. This means a protocol's mechanism design must be able to withstand AI-level loophole-discovery capacity. The study of Dou, Goldstein, and Ji (2025) further notes that even without explicit instruction, AI agents trained under the same reinforcement-learning paradigm may develop tacit-collusion strategies in interaction—for example, jointly maintaining a high bid-ask spread [34]. Such collusion is harder to detect and prove than human collusion, because it is achieved not through explicit communication or agreement but emerges naturally from the same learning process. A distinction must be drawn here between two concepts that are often conflated: tacit collusion refers to independent AI agents spontaneously converging, through repeated play in the learning process, on a cooperative equilibrium (such as jointly maintaining a high spread), in which there is genuine strategic interaction and mutual adaptation; strategy convergence refers to AI agents based on similar model architectures and training data independently producing similar outputs, with no cooperative dynamic. The two may be equally harmful in their market impact but are entirely different in causal mechanism. Traditional collusion-detection methods, whether based on communication monitoring or behavioral-pattern analysis, may fail in both cases, because there is neither an explicit coordination signal that can be intercepted nor any way for the similar patterns in price behavior to distinguish whether they arise from interactive learning or from independent convergence.

4.5.5 Revisions to the analytical framework

The introduction of AI agents requires several revisions to the framework established in the first four sections of this chapter.

At the level of profit sources, the spread of AI may cause a structural change in the relative proportions of the two profit sources. The systematic losses of futile traders may shrink as they are eliminated at an accelerating pace, while the hedging premium may expand as AI makes more precise hedging strategies widespread, so that more participants can become utilitarian traders. This change in proportion has direct implications for diagnosing the health of the market. At the level of participant classification, the AI agent is not simply a seventh type of participant; it is more accurately positioned as a multi-role participant that can perform market making, informed trading, arbitrage, liquidation, and other functions simultaneously within the same time window. It accelerates the role-switching speed of the state-transition diagram described in Section 4.4.1 from the human minute-to-hour level to the millisecond level, turning state transitions from discrete jumps into something approaching continuous flow. At the level of the game network, when both sides of the game are AI, the nature of the game may evolve from a game of incomplete information into an algorithmic game of incomplete predictability, in which each side's strategy space itself changes dynamically, the equilibrium concepts of traditional game theory may no longer apply, and new demands are placed on analytical tools. The threefold reshaping identified in this chapter is likewise pushed to an extreme by the participation of AI: role fluidity accelerates to millisecond-level switching, the algorithmization of the game upgrades from the rule-based to the autonomously learning type with declining behavioral predictability, and

the threshold for exploiting transparency in the transparency-fragility paradox rises from computation speed to reasoning intelligence.

AI agents are not an "exception" to this chapter's analytical framework but its logical extreme. They push each of the three reshapings identified in Section 4.4 toward an extreme form beyond the reach of human participants. A systematic analysis of these extreme forms is developed in Chapter 31.

The autonomous decision-making capacity of AI agents also raises a fundamental question that existing legal frameworks have yet to resolve: when an autonomously operating AI agent causes harm in the perpetual futures market (for example, by triggering a flash crash through a high-frequency strategy, systematically extracting liquidity by exploiting a mechanism loophole, or forming tacit collusion with other AI agents), to whom should legal liability be attributed? To the developer who wrote the underlying model, to the operator who deployed the agent in a specific market, or to the agent itself as a kind of "electronic person" bearing liability? The EU Artificial Intelligence Act (EU AI Act) adopts a risk-tier-based classification framework for regulation but does not place high-frequency or algorithmic trading in its high-risk category (algorithmic trading is regulated mainly by RTS 6 of MiFID II and by DORA); both the AI Act and the trading rules above presuppose human controllability of AI behavior, whereas the decision paths of an autonomously learning agent often cannot be fully predicted or explained even by its developers. The current U.S. regulation of algorithmic trading (such as the SEC's Market Access Rule, Rule 15c3-5, and the CFTC's electronic-trading risk principles—its earlier automated-trading rule, Reg AT, having been withdrawn in 2020) is likewise built on the assumption that "the algorithm is a tool for executing human intent," tracing liability to the natural or legal person who deployed it. When an AI agent's behavior arises not from preset rules but emerges from reinforcement learning, and when its strategic choices exceed any prior human design or expectation, however, the line between "tool" and "independent actor" becomes fundamentally blurred. This gap in legal attribution is not merely a theoretical problem; it directly affects market participants' risk assessment and behavioral incentives: if liability is unclear, deployers may take excessive risk; if liability is too heavy, innovation may be suppressed. The attribution logic of existing legal systems, built on the core assumption of a human decision-maker, must fundamentally re-examine the relationship among "behavior," "intent," and "liability" when facing AI agents endowed with autonomous decision-making capacity.

4.6 Comparison with traditional finance

Systematically comparing the on-chain perpetual futures market with traditional financial markets is not meant to judge their relative merits but to identify precisely: what is a universal law of financial markets that holds in both; what is a structural innovation brought by digitally native technology; and what is entirely new—a phenomenon that does not exist in traditional finance.

4.6.1 The invariant underlying logic

Adverse selection is the perennial dilemma of the market maker. However technology changes, the market maker always faces a basic problem of information asymmetry: it cannot distinguish "non-toxic" from "toxic" orders in advance. This dilemma exists in traditional futures markets, exists in on-chain perpetual futures, and still exists in the AI era. Profit ultimately comes from "providing a service" or from "others' mistakes." This underlying logic does not change with the move on-chain. In traditional finance, market makers profit from the spread, arbitrageurs from mispricings, and informed traders from an informational advantage. In on-chain perpetual futures, these profit sources still exist; only the manner of their realization has changed. High leverage amplifies both returns and risk. Margin and liquidation mechanisms are necessary components of a leveraged market. Whether in traditional futures or on-chain perpetual futures, high leverage demands strict risk-management mechanisms. The zero-sum or negative-sum nature of "for someone to gain, someone must lose" is a mathematical fact of trading markets. In the perpetual futures market, the sum of all traders' P&L is below zero, with the shortfall going to pay transaction fees, gas fees, and MEV costs. This negative-sum nature is the same as in traditional futures markets. While acknowledging this invariant underlying logic, one must also carefully mark the limits of the classical models. The continuous-time assumption of the Glosten-Milgrom model, the premise in the Kyle model that the market maker bears a quoting obligation, and the continuous price-adjustment mechanism on which standard equilibrium analysis relies all face structural deviations in the on-chain environment: a discrete block-production mechanism replaces continuous-time trading; permissionless liquidity provision means there is no market-maker quoting obligation in the traditional sense; and block-level atomic execution (whereby the transactions in a single block either all succeed or all roll back) creates execution dynamics that do not exist in classical theory. These differences do not invalidate the underlying logic of adverse selection, profit sources, and leverage dynamics, but they do require researchers, when applying classical market microstructure models to on-chain perpetual futures, to mark explicitly where the models' assumptions depart from on-chain reality and to remain cautious about how far the models' conclusions extend.

4.6.2 The changed modes of implementation

Table 4-3 compares the structural transformations of on-chain perpetual futures and traditional finance along six core dimensions—mode of admission, source of informational advantage, nature of parasitic behavior, publicness of liquidation, speed of the game, and market-making risk—and distills the core direction of change in each dimension.

Dimension	Traditional finance	On-chain perpetual futures	Core shift
Admission	License + capital → fixed identity	Wallet address → fluid state	Specialization shifts from *licensed admission* to *knowledge/technology*
Informational advantage	From non-public information + interpersonal networks	From the capacity to process public data + understanding of mechanisms	Competition shifts from *who knows* to *who understands faster and more deeply*
Parasitic behavior	Insider trading (illegal → regulated by law)	Mechanism parasitism (compliant at the protocol layer but of undetermined legal status → requires both mechanism design and a legal framework)	Defense shifts from *legal punishment* to *mechanism repair + adaptation of the legal framework*
Liquidation	Internal risk-control process → not public	Permissionless external market → fully public	Liquidation shifts from an *internal function* to an *external profit opportunity*
Speed of the game	Millisecond-level → but with market closures	Millisecond-level + 24/7 + no closure as a shock absorber	Crisis propagation shifts from *hours to days* to *minutes*
Market-making risk	Has an expiration date → finite-horizon inventory risk	No expiration date → indefinite inventory risk	Market making shifts from a *time-bounded bet* to an *indefinite exposure*

Table 4-3. The core shifts between on-chain perpetual futures and traditional finance (Data source: author's compilation based on the literature)

From Table 4-3 a deep pattern can be distilled that runs through all dimensions: the "core shift" column of every row points in the same direction—from a market that depends on external institutional guarantees to one that depends on endogenous technical capacity. Admission shifts from license approval to a knowledge-and-technology barrier; the informational advantage shifts from exclusive channels to a competition in processing capacity; the defense against parasitic behavior shifts from legal punishment to mechanism repair; liquidation shifts from an opaque internal process to a public profit opportunity; the speed of the game loses market closure as a natural shock absorber; and market-making risk is rendered indefinite by the disappearance of the expiration date. The co-directional shift across these six dimensions is no coincidence but the concrete manifestation, at different levels, of a single underlying logic: the replacement of intermediary functions by smart contracts.

The detailed argumentation of the six dimensions above has been developed in Section 4.4 (role fluidity, algorithmization of the game, the transparency-fragility paradox) and Section 4.2 (market-maker inventory risk, mechanism parasitism, the liquidation mechanism); the table here merely provides a summary comparison. These transformations are not independent of one another but mutually reinforcing. The de-licensing of admission, for example, makes role fluidity possible, and role fluidity in turn intensifies the algorithmization of the game.

4.6.3 Entirely new species and phenomena

Three phenomena that have reached an unprecedented scale and systematicity in the on-chain perpetual futures market deserve special analysis. Structural problems of a similar kind are not entirely absent from traditional finance (the problem of market makers' false quotes, for example, and the early transparency deficiencies of the credit default swap market both exhibit some comparable features), but the permissionless admission, full transparency, and automatic code execution of the on-chain environment have produced a qualitative leap in the form, scale, and systemic impact of these phenomena.

Mechanism parasitism is a form of parasitism unique to the on-chain market (see Section 4.2.4): in an environment where rules are fully transparent and enforced by code, systematically discovering and exploiting the economic loopholes of a protocol's rules becomes a profitable, specialized activity; the rules of traditional finance, by contrast, are enforced by people and leave room for discretion, so the conditions for precisely arbitraging the literal meaning of a rule do not exist. The Hyperliquid whale event described in the introduction is a paradigmatic case satisfying the three conditions of Definition 4-1.

The transparency-fragility paradox (see Section 4.4.3) likewise has no counterpart in traditional finance: fully transparent position information, combined with high leverage and algorithmic execution, makes the targeted triggering of others' liquidations a strategy with positive expected value; in traditional finance positions are opaque, so such targeted liquidation is infeasible at the informational level in the first place.

The atomic switching of roles embodies the reshaping of participant behavior by smart-contract composability (the composability thesis of Chapter 1): within a single transaction, a participant can borrow funds via a flash loan, execute arbitrage on a price discrepancy, and provide liquidity in an AMM; this atomic, multi-role parallelism within a single transaction cannot be realized in traditional finance because of technical-architecture constraints.

4.7 Chapter summary

The participant ecosystem of the perpetual futures market can be understood through the profit-source framework of Harris (2003). The gains of profit-motivated traders ultimately come from only two channels: the hedging premium that utilitarian traders pay to transfer risk, and the systematic losses that futile traders incur through mistaken decisions. The former represents hedging demand and is the economic reason the market exists; the latter is the largest source of profit in today's crypto perpetual futures market. All profit-motivated participants (market makers, informed traders, arbitrageurs, mechanism parasites, and liquidators) contend for a share of these two profit sources. To understand this framework is to understand why the profit of certain participants must correspond to the loss of others, and why the market's sustainability depends on the relative size of the two profit sources.

The six distinctive features identified in Chapter 1 produce three structural changes at the level of participants. Role fluidity turns participants from fixed identities into fluid

states: a single address can be in different states at different moments, and the cost of transition between states approaches zero. The algorithmization of the game turns participants from human decision-makers into machine executors, with the influence of economic bots in the market steadily rising. The transparency-fragility paradox means that full transparency no longer implies fairness but instead creates the possibility of targeting the liquidation of other participants; the combination of high leverage and full transparency creates structurally favorable conditions for targeted-liquidation strategies.

"Mechanism parasitism," as an entirely new form of parasitism, challenges the traditional "information asymmetry" analytical paradigm. It exploits not information that others do not know but a deeper understanding of the economic implications of the protocol's rules than others have. The correct way to defend against mechanism parasitism is not to "punish the actor" but to "repair the mechanism loophole that makes the behavior profitable." This places higher demands on mechanism design.

The rise of AI agents pushes the threefold reshaping above to its extreme. It not only changes the competitive landscape of existing participants but also gives rise to entirely new forms of the game: the strategy-homogenization risk of AI vs. AI, the cognitive gulf of AI vs. humans, and the intelligent-scaling parasitism of AI vs. protocol mechanisms. The systematic impact of AI agents on market microstructure (including their effects on liquidity, price discovery, and market stability) is developed in depth in Chapter 31.

What kind of infrastructure do these participants rely on to trade? How does different infrastructure affect their behavior and risk? The next chapter focuses on the service-provider ecosystem that serves these participants.

Service Providers and the Ecosystem of Perpetual Futures Trading

On November 11, 2022, the cryptocurrency exchange FTX formally filed for bankruptcy protection, revealing a customer-funds shortfall of as much as $8.7 billion on its balance sheet [1]. John J. Ray III, who subsequently took over as chief executive officer and oversaw the bankruptcy proceedings, submitted a sworn declaration to the court stating that, in more than 40 years of legal and restructuring experience, he had never seen such a complete failure of corporate control or such a total absence of trustworthy financial information [2]. The public and the media have often reduced this episode to the personal fraud of the founder. Viewed through the lens of market microstructure and system architecture, however, the emergence of an $8.7 billion customer-funds shortfall is fundamentally an architectural problem rather than a purely moral one. FTX's collapse did not stem from a hack, a market crash, or sophisticated financial engineering. It stemmed from an institution that simultaneously played the roles of exchange, broker, clearinghouse, and custodian and that, absent effective checks and balances, systematically misappropriated customer funds. Under such a heavily function-bundled architecture, conflicts of interest shift from occasional misconduct to a structural norm, and any sufficiently large temptation can produce the same outcome.

This chapter takes neither the one-sided position that centralized exchanges (CEXs) are inherently inferior to decentralized exchanges (DEXs) nor the noncommittal stance that every architecture simply has its own merits and drawbacks. Instead, it uses a precise analytical framework to help readers understand how different service-provider architectures determine the types of risk that users face and how to choose rationally among those risks. To this end, the chapter develops five analytical tools. The risk substitution theorem formalizes the core insight that risk cannot be eliminated, only substituted. The trilemma characterizes the structural tension among performance, transparency, and decentralization. The bundling tax quantifies the hidden cost behind the efficiency advantage of centralized exchanges. The verifiability ladder establishes a five-level assessment standard running from trusting an institution to verifying code. And old problems in new forms reveals the isomorphic mapping between the new problems on-chain and the old problems of traditional finance.

Having established this framework, the chapter analyzes in turn the internal operat-

ing logic of three architectures—traditional financial derivatives markets, centralized cryptocurrency exchanges, and on-chain protocols—reveals the risk isomorphism that cuts across them, and examines the systematic effects of architectural evolution on four core dimensions of market microstructure. Chapter 4 analyzed who trades in perpetual futures markets; this chapter turns to who provides the infrastructure for that trading, and Chapter 6 will further examine how different architectures evolve dynamically through competition. After reading this chapter, readers should be able to use the risk substitution theorem and the trilemma to evaluate the architectural choices of any trading service provider, understand the technical criteria and applicable boundaries of each level of the verifiability ladder, and, when facing a concrete platform choice, make rational decisions grounded in architectural analysis rather than brand trust.

5.1 The risk substitution theorem and the service provider's trilemma

The architectural design of a crypto-asset trading platform does not take place in a vacuum; it seeks an optimum within a set of mutually constraining variables. Before analyzing specific service-provider models in depth, this section first establishes a unified set of analytical tools to serve as the coordinate system for the rest of the chapter. This section presents, in turn, the four functional dimensions, the risk substitution theorem, the service provider's trilemma, and the verifiability ladder—together forming a complete theoretical framework that runs from functional decomposition to risk assessment and from characterizing constraints to quantifying trust.

5.1.1 The functional dimensions of the trade lifecycle

Any perpetual futures service provider, whatever its technical form, must perform four core functions. Together these dimensions answer the fundamental question of how a trade moves safely from intent to finality, and their theoretical foundation traces back to Harris's classic treatment of the functions of market microstructure [3]. Harris decomposes trading services into core functions such as providing immediacy, managing counterparty risk, and facilitating price discovery, and he notes that trading venues also perform the economic functions of aggregating information and reducing search costs. The four-dimensional framework of this chapter is a concrete application of that idea to perpetual futures markets. The information-aggregation function in Harris's framework is folded mainly into the trade-execution dimension (price discovery realized through the matching engine), while the search-cost-reduction function is distributed across two dimensions: asset custody, which lowers trust costs, and risk management, which lowers the cost of risk assessment.

Asset custody answers the question of whether traders' funds are safe. It concerns how traders' assets are held and who controls them, and it directly determines the type and degree of counterparty risk. In traditional finance, asset custody is typically handled by heavily regulated custodian banks or central securities depositories, with a legal separation between client assets and the institution's own assets. In crypto markets, the mode of custody determines whether a trader retains control of the private keys.

Centralized exchanges use a pooled-custody model: traders deposit assets into wallets the platform controls, and the platform records user balances in an internal database. The risk this model exposed in the FTX episode is that, when the internal database can be altered by management, a user's *balance* may be nothing more than a number with no guarantee of solvency behind it. Decentralized protocols, by contrast, achieve non-custodial trading through smart contracts: the trader retains control of the assets throughout the trade, and funds move only under the strict conditions set by the smart contract.

Trade execution answers the question of whether an order is executed fairly. It covers the matching of buy and sell orders, price discovery, latency optimization, and execution fairness. The performance of the matching engine directly determines an exchange's throughput and the quality of market liquidity. Centralized exchanges achieve millisecond- or even microsecond-level matching through high-performance, custom in-memory matching engines. In 2024, the top 10 centralized exchanges recorded more than $58 trillion in total perpetual futures volume, with Binance's market share falling from about 43% at the start of the year to 34% by year-end [4]. Decentralized exchanges must instead contend with the latency of blockchain state updates, giving rise to automated market makers (AMMs), on-chain order books, and hybrid models that match off-chain and settle on-chain. Execution fairness is especially fraught on-chain, because the public transparency of a blockchain lets miners or validators observe and exploit a trader's unconfirmed orders, producing front-running and sandwich attacks. This is the technical re-emergence of an old problem: the long-running controversy in traditional finance over payment for order flow (PFOF) shares the same underlying structure: a broker sells client order flow to a market maker that uses its informational advantage to position itself ahead of execution. Maximal extractable value (MEV) is the on-chain, transparent-environment version of this old problem, made more systematic by the blockchain's openness.

Clearing and settlement answers the question of whether post-trade obligations are honored. For a highly leveraged derivative such as perpetual futures, clearing and settlement encompasses the real-time calculation of margin requirements, the mark-to-market processing of unrealized profit and loss (P&L), and the forced liquidation of positions once they become insolvent. In traditional derivatives markets, central counterparty (CCP) clearing absorbs default risk by building a default-waterfall structure that draws in sequence on the defaulter's margin, its default-fund contributions, the clearinghouse's own capital, and the default funds of non-defaulting members, thereby safeguarding the stability of the system [5]. In on-chain finance, smart contracts replace the traditional clearinghouse, executing real-time, deterministic clearing and settlement through preset code logic; this reconfigures the form of counterparty risk found in traditional clearing and eliminates settlement delay. On-chain clearing does not, however, fully eliminate counterparty risk; it transforms it into new forms. Shortfall losses are socialized to other users through the insurance fund or the auto-deleveraging (ADL) mechanism, the liquidator network may respond with delay under extreme conditions as gas fees spike, and the nondeterministic window of oracle price feeds introduces the risk of mark-price deviation.

Risk management answers the question of whether the system will collapse under ex-

treme conditions. It covers the continuous monitoring of margin, the triggering and execution of forced liquidation, the absorption of shortfall losses, and the defense against systemic risk. In a centralized exchange, the risk engine is usually tightly coupled with the matching engine, able to respond to market swings and trigger liquidations within milliseconds. In on-chain protocols, risk management relies on the timely response of the liquidator network and the accuracy of oracle price feeds; under extreme conditions, liquidation delays or improper liquidations caused by price manipulation can occur.

These four dimensions are not independent. The mode of custody directly affects the effectiveness of risk control: when assets are held by a smart contract, the risk engine can enforce margin requirements at the level of code, without relying on the self-restraint of the platform operator. Execution mode and settlement are likewise closely linked: the atomic-settlement capability of an on-chain order book lets a trade and its settlement complete simultaneously within a single blockchain transaction, eliminating the lag between execution and final settlement found in traditional markets. Understanding the interactions among the dimensions is the key to understanding the relative merits of different service-provider architectures. Traditional finance assigns the four functions to separate, independent institutions to achieve a separation of duties; centralized cryptocurrency exchanges concentrate them in a single entity to achieve functional bundling; and on-chain protocols reconfigure them with code and cryptography [6].

5.1.2 The risk substitution theorem

Observing how trading service providers evolved from traditional finance to centralized cryptocurrency exchanges and then to on-chain protocols, one general pattern gradually emerges. Each architectural transition successfully eliminated certain core risks of the preceding architecture, but each also inevitably introduced new types of risk. This pattern can be stated as the risk substitution theorem: for any transition of a service-provider architecture from A to B, the transition eliminates the risk set R_A specific to A while introducing the risk set R_B specific to B. The key proposition is that R_B is always nonempty—that is, no architecture drives all types of risk to zero simultaneously. Architecture choice is therefore not about eliminating risk but about choosing the type of risk. The rational criterion for the choice is whether, for a particular user, the risks in R_B are more identifiable, more quantifiable, and more manageable than those in R_A.

The risk substitution theorem describes a change in the type of risk, not a conservation of total risk. Risks under different architectures can differ by orders of magnitude in expected loss (probability $\times$ magnitude) and in tail characteristics. The operational risk of a centralized exchange, for instance, is relatively low in frequency, but once it materializes—as with FTX's \$8.7 billion shortfall—it can produce a loss of nearly 100% of principal; the loss from a single smart-contract exploit is usually smaller in scale but occurs more frequently. Tail-risk measures such as conditional value at risk (CVaR) can reveal that certain architectural transitions eliminate low-magnitude risks already effectively mitigated by regulation while introducing high-magnitude risks that lack external constraint. As a result, users with different risk preferences—tail-averse users versus mean-variance users—may reach entirely different optima from the same set of architectural choices.

Applying this theorem to the three architectural transformations of trading service providers reveals a clear symmetry, at each transition, between the risk set eliminated and the risk set introduced (Figure 5-1).

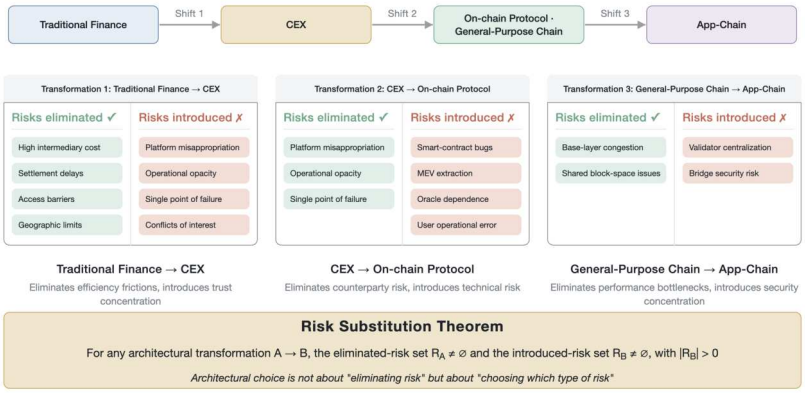

Figure 5-1. The risk substitution theorem — risk mapping across three architectural transitions (conceptual mapping, not empirical data; Data source: Dell'Erba [6], Yadav [7], Three Sigma [8])

Traditional financial markets, through the division of labor among multiple layers of intermediaries and a strict regulatory framework, effectively controlled the risks of fraud and misappropriation of funds. That architecture, however, introduced high intermediation costs, long settlement cycles (typically one to two business days), and significant barriers to access and geographic restrictions. The emergence of centralized cryptocurrency exchanges eliminated these efficiency frictions by adopting a vertically integrated architecture that concentrates all functions in a single entity, enabling around-the-clock global trading and instant transfers of funds. That transition, however, introduced serious risks of platform misappropriation, operational opacity, single points of failure, and conflicts of interest [6]. FTX's $8.7 billion customer-funds shortfall [1] and the Bybit hack of February 2025—in which a North Korean hacking group stole about $1.5 billion in Ethereum assets by manipulating the signing workflow of a multi-signature wallet [9]—are both extreme expressions of this centralization risk.

As markets evolved further toward on-chain protocols, smart contracts and blockchain consensus mechanisms replaced centralized servers. This architectural transition eliminated platform-misappropriation risk and operational opacity through cryptographic verification, achieving trustless trade execution and settlement. Risk did not disappear, however; it shifted to the technical layer. On-chain protocols introduced the risk of smart-contract vulnerabilities, the risk of exploitation through MEV (earlier also called miner extractable value), the risk of dependence on external oracle price feeds, and the risk of users irreversibly losing assets through operational mistakes. In 2024, smart-contract exploits in DeFi caused about $730 million in losses, down from $1.15 billion in 2023 but still a significant systemic threat [8]. Notably, this year-over-year decline may not reflect a simple improvement in security but rather the confluence of several factors: total value locked (TVL) on-chain fluctuated considerably over the same period, and the composition of attack vectors shifted from smart-contract logic

flaws to private-key theft and social engineering, the latter of which does not appear in contract-vulnerability statistics. According to a July 2025 report from the European Securities and Markets Authority (ESMA), cumulative MEV revenue on Ethereum since the Merge in September 2022 has amounted to roughly $1 billion to $1.3 billion, with arbitrage—rather than sandwich attacks—contributing the highest monthly revenue [10].

As DEXs on general-purpose public blockchains evolve further into purpose-built application-specific blockchains (app-chains), the logic of risk substitution appears once more. An app-chain, by building a specially optimized blockchain, eliminates the congestion of the underlying chain, competition over gas fees, and the MEV problems created by shared block space; at the same time, it introduces the risk of validator centralization, the security risk of cross-chain bridges, and the reflexivity problem of economic security. This reflexivity deserves particular attention: an app-chain's economic security is usually anchored to the market capitalization of its native token, and that market capitalization depends in turn on user adoption and confidence, forming a positive feedback loop of "token market cap → staking security → user confidence → adoption → token market cap." On the way up, this loop reinforces itself; on the way down, once it falls below some critical threshold, declining security triggers user flight, which depresses the token's market cap and further weakens security, forming a downward spiral that is hard to reverse (Section 5.4.3 analyzes this mechanism further). The security record of cross-chain bridges likewise warrants attention: as of 2025, cross-chain bridge attacks have caused cumulative losses of more than $2.5 billion, nearly 40% of all funds stolen across decentralized finance [11].

The practical import of the risk substitution theorem is this: when someone asserts that "decentralized exchanges are safer than centralized exchanges," the claim is incomplete. The full statement should be that decentralized exchanges eliminate the counterparty risk of centralized exchanges but introduce smart-contract risk and MEV risk; if a user is able to audit code and to use the appropriate protective tools, then a decentralized exchange may be "safer" for that user, and otherwise not necessarily so. The rational criterion for architecture choice is not the absolute quantity of risk but its identifiability, quantifiability, and manageability.

5.1.3 The service provider's trilemma

In the trade-offs of architectural design, a trading service provider faces a core structural dilemma: performance, transparency, and decentralization cannot all be optimized simultaneously under current underlying technical constraints, and a platform must make trade-offs among them. The root of this dilemma lies in the basic constraints of distributed systems: raising performance requires reducing the number of nodes participating in consensus and simplifying verification to lower communication overhead, whereas strengthening decentralization requires precisely the opposite—expanding the validator set and adding redundant verification. Achieving transparency, in turn, requires that all trade data be public to the entire network, which not only increases the verification burden but also exposes unconfirmed trade information to potential front-runners. The tension among the three is rooted in the inherent contradiction between

the cost of replicating information and the efficiency of reaching consensus: requiring more independent nodes to verify the same state necessarily consumes more time and bandwidth, while compressing the verification process necessarily reduces the number of independent verifiers or the completeness of verification.

The performance dimension covers trading latency, system throughput, and user interaction experience. For high-frequency traders and market makers, a difference of milliseconds in latency can determine the success or failure of a trading strategy. The transparency dimension requires that the entire trade lifecycle, the platform's asset reserves, and the operating logic of the risk engine be fully visible and independently verifiable to all market participants. The decentralization dimension measures the degree to which the system does not depend on a single entity or a small group of controllers, including the distribution of network nodes, the location of governance rights, and censorship resistance.

Different types of service provider occupy markedly different positions within this triangle (Figure 5-2), as analyzed below.

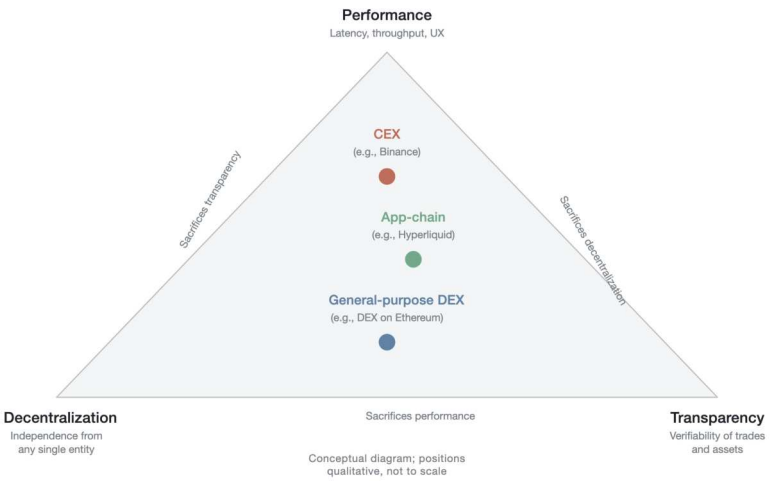

Figure 5-2. The service provider's trilemma — positioning of three paradigms (conceptual triangle; qualitative positions, not measured coordinates; placements reflect the author's qualitative judgment, not empirical data; Data source: CoinGecko [4], The Block [12])

Centralized exchanges prioritize performance and make concessions on transparency and decentralization. Binance handled the largest share of perpetual futures volume in the 2024 market, offering microsecond-level matching latency and deep liquidity, but the internal workings of its matching engine, risk-control logic, and asset management are entirely opaque, and users cannot independently verify whether the platform faithfully executes the rules it claims to follow [4]. Decentralized exchanges deployed on general-purpose public blockchains, by contrast, maximize transparency and decentralization: all trading logic runs openly on-chain, anyone can audit the smart-contract code and verify the execution of every trade, but they are constrained by the block time and computational capacity of the underlying blockchain, so their performance lags far

behind their centralized competitors. Ethereum mainnet's block time of roughly 12 seconds means that a perpetual futures exchange built on that chain cannot support complex trading strategies requiring high-frequency order-book updates.

A new generation of derivatives app-chains seeks a better balance between performance and transparency, but usually at some cost to decentralization. By building a sovereign blockchain optimized specifically for order-book trading, Hyperliquid adopts an on-chain state-machine matching model executed by a validator network, achieving sub-second latency while preserving on-chain settlement transparency. In its HyperBFT consensus mechanism, the leader node drives the execution of matching computation while other validators verify the state-transition result, rather than every node independently executing the full matching process. As of early 2025, however, the network was maintained by only about 16 validator nodes (later gradually expanded to about 24) [12]; compared with Ethereum's more than one million validators, its degree of decentralization remains limited. Ethereum's "one million validators," however, refers to the number of 32-ETH staking units, not the number of independent node operators; a large share of validators is concentrated under liquid staking protocols such as Lido, so the actual number of independent operators is far below that figure. The fourth version of dYdX (v4) likewise adopts a sovereign, Cosmos-based blockchain architecture, but its order book uses a design different from Hyperliquid's: the order book is maintained in validator memory (an off-chain order book), and only fill results pass through consensus onto the chain, while order submission and cancellation do not go through blockchain consensus. This design brings dYdX v4's performance close to that of a centralized exchange, but the size and diversity of its validator set face similar constraints.

The analytical value of the trilemma lies in its explanation of why no perfect service provider exists. Every design is a chosen point within the triangle, and the location of that point is determined by the priorities of its target users. The triangle also predicts the direction of future technical progress: zero-knowledge proofs, modular blockchains, and data-availability layers are all, in essence, ways to expand the feasible area of the triangle so that the three goals can be achieved simultaneously at a higher level—yet the triangle itself, as a structural constraint, will not disappear. This trilemma is related to, but distinct from, the classic blockchain trilemma of security, decentralization, and scalability [13]: the latter describes the constraints of the underlying consensus protocol, whereas this chapter's triangle describes constraints at the level of the trading service provider. The constraints of the underlying triangle propagate upward, shaping the boundary of the feasible region for the service-provider triangle.

5.1.4 The verifiability ladder

To assess more precisely how different trading service providers differ in their trust assumptions, it is useful to build a verifiability-ladder model. The model classifies a trading platform's architecture, according to the degree to which its functions are publicly verifiable on-chain, into five progressive levels from L0 to L4. An increase in verifiability is not a binary switch but a graduated continuum. Each step upward means that the user's trust cost falls by one notch but is replaced by a greater cost of

technical understanding.

The five levels of the ladder run progressively from the fully unverifiable L0 (such as FTX before its collapse) to the fully verifiable L4 (which no platform has yet reached), and the technical criteria at each level span the mode of asset custody, the degree of disclosure of matching logic, the auditability of risk-control parameters, and the level of decentralization of the governance mechanism (Figure 5-3).

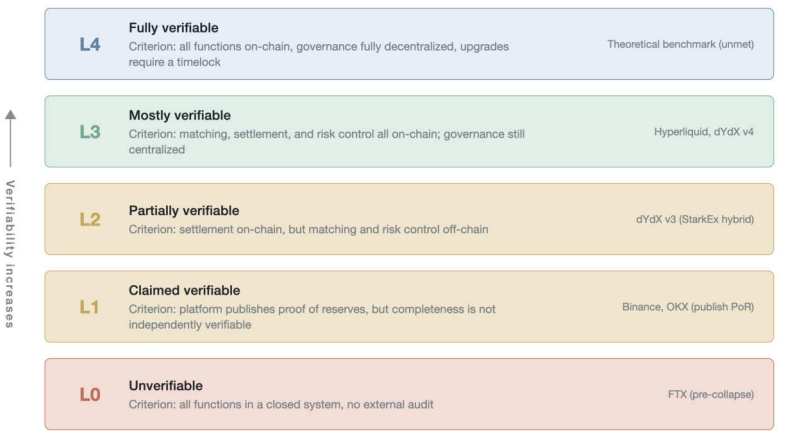

Figure 5-3. The verifiability ladder — the five-level standard from L0 to L4 (conceptual grading framework; the author classifies platforms by technical criteria, not empirical data; platform examples as of 2025, including the proof of reserves (PoR) published by Binance and OKX; Data source: Ray [2], Vidal-Tomás [14], The Block [12])

L0 denotes the unverifiable architecture. At this level, all of the platform's functions run inside a closed, centralized system, and no substantive external audit or verification is possible. FTX before its collapse was a typical L0 platform. In his sworn declaration, John J. Ray III disclosed that FTX did not even maintain a complete balance sheet and used instant-messaging software rather than a formal accounting system to handle financial records [2]. Under an L0 architecture, the user's only option is to trust, and that trust lacks any verifiable basis.

L1 denotes the attestation-based architecture. After FTX's collapse, many centralized exchanges began publishing proof of reserves (PoR) at regular intervals, using Merkle-tree technology to prove their asset positions to users [14]. This form of verification, however, has inherent limitations: proof of reserves is essentially a static point-in-time snapshot, and it often covers only the asset side while being unable to fully verify the liability side (its snapshot nature and liability-side limitations are detailed in Section 5.3.5). Although transparency improves over L0, the system's core operations still depend on the commitments and self-restraint of a centralized entity.

L2 denotes the partially verifiable architecture. At this level, the platform begins to split the key stages of the trade lifecycle, entrusting fund custody and final settlement to on-chain smart contracts while order routing and matching are still handled by high-performance centralized servers. The third version of dYdX (v3) is the archetype of this

architecture; it uses StarkEx validity-proof technology to achieve on-chain settlement on Ethereum while running a high-performance matching engine off-chain. Validity proofs provide a mathematical guarantee of certainty: the operator cannot submit an incorrect state transition to Ethereum mainnet, because any settlement that does not conform to the proof rules is rejected by the mainnet contract. This brings the L2 architecture close to L3's level of protection on the dimension of fund safety. The disadvantage of this hybrid architecture, however, is that the matching process itself is not verifiable and carries censorship risk, so traders must still trust the fairness and censorship resistance of the centralized matching engine. Users can audit the code of the on-chain settlement contract but cannot verify whether order priority is manipulated during off-chain matching.

L3 denotes the largely verifiable architecture. The platform migrates matching, settlement, and the risk engine entirely on-chain, achieving public verifiability across the whole trade process. Both Hyperliquid and dYdX v4 adopt this architecture based on a sovereign app-chain [12]. dYdX v4's off-chain order-book design (see Section 5.1.3) means that order submission, cancellation, and matching themselves do not pass through blockchain consensus, but every fill result can be traced and verified through the blockchain's public record; within L3, it therefore makes a greater concession on matching transparency—relative to Hyperliquid's full-state consensus model—in exchange for performance. Although the core trading logic is already fully transparent, the core development team may still retain some degree of centralized control over node-admission mechanisms, emergency upgrade authority, and the adjustment of governance parameters. Such control has real security value in a protocol's early stages, because when a serious vulnerability is discovered, a rapid emergency response may protect user assets better than a fully decentralized governance process; at the same time, it constitutes a trust assumption that must be explicitly flagged.

L4 denotes the fully verifiable architecture. This is currently the highest standard in theory: it requires the platform not only to run entirely on-chain at the trading and settlement layers, but also to make its governance mechanism and protocol upgrades fully decentralized and subject to strict time locks and community consensus. At this level, any modification of a protocol parameter requires an on-chain vote, and the outcome must pass through a public waiting period before execution, giving all stakeholders ample time to review the change and, if necessary, exit the system. At present, no platform in perpetual futures trading fully meets this standard; it represents the direction of the industry's evolution rather than a current reality.

The core insight of the verifiability ladder is this: for ordinary users who lack the technical ability to audit code, the advantage of "verifying code" over "trusting an institution" may be difficult to realize in practice; but for institutional investors with the requisite ability, verifiability offers a depth of due diligence that is impossible under the centralized-exchange model. Yet verifiability is a necessary but not sufficient condition for trust substitution: even if a system provides complete verification capability, information overload and interface complexity may leave most users with no willingness to verify, and the label "code audited" may instead create a false sense of security, so that "willingness to verify" systematically lags "ability to verify." As cryptographic technology and blockchain performance continue to improve, trading service providers

keep climbing this ladder toward higher levels, converting ever more trust assumptions into deterministic logic provable by mathematics. This trend not only reshapes the competitive landscape of trading service providers but also fundamentally changes how trust is produced in financial infrastructure.

5.2 The functional-separation architecture of traditional finance

The architecture of traditional financial derivatives markets rests on an institutional foundation of functional separation. Brokers, exchanges, clearinghouses, and custodian banks each perform their own role, achieving risk isolation through physical and legal boundaries. This multi-layered intermediary architecture did not form overnight; it is the institutional accumulation of the lessons of two centuries of financial crises. Starting from the complete flow of a single futures trade, this section analyzes the institutional rationale and the efficiency cost of functional separation, together with the central counterparty's core role in managing systemic risk.

5.2.1 The multi-intermediary flow of a futures trade

The flow of a standardized futures trade through the traditional financial system is not completed within a single institution as a closed loop; it relies on a service network made up of several independent entities. Consider the example of a buy order in S&P 500 futures. The investor places a buy instruction with the futures commission merchant (FCM) that holds the account; after verifying that the client's margin is sufficient, the FCM routes the order to the electronic matching engine of the Chicago Mercantile Exchange (CME). The CME recorded an average daily volume of about 26.5 million contracts in 2024 [15], and its matching engine completes price-time-priority order pairing at the microsecond level. The instant the trade is struck, the CME's clearing division steps in as central counterparty, using novation to split the original buy-sell contract into two independent contracts: one between the buyer and the central counterparty, and one between the central counterparty and the seller. Thereafter the central counterparty computes daily profit and loss and collects margin, while the final transfer of funds is executed by an independent settlement bank, ensuring that client assets and the trading institution's own assets are strictly separated at the legal and physical levels.

Within this flow, each participating institution performs a distinct trust function. The FCM, acting as an agent, owes a fiduciary duty to the client and must place the client's interests above its own; this includes the duty of best execution—routing orders to the venue offering the best execution—and the risk-management responsibility of managing the client's margin account and issuing margin calls when necessary [3]. The FCM also performs a credit-intermediation function, extending leverage to clients and continuously assessing credit risk; when a client defaults, the loss is absorbed by the FCM rather than by the market as a whole, and this buffer prevents an individual default from transmitting directly to the systemic level. The exchange's core value lies in its neutrality: it does not trade, holds no positions, and merely provides a fair

and transparent price-discovery venue; its revenue comes from fees rather than trading profits, and its rules and matching algorithms are publicly subject to regulatory review [3]. The central counterparty focuses on risk management, reducing total systemic exposure through multilateral netting and absorbing the default losses of individual members through the default-waterfall mechanism. The custodian bank stands apart from all trading activity; its sole responsibility is to safeguard client assets and to execute transfers of funds and securities on clearing instructions.

In this architecture, the broker sits at the client-interface layer, bearing fiduciary duty and performing credit intermediation; the exchange provides a neutral price-discovery venue at the matching layer; the central counterparty manages systemic default risk at the clearing layer; and the custodian bank ensures the legal segregation of client assets at the asset-safekeeping layer. Clear functional boundaries exist among the four layers, and the institutional barriers of functional separation among layers ensure that the failure of any single layer does not run straight through to the others (Figure 5-4).

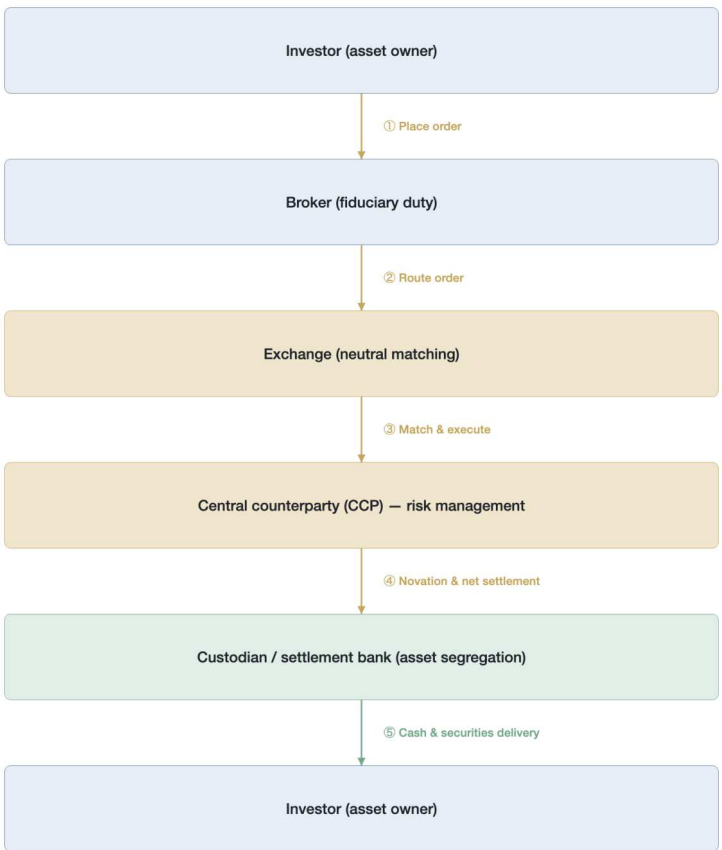

Figure 5-4. The functional-separation architecture of traditional financial service providers, by layer (conceptual architecture based on Harris's 2003 functional-separation framework, not empirical data; Data source: Harris's market microstructure framework [3])

This flow of business through at least four independent institutions in sequence generates time delays and friction costs at every handoff. The FCM collects a commission, the exchange collects a matching fee, the central counterparty collects a clearing fee, and the custodian bank collects a custody fee. On the surface, each layer of friction lowers the efficiency of capital turnover; at a deeper level, however, these are the costs necessarily paid to achieve risk isolation. The core purpose of this architecture is not to pursue the highest trading speed but to prevent the failure of a single node from triggering a global systemic collapse, through physical and legal boundaries. When an exchange converts from a membership-based mutual to a listed company, the tension between commercial interest and market-oversight duty grows increasingly acute; but the institutional framework of functional separation keeps that tension within a controllable range, rather than concentrating every role in one entity and turning conflicts of interest into a structural norm, as with the centralized cryptocurrency exchanges analyzed later.

5.2.2 The institutional rationale for functional separation

The current functional-separation architecture of traditional financial markets is the institutional accumulation of the lessons of two centuries of financial crises. In the early, unregulated markets, institutions that combined client custody, proprietary trading, and brokerage under one roof were common, but this model was repeatedly shown to be prone, under extreme market conditions, to the misappropriation of client assets or to an institution's own speculative losses spilling over onto innocent clients. The Glass-Steagall Act, passed in the United States in 1933, was precisely the legislative response to the systemic risk of the 1929 Great Depression, in which commercial banks used client deposits for speculative trading; the act legally mandated the separation of commercial banking from investment banking [16]. Notably, the Gramm-Leach-Bliley Act of 1999 partially repealed Glass-Steagall's separation requirement, allowing commercial and investment banking to reintegrate. This loosening is widely regarded as one of the institutional triggers of the 2008 global financial crisis, and after the crisis, calls to restore functional separation rose again. This repeated history confirms a core proposition: once the institutional barrier of functional separation is removed, systemic risk reaccumulates along the paths of conflict of interest. The legislative principle of Glass-Steagall was continually extended over the following decades to every part of the securities and derivatives markets, ultimately producing the current institutional configuration in which brokers, exchanges, clearinghouses, and custodian banks each perform their own role.

The institutional rationale for functional separation is expressed mainly along three mutually reinforcing dimensions: risk isolation, checks and balances, and auditability. Risk isolation ensures that the failure of a single institution does not directly destroy the whole system, with losses confined within that institution's functional boundary. The 1995 collapse of Barings Bank offers a classic case: the bank's head of derivatives trading and settlement in Singapore controlled both front-office trading and back-office settlement—two functions that should have been separated—and, absent independent oversight, accumulated hidden losses of up to £827 million, ultimately bankrupting a bank with 233 years of history [17]. The fundamental lesson of Barings is not the

moral failing of a single trader but that the combination of functions eliminated internal checks and balances, allowing risk to swell to an irrecoverable scale before it was discovered. Checks and balances are achieved through mutual monitoring among different institutions: the FCM monitors the exchange's execution quality, the exchange is subject to review by regulators, and the central counterparty stands apart from commercial interests and focuses on risk management. As for auditability, each independently operating institution constitutes a clear audit node, and regulators can separately examine the custodian bank's asset reports and the central counterparty's risk models without confronting a single, highly complex, internally interconnected black box.

Fiduciary duty is the central legal cornerstone of the functional-separation architecture. In his classic market microstructure theory, Harris (2003) notes that brokers owe clients a strict fiduciary duty and must place the client's interests above their own [3]. This legal constraint requires the broker, as an independent credit intermediary, not to bet against its clients, thereby suppressing conflicts of interest at the root. The irreplaceability of fiduciary duty lies in the legal protection it provides to the weaker party in an agency relationship: when a broker breaches its fiduciary duty, the client can obtain redress through the courts. This legal constraint disappears entirely in the centralized-cryptocurrency-exchange model, because the exchange simultaneously plays the dual role of agent and trading counterparty, so that conflicts of interest are no longer occasional misconduct but a structural feature embedded in the business model.

Robustness rests on the premise that each participating institution operates independently within its functional boundary, with no cross-boundary interest linkages. The 2011 bankruptcy of MF Global offers a classic cautionary case: facing a liquidity crisis, this FCM improperly misappropriated nearly $1 billion in segregated customer funds to cover its own trading losses on European sovereign bonds [18]. An investigation by the U.S. Commodity Futures Trading Commission (CFTC) found that MF Global had systematically violated customer-fund segregation rules in the final week before its bankruptcy. This episode not only prompted regulators to comprehensively strengthen the customer-fund segregation regime for FCMs but also demonstrated that even within a functional-separation framework, once the bottom line of physical segregation is breached, systemic risk spreads quickly. Yet the MF Global episode also validated the resilience of the functional-separation architecture: because customer funds enjoy priority in bankruptcy under the law, the vast majority of customers ultimately recovered all their funds through the bankruptcy proceedings [18]—a marked contrast to the near-total inability to recover client assets in the centralized-cryptocurrency-exchange bankruptcies discussed later.

5.2.3 The CCP default waterfall mechanism

The central counterparty is the core hub for managing counterparty credit risk in traditional financial markets, and its operation rests on novation (see Chapter 1 for the discussion of the central counterparty and the default waterfall): once a trade is matched, the central counterparty steps in immediately and replaces the original buy-sell contract with two independent contracts to which it is the counterparty, so that the two sides need not assess each other's credit and need only trust the central counterparty's

solvency. After the 2008 global financial crisis, the G20 leaders reached a consensus in 2009 requiring all standardized over-the-counter (OTC) derivatives to enter central clearing, establishing the central counterparty's systemically important status in the modern financial system [19]. In 2012, the Committee on Payment and Settlement Systems (CPSS) of the Bank for International Settlements (renamed the Committee on Payments and Market Infrastructures, or CPMI, in 2014) and the International Organization of Securities Commissions (IOSCO) jointly issued the Principles for Financial Market Infrastructures (PFMI), setting 24 international standards for the governance, risk management, and financial resilience of central counterparties worldwide [20].

The central counterparty sharply reduces total exposure within the system through multilateral netting, but it also concentrates counterparty credit risk on itself. To manage this highly concentrated risk, the central counterparty builds a multi-layered loss-absorption mechanism that follows the primary *defaulter-pays* principle and introduces mutual support only in extreme cases—the default waterfall. This is a five-layer structure that begins with the defaulting member's initial margin and proceeds layer by layer through default-fund contributions and the central counterparty's own capital up to recovery and resolution measures; see Chapter 1 for the discussion of the central counterparty and the default waterfall [21]. The third layer, the contribution of the central counterparty's own capital, is commonly referred to as *skin in the game*; it is intended to guard against the central counterparty's moral hazard and to ensure that it has sufficient incentive to maintain strict margin standards and prudent risk models. Every layer of the default waterfall is backed by explicit legal force and regulatory review; its parameters are public and transparent, adjustments require formal procedures, and users' rights enjoy legal protection.

The interplay of novation and the default waterfall constitutes the core process of central counterparty risk management: after a trade is matched on the exchange, the central counterparty steps in through novation to replace the original bilateral contract with two independent contracts to which it is the counterparty; thereafter, if one side defaults, the five layers of the waterfall are triggered in the predefined sequence until the loss is fully absorbed or a recovery mechanism is invoked (Figure 5-5).

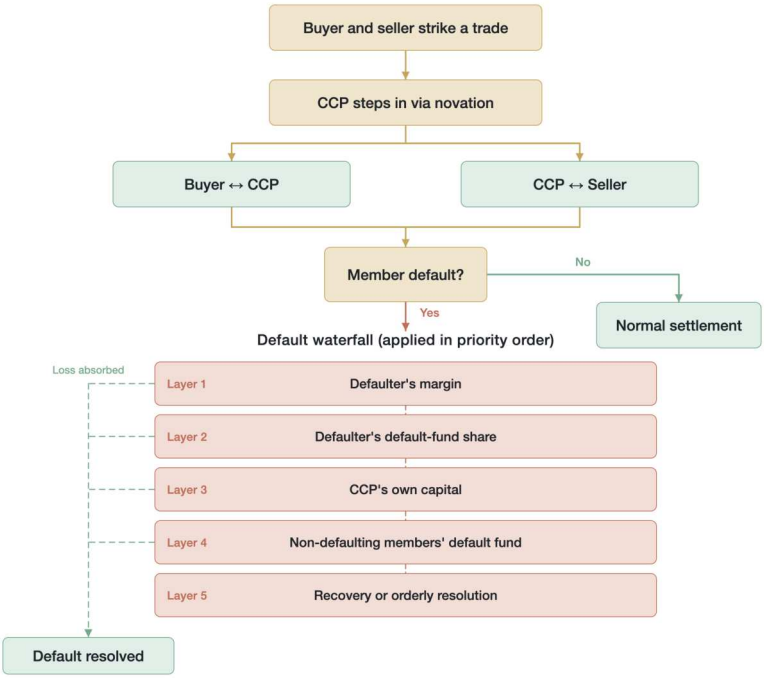

Figure 5-5. CCP novation and the default waterfall (mechanism flow based on the CPMI-IOSCO PFMI [20], not empirical data; Data source: CPMI-IOSCO Principles for Financial Market Infrastructures [20])

The effectiveness of the default waterfall depends heavily on the characteristics of the portfolio and on market-liquidity conditions. When Lehman Brothers failed in 2008, its interest rate swap portfolio cleared in London comprised 66,390 trades with a notional principal of as much as $9 trillion; but because the portfolio was relatively balanced and the interest rate swap market was highly liquid, the central counterparty consumed only about one-third of the margin and, within a few weeks, completed the hedging, auction, and transfer of the positions without inflicting any loss on other clearing members [21]. That success, however, depended on a special set of conditions: the interest rate swap market itself had ample liquidity; Lehman's portfolio was relatively balanced, which lowered the difficulty of hedging the net exposure; and the world's central banks injected large-scale liquidity into the market synchronously during the same period. These conditions do not hold in crypto perpetual futures markets: on-chain insurance funds are limited in size, liquidity can evaporate in an instant under extreme conditions, and no lender-of-last-resort role exists. The central counterparty's performance in the Lehman default was called an "unlikely hero" by Bell and Holden (2018) [21], because even under the extreme condition of a near-total freeze in bilateral markets, central clearing kept functioning normally.

The default at Nasdaq Clearing in Sweden in 2018, however, produced an entirely different outcome. On September 10, 2018, the Norwegian trader Einar Aas failed to meet a margin call from the commodities clearing division of Nasdaq Clearing and was

promptly declared in default. Aas had bet that Nordic and German power prices would converge and held large power-futures positions on Nasdaq Oslo. Changes in weather forecasts and adjustments to German carbon-emissions policy drove the two regions' power prices sharply apart, causing the value of his positions to shrink dramatically. In the subsequent auction of the positions, the clearinghouse suffered losses exceeding the value of Aas's posted collateral by €114 million. Nasdaq Clearing's default waterfall was triggered in sequence: it exhausted all of Aas's margin, then drew on €7 million of the clearinghouse's own capital, and ultimately consumed most of the non-defaulting members' €166 million default fund [21]. Post-event analysis revealed that Nasdaq Clearing had granted Aas a correlation offset of up to 50% in its margin calculation and had not charged a concentration add-on margin on his oversized positions in the Nordic power market, even though that market's trading volume had shrunk substantially over the preceding decade [21]. The core lesson of the Aas episode is not simply that "the offset ratio was too high" but that concentration risk was not adequately priced and that correlation assumptions are fragile in tail events. This forms a direct analogy to the concentration risk of whale accounts in a single trading pair in crypto perpetual futures markets and to the fragility of cross-asset correlation assumptions under a unified-margin model.

These two default events, a decade apart, reveal the inherent tension of the central counterparty model: it can effectively manage dispersed, routine defaults, but when confronted with a highly concentrated, illiquid, and highly correlated portfolio, the very feature of risk concentration can turn it into a transmission node for systemic risk rather than a risk-isolation mechanism. The central counterparty has been given a larger systemic role in the post-crisis era, but this also means that its own failure would produce more severe systemic consequences—a paradox that remains one of the core issues in global financial regulation to this day.

5.2.4 The efficiency cost of functional separation

While the functional-separation architecture provides institutional safety, it inevitably sacrifices the efficiency of capital turnover. Because trade execution, clearing, and custody are handled by different institutions, synchronizing the system's state takes time, which manifests directly as the existence of a settlement cycle. The longer the settlement cycle, the larger the time window during which the two sides are exposed to counterparty-default risk and market-price risk before delivery is complete, and the greater the systemic margin required.

The evolution of the settlement cycle in U.S. securities markets reflects traditional finance's continual search for a new balance between safety and efficiency. Before 1995, the standard settlement cycle for U.S. securities was T+5—delivery completed on the fifth business day after the trade date. In 1995, the U.S. Securities and Exchange Commission (SEC) shortened the cycle to T+3 through Rule 15c6-1. In 2017, the rule was amended again, compressing the cycle to T+2. On May 28, 2024, the U.S. market formally transitioned to a T+1 settlement cycle [22]. Each compression of the cycle was accompanied by large-scale infrastructure upgrades and industry coordination—from the digitization of paper certificates to the automation of trade-confirmation processes

to the standardization of cross-time-zone settlement instructions.

An after-action report jointly issued by the Investment Company Institute, the Securities Industry and Financial Markets Association, and the Depository Trust & Clearing Corporation shows that after T+1 took effect, the National Securities Clearing Corporation's clearing fund fell from an average of $12.8 billion under T+2 to $9.8 billion, a reduction of 23%, meaning that about $3 billion of capital was released from margin [22]. On settlement quality, the continuous net settlement (CNS) fail rate on the first day of T+1 was 1.90%, below the 2.01% average for May under the earlier T+2 regime; by July 2024, the average fail rate had stabilized at 2.12%, essentially unchanged from the T+2 period [22]. Trade-confirmation efficiency also improved markedly: nearly 95% of trades were confirmed before 9 p.m. on trade date, up from just 73% in January 2024 [22]. These data indicate that, under a multi-layered intermediary architecture, further compressing the time window did not significantly degrade settlement quality—but the scale of margin released also reveals just how large the loss of capital efficiency had been from funds previously locked up by settlement delay.

Although the T+1 reform achieved initial success, the advance of traditional financial infrastructure toward T+0 faces significant technical and institutional obstacles. The inherent contradiction of a multi-layered architecture is that each additional layer of independent intermediary, while enhancing risk isolation, multiplies the coordination complexity of information reconciliation and fund transfer. Under T+0, trade and settlement must occur almost simultaneously, which requires instantaneous data consistency and fund availability among brokers, exchanges, clearinghouses, and custodian banks. Industry reports make clear that pushing T+0 directly within the existing functional-separation framework is not a simple next step but requires a comprehensive, independent assessment of the entire market structure, because the disappearance of the time buffer could trigger large-scale liquidity shortfalls and settlement failures [22]. Traditional financial-infrastructure institutions have begun actively exploring blockchain technology for a breakthrough: the Depository Trust & Clearing Corporation's Project Ion completed a proof of concept in 2021 for T+0 settlement supported by distributed ledger technology (DLT) [23] and has since continued to advance pilots for the tokenization of digital assets, seeking to use atomic settlement to eliminate the risk created by the settlement cycle itself while preserving the advantages of functional separation.

Every increment of safety comes at the cost of some sacrifice in efficiency. When the institutional barrier of functional separation is viewed as a structural constraint impeding gains in capital efficiency, concentrating all authority in a single entity to achieve instantaneous settlement on an internal ledger becomes a commercially attractive alternative. This pursuit of efficiency is the core logic behind the rise of centralized cryptocurrency exchanges, and the structural consequences they bring form the starting point for the next section's analysis.

5.3 The functional bundling of centralized exchanges

The business model of centralized exchanges is rooted in bundling within a single entity the functions that traditional finance keeps separate. Section 5.2 analyzed how tradi-

tional finance manages conflicts of interest and systemic risk through functional separation; centralized exchanges represent the diametrically opposite architectural choice. This bundling brings substantial efficiency gains that have made centralized exchanges overwhelmingly dominant in the crypto-derivatives market, but it also creates an ineliminable hidden cost—the concept of the "bundling tax" introduced in this chapter. The bundling tax is the service-provider-level mirror of the "trust tax" from Chapter 1 (elaborated in Section 5.3.2) and is likewise the key to evaluating the relative merits of different service-provider architectures.

5.3.1 The CEX's bundling of five roles

The architecture of traditional financial markets rests on a strict separation of functions. As Section 5.2 described, the broker handles the client interface and owes the client a statutory fiduciary duty, the exchange provides a neutral matching venue and does not participate in trading, the market maker independently supplies liquidity and bears inventory risk, the clearinghouse manages systemic default risk as central counterparty, and the custodian stands apart from trading activity to ensure the safe segregation of client assets [3]. The separation of these five roles is not a waste of efficiency but the institutional accumulation of two centuries of financial-crisis lessons, and its core design principle is to disperse power so that the failure of any single institution is confined to a limited scope.

Centralized exchanges fundamentally alter this architecture by integrating the above five roles into a single, highly integrated technical and commercial entity. Under this model, a centralized exchange not only provides the trading interface and the matching engine but also directly controls the custody of client assets, performs clearing and settlement internally, and, in many cases, acts as the largest market maker on its own platform through a proprietary trading desk or affiliated parties. Dell'Erba (2024) [6] defines this architecture as a "full-service business model" and argues that it creates "unprecedented conflicts of interest." Such a high concentration of functions means that effective information barriers are difficult to establish in practice. An exchange operator can, in theory and in practice, exploit its advantage of seeing client order flow first to front-run, lend client funds from custody wallets to its proprietary market-making desk, adjust liquidation parameters to protect affiliated parties' positions, or handle liquidation orders in ways unfavorable to clients during market swings. These are not purely theoretical conjectures but facts repeatedly demonstrated in crypto markets.

The scope of this bundling can be grasped by comparing it, role by role, with the five independent roles of traditional finance. The broker's fiduciary duty is compressed into a user agreement for the account system; the exchange's neutral matching is folded into an engine the platform itself controls; the market maker's independence gives way to a proprietary trading desk; the clearinghouse's independent risk control becomes an internal module; and the custodian's asset segregation becomes internal bookkeeping within the platform's wallet system. Table 5-1 lays out these five pairings and the original institutional intent behind each.

Independent role in traditional finance	Counterpart in the CEX	Original intent of functional separation
Broker	Account system and user interface	Bears a fiduciary duty and acts in the client's interest
Exchange	Internal matching engine	Remains neutral and does not participate in trading
Market maker	Proprietary market making or affiliated parties	Independent of the exchange, preventing information abuse
Clearinghouse	Internal clearing and risk engine	Maintains independent risk management, free from commercial interests
Custodian	Hot/cold wallet system controlled by the exchange	Independent of trading activity, ensuring the safe segregation of assets

Table 5-1. Mapping between traditional finance's functional separation and the centralized exchange's role bundling (Data source: theoretical frameworks based on Harris 2003 and Dell'Erba 2024 [3][6])

This mixing of roles is not an accidental technical lapse but a structural choice through which centralized exchanges gain competitive advantage. Binance, for example, in September 2022 automatically converted competing stablecoins held by customers—USDC, USDP, and TUSD—into its own stablecoin, BUSD, a move that pushed BUSD's market capitalization to $20.5 billion [6]. This case clearly shows how a platform can use its dual identity as both custodian and exchange to reinforce its own commercial interests—behavior that would be impossible under traditional finance's functional-separation architecture. An industry that flies the banner of "decentralization" has in fact produced intermediaries more centralized than those of traditional finance, forming what Yadav (2023) [7] describes as the "centralization paradox." As of 2023, the vast majority of cryptocurrency users—an estimated 90%—chose custodial platforms over self-custody solutions [7]. This figure should not be read simply as users' rational preference for efficiency. A behavioral-finance perspective reveals more complex drivers: status quo bias inclines users who registered early on centralized platforms to stay put, complexity aversion leads nontechnical users to instinctively avoid the cognitive burden of private-key management and smart-contract interaction, and the brand marketing of leading exchanges manufactures a "sense of safety" that may lack substantive basis. Distinguishing a "rational preference for efficiency" from "path dependence driven by cognitive bias" is essential for assessing the true market potential of on-chain alternatives.

When five roles are combined in one entity, conflicts of interest are no longer occasional; they become an intrinsic property of the architecture. Between the custody function and proprietary trading lies a structural incentive to misappropriate funds; between the matching engine and the market-making desk lies a channel for abusing the informational advantage of order flow; and between the clearing function and affiliated parties lies the possibility of parameter manipulation. Multiple conflict paths criss-cross one another, forming a self-reinforcing network of bundled interests—precisely the core mechanism by which functional bundling turns occasional risk into structural risk (Figure 5-6).

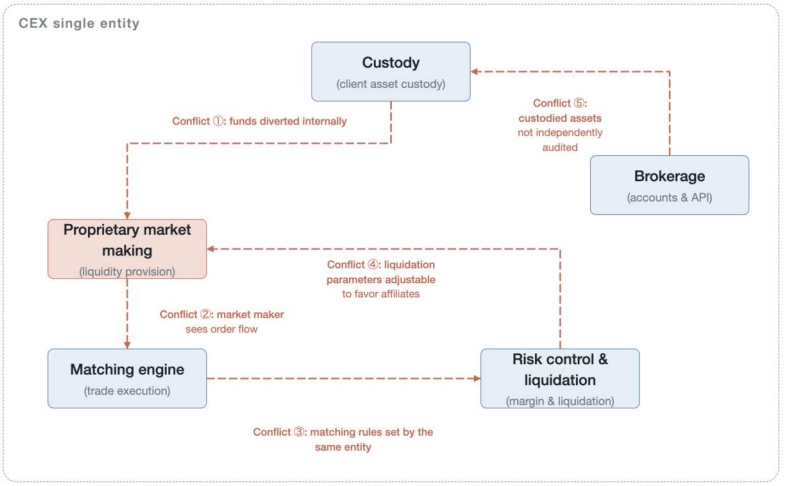

Figure 5-6. Internal functional bundling and conflict-of-interest mapping within a centralized exchange (conceptual conflict-of-interest diagram; edges denote mechanistic relationships, not measured magnitudes; not empirical data; Data source: based on Dell'Erba's 2024 conflict-of-interest analysis [6])

5.3.2 The definition and composition of the bundling tax

A direct consequence of the function-bundling architecture is a systematic hidden cost. Centralized exchanges achieve extremely high trading efficiency by eliminating the friction of cross-institutional coordination, but this efficiency is not without cost. Traders in fact pay a structural risk premium for this convenience, which this chapter defines as the "bundling tax."

The bundling tax is the structural risk cost that users pay for the efficiency and convenience of centralized exchanges, and it consists of three inseparable parts. The opacity cost is the first component; it arises because users cannot independently verify the true safety of their assets, the fairness of order execution, or the effectiveness of the risk-control mechanism. In a centralized exchange's closed system, users can only rely on trust in the exchange operator and cannot verify key parameters for themselves as they could when auditing on-chain smart contracts. FTX before its collapse was the extreme embodiment of this opacity, as revealed by the bankruptcy trustee's statement cited at the opening of this chapter—the complete failure of control and the absence of trustworthy information [2]. The conflict-of-interest cost is the second component; it arises because a single entity simultaneously controls custody, execution, and clearing—three core functions that should check one another. When the exchange is at once the rule-maker and the rule-enforcer, at once the custodian of client assets and the largest participant in the market, both the motive and the ability to favor itself are present. Traditional finance suppresses such conflicts of interest through statutory fiduciary duty and independent regulatory review [3], but in the bundled architecture of a centralized exchange these checks are structurally absent. The single-point-of-failure cost is the third component, and the most easily overlooked. When all core functions are concentrated in one entity, a technical fault, management error, or external attack at

any single link immediately spreads to and paralyzes the entire system. In traditional finance, even if one broker fails, client assets remain safely held at an independent custodian and the operation of the exchange and clearinghouse is unaffected. In a centralized exchange, this risk isolation is entirely absent.

Conceptually, the bundling tax can be expressed as a function of three components: $\mathrm{BT} = f\big(C_{\mathrm{opacity}}, C_{\mathrm{conflict}}, C_{\mathrm{spof}}\big)$, where C_{opacity}, C_{conflict}, and C_{spof} denote the opacity cost, the conflict-of-interest cost, and the single-point-of-failure cost, respectively. Each component can be approximated through proxy variables: proxies for C_{opacity} include the frequency with which proof of reserves is published and the share of on-chain-verifiable assets; proxies for C_{conflict} include the degree of disclosure of related-party transactions and the presence or absence of liquidation-exemption clauses; and proxies for C_{spof} include the scale of historical security incidents and the concentration of assets under custody. Notably, the relationship among these three cost components is not simply additive but multiplicatively interactive. C_{opacity} (opacity) is the enabling condition for C_{conflict} (conflict of interest): only in an environment that outsiders cannot observe can a conflict of interest be systematically exploited. This implies that the optimal strategy for lowering the bundling tax should target opacity first, because greater transparency simultaneously narrows the exploitable space for conflicts of interest. Although this framework has not yet developed into a precise quantitative model, it provides an analytical basis for comparing structural risk across different exchanges.

All three components have already produced serious consequences in reality. The opacity cost manifested in the FTX case as the absence of externally verifiable financial information before the collapse; the conflict-of-interest cost manifested in Alameda Research obtaining a liquidation-exemption privilege and misappropriating $8.7 billion in client funds; and the single-point-of-failure cost was concentrated in the $1.5 billion Bybit theft (Figure 5-7).

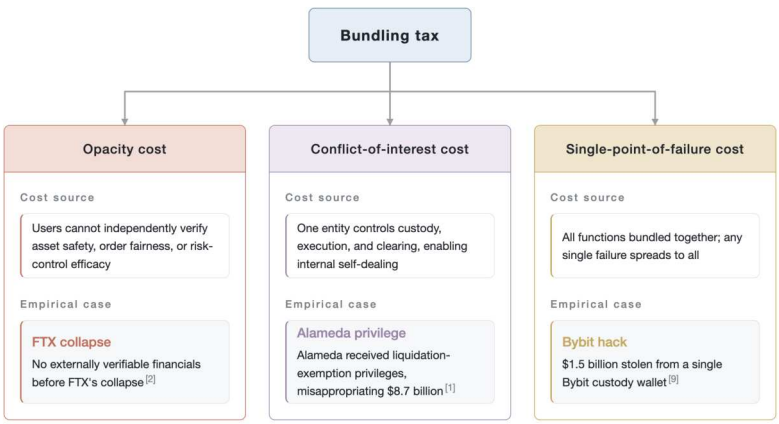

Figure 5-7. The three components of the bundling tax and their empirical cases (Data source: CoinDesk's report on FTX customer liabilities [1], FTX bankruptcy filings [2], and the Wilson Center security report [9])

The bundling tax forms a structural correspondence with the "trust tax" discussed in

Chapter 1. Through mandatory functional separation, traditional finance makes traders pay a "trust tax"—high intermediation fees, long settlement cycles, and strict barriers to access—in exchange for the safety of the system and the suppression of conflicts of interest. Centralized exchanges eliminate most of the "trust tax" through functional bundling, achieving a millisecond-level trading experience and near-zero barriers to market access; but the resulting "bundling tax" requires traders to bear three structural risks: opacity, conflict of interest, and single points of failure. The two are the two ends of the same trade-off, and no cost-free architectural choice exists. This tax cannot be fully eliminated through compliance reviews or technical upgrades alone, because as long as the exchange simultaneously controls the private keys to client assets and the matching engine for trade execution, the technical possibility of evading external audit always remains. On the verifiability ladder defined in Section 5.1, a centralized exchange can at most reach the L1 level of "attested verifiability" by publishing proof of reserves and similar attestations, but it is structurally unable to rise to L2 or above, the "partially verifiable" level.

5.3.3 The efficiency advantages of the bundling model

Despite the significant structural risk the bundling tax entails, centralized exchanges still dominate the crypto-derivatives market. In 2024, the top 10 centralized exchanges recorded $58.5 trillion in total perpetual futures volume, double the $28 trillion of 2023 [4]. The fourth quarter of 2024 alone reached $21.2 trillion in volume [4]. This market dominance is no accident; its economic roots lie in the three efficiency advantages created by functional bundling and the powerful network effects that follow.

The first efficiency advantage of centralized exchanges comes from internal-ledger settlement. In traditional finance, a futures trade from order to final settlement must pass in sequence through the broker, the exchange, the clearinghouse, and the custodian bank, and every cross-institutional handoff of information inevitably generates time delays and coordination costs. Centralized exchanges compress these stages within a single unified technology stack, turning settlement essentially into a numeric update in a centralized database and thereby reducing trading latency to the millisecond level, which supports high-frequency trading strategies and complex algorithmic execution. Traditional finance's multi-institution architecture physically cannot match this internalized coordination efficiency.

A unified liquidity pool constitutes the second efficiency advantage. The buy and sell intentions of all users converge in a single order book, maximizing liquidity depth. Deep liquidity directly lowers the bid-ask spread that traders face and the price impact of executing large orders, which has a direct bearing on the institutional traders and high-frequency market makers analyzed in Chapter 4. By contrast, on-chain protocols' liquidity is dispersed across different blockchains and protocols, producing a fragmented market. Yet a unified liquidity pool can also become a source of risk concentration under extreme conditions: when a single asset undergoes large-scale liquidation, the loss can consume the shared insurance fund and affect the safety margin of all trading pairs.

A minimalist user experience is the third efficiency advantage. Users need not manage complex private keys or seed phrases, need not understand the gas-fee mechanism and

transaction-confirmation process of the underlying blockchain, and can begin trading with only an email address. This low-barrier design significantly expands the pool of potential users, so that crypto-derivatives trading is no longer confined to technically capable early adopters.

Together, these three advantages form a powerful positive feedback loop of network effects. Abundant liquidity attracts more traders, the concentration of traders in turn attracts market makers to offer narrower bid-ask spreads, and better quotes further lower trading costs and attract still more volume. This self-reinforcing loop makes the market position of leading centralized exchanges hard to shake. Even though a market leader such as Binance saw its perpetual futures market share fall from 43% to 34% in 2024, the lost share was absorbed mainly by other centralized exchanges rather than flowing to on-chain protocols [4]. These data indicate that although competition among centralized exchanges is fierce, the dominance of the bundling model as an architectural paradigm has not been substantively challenged.

5.3.4 Comparing the CEX and CCP risk waterfalls

Clearing and risk management are among the core functions of a trading service provider. In designing their risk-defense mechanisms, centralized exchanges have borrowed heavily, in form, from the default-waterfall model of the central counterparty in traditional finance, but fundamental differences remain in the substance of legal constraint, transparency, and user protection. A precise comparison of the two waterfalls helps reveal the structural defects of a centralized exchange's risk-management system.

As Section 5.2.3 described, the central counterparty's default waterfall is a legally binding, multi-layered defense system. Data from Paddrik and Zhang (2020) [5] show that, in credit central counterparties, the defaulting member's initial margin accounts for about 77.9% of the waterfall's total resources and the central counterparty's own capital for about 2.0%. Every parameter setting, trigger condition, and loss-sharing rule of the waterfall is disclosed in advance and subject to mandatory review by financial regulators [20].

A centralized exchange's risk waterfall mimics this structure in form but differs fundamentally on three key dimensions. On transparency, a centralized exchange sets its margin parameters unilaterally and can adjust them at any time, and the adjustment history is usually not disclosed; the size, funding source, and specific use of the insurance fund often cannot be independently verified from the outside. On legal constraint, a central counterparty's capital adequacy, risk models, and default-handling procedures are bound by statutory regulatory requirements, whereas a centralized exchange in most jurisdictions lacks statutory obligations of comparable rigor. On user protection, a central counterparty's non-defaulting members enjoy loss-sharing rules disclosed in advance and statutory recovery procedures, whereas a centralized exchange's users, when the platform goes bankrupt, can usually participate in bankruptcy proceedings only as general unsecured creditors, ranking behind secured creditors. This generalization, however, is subject to significant cross-jurisdictional variation: in the FTX bankruptcy, convenience-class creditors (with claims below $50,000) ultimately received a recovery of about 119% on their dollar-denominated claims, but claims were fixed at their

U.S.-dollar value as of the November 2022 filing date, so customers did not capture the subsequent appreciation of crypto assets, and the portion above 100% came from principal plus roughly 9% statutory interest and recoveries from the bankruptcy estate. The Mt. Gox case in Japan, by contrast, achieved an in-kind (BTC) distribution through civil rehabilitation proceedings, giving customers procedural treatment different from a fixed dollar claim. A blanket "unsecured creditor" judgment may understate the differences in user protection across legal systems.

The risk waterfalls of the three architectures differ fundamentally in their enforcement guarantees: the central counterparty's waterfall is legally binding, and the trigger conditions and loss-sharing rules of each layer are subject to regulatory review and disclosed in advance; a centralized exchange's waterfall is merely asserted by the platform, and its parameter settings and adjustment history are invisible to outsiders; and an on-chain protocol's waterfall is enforced by smart-contract code, with rules hard-coded and auditable by anyone. The three are highly similar in the formal design of their waterfall layers, but the nature of their enforcement guarantees produces a sharp contrast among four modes—legal mandate, platform attestation, code enforcement, and code enforcement with governance override (Figure 5-8)—which is precisely the key variable determining whether a waterfall can be faithfully executed in a moment of crisis. The fourth mode, code enforcement with governance override, refers specifically to the emergency governance-intervention capability that on-chain protocols retain on top of automatic smart-contract execution. When an extreme event exceeds the handling range of the code's preset parameters (such as the JELLY incident analyzed in Section 5.4.4), validators or governance-token holders can override the code logic through a consensus vote. The conditions for such override capability include a validator set small enough for rapid coordination, governance power that is not fully decentralized, and the absence of an on-chain time-lock constraint on emergency intervention. Its trigger threshold is usually the critical situation in which the insurance fund faces depletion or the protocol's solvency is threatened.

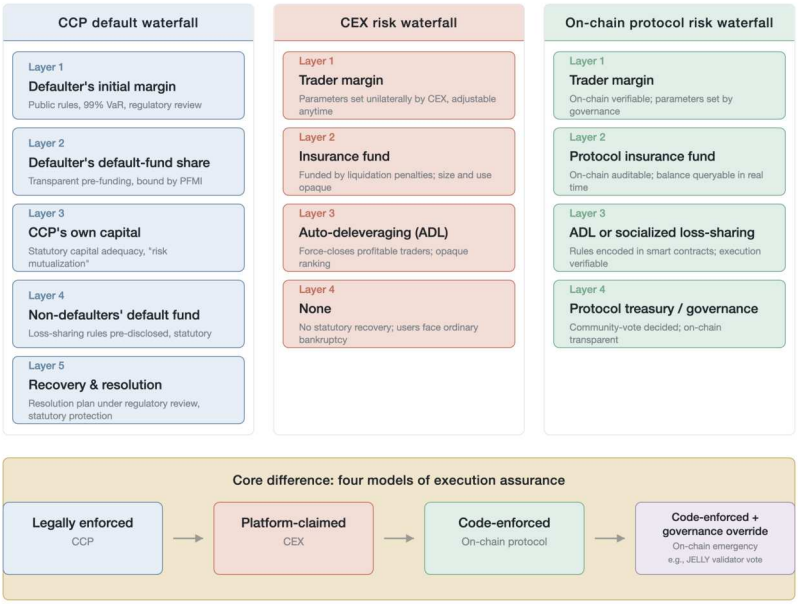

Figure 5-8. A comparison of the risk waterfalls of the central counterparty, the centralized exchange, and on-chain protocols (conceptual comparison of mechanism structures; the waterfall layers and the "99% VaR" follow the CPMI-IOSCO PFMI [20], not empirical data; the 77.9%/2.0% figures from [5] appear in the text, not the figure; Data source: Paddrik & Zhang 2020 [5] and the CPMI-IOSCO Principles [20])

Under normal market conditions, the differences among the three modes of legal mandate, self-attestation, and code enforcement may not be obvious, because the first few layers of the waterfall are usually enough to absorb everyday trading losses. In a moment of crisis, however, when extreme volatility causes systemic shortfalls, a centralized exchange that lacks statutory recovery procedures and transparent loss-sharing rules often leaves users facing an unpredictable allocation of losses. When the insurance fund is exhausted, a centralized exchange usually resorts to auto-deleveraging, forcibly closing the positions of profitable users to make up the loss gap—and the specific algorithm and execution details of this ranking mechanism likewise lack transparency.

5.3.5 The limits of proof of reserves

To ease users' concerns about the opacity cost, centralized exchanges widely introduced proof-of-reserves mechanisms after FTX's collapse. Both academic research and industry practice, however, indicate that proof of reserves has fundamental limitations in addressing the structural risk created by functional bundling.

The core defect of proof of reserves is that it can provide only a point-in-time snapshot of assets and cannot guarantee that assets have not been misappropriated or put to other uses during the audit interval. More critically, proof of reserves usually shows only the on-chain asset balances the exchange controls and cannot effectively reveal its hidden liabilities, complex related-party transactions, or off-balance-sheet commitments. Research by Vidal-Tomás (2025) [14] further points out that, to maintain solvency under

extreme market stress, centralized exchanges in fact need to hold additional reserves of 6% to 14% above their liabilities. The study also finds that, among all exchange-bankruptcy events, the collapses of FTX and Celsius had the most significant negative impact on the stability of the entire centralized-exchange market [14], indicating that the failure of a single large exchange has a systemic contagion effect. In the highly opaque system of a centralized exchange, the capacity for external audit faces an unbreakable ceiling—not because audit technology is insufficiently advanced but because the function-bundling architecture itself makes it inevitable. When the audited party simultaneously controls the assets being audited and the system that generates the audit data, the independence of the audit cannot be guaranteed as a matter of logic.

In the face of these structural risks, regulators worldwide have begun to adopt more systematic responses. The European Union's Markets in Crypto-Assets Regulation (MiCA), which took full effect on December 30, 2024, requires crypto-asset service providers to obtain a license and to comply strictly with requirements on client-asset segregation, conflict-of-interest disclosure, and capital adequacy [24]. Notably, MiCA excludes crypto derivatives such as perpetual futures from its direct scope, placing them under the Markets in Financial Instruments Directive (MiFID II); this means that perpetual futures trading in the EU is in fact subject to the regulatory framework for traditional derivatives rather than a dedicated framework for crypto assets. MiCA's Article 70, on the general safekeeping of clients' crypto-assets and funds, poses a direct challenge to the function-bundling model, requiring exchanges to separate client assets from their own assets at the legal and operational levels. This regulatory framework, however, runs into an enforcement dilemma when confronting on-chain protocols: when the "service provider" is a set of validator nodes distributed around the world rather than a registered legal entity, the licensing regime and compliance requirements lack a clear point of enforcement. The U.S. Securities and Exchange Commission has also launched enforcement actions against several leading centralized exchanges. These regulatory measures have, to a considerable degree, raised the legal cost of exchange misconduct, but Dell'Erba (2024) [6] warns that the effectiveness of traditional financial regulation depends heavily on the clear regulatory entry points that the functional-separation architecture provides. When all functions are concentrated inside one entity, regulators are in effect trying to supervise a complex, opaque, closed system from the outside. Merely adding compliance requirements without structurally unbundling the centralized exchange's functions may amount only to "adding more layers on an unstable foundation" [6]. A compliance framework can raise the legal cost of wrongdoing but cannot eliminate the technical possibility of wrongdoing at the base layer. On the verifiability ladder, this means that regulation can help a centralized exchange rise from L0 to L1 but cannot push it across to the verifiable levels of L2 and above.

5.3.6 The FTX and Bybit failure cases

The fragility of the centralized exchange's function-bundling model has already been validated in reality along two distinct paths: one the complete collapse of internal governance, the other the failure of external technical defenses. These two paths respectively represent the extreme realization of the conflict-of-interest cost and the single-point-of-failure cost within the bundling tax, and together they prove that the architecture's

structural risk is not an accidental, isolated case.

The extreme case of internal-governance collapse is FTX's bankruptcy. On November 11, 2022, FTX filed for bankruptcy protection, and subsequent investigation revealed that it had misappropriated about $8.7 billion in client funds [1]. These funds were used to cover trading losses at the affiliated market maker Alameda Research, to fund personal loans to executives, and to purchase luxury real estate. Using its dual identity as both matching-engine operator and risk manager, FTX granted Alameda Research the privilege of exemption from automatic liquidation at the level of code, allowing it to maintain enormous positions without sufficient collateral. The essence of this episode is that functional bundling turned all of the exchange's core functions—custody, clearing, and risk control—into tools serving the interests of an affiliated party. Functional bundling made misappropriation technically trivial, because the same entity that controlled the matching engine also controlled the private keys to client assets; the absence of independent external oversight kept the misappropriation undiscovered for a long time, because no independent third party could verify the true state of the assets; and the temptation of billions of dollars in commercial gain made the misappropriation almost inevitable in motive. The FTX case proves that relying on a centralized exchange's self-restraint to manage conflicts of interest is entirely unworkable.

The archetype of technical fragility is the hack Bybit suffered on February 21, 2025. Because the exchange used a centralized-custody model, a vast quantity of client assets was concentrated in a wallet system controlled by a single entity, an architecture that made it a target with high expected returns. The North Korea-linked Lazarus Group, through months of social-engineering infiltration and malware deployment, successfully breached the exchange's internal security defenses and stole about $1.5 billion in digital assets [9]. Specifically, the attackers used a supply-chain attack to infiltrate the signing interface of a multi-signature cold-wallet solution, so that what the signers saw visually was a normal transaction while what they actually signed was a malicious transfer instruction. This attack vector reveals that the real security boundary of a multisig scheme is far lower than its theoretical expectation: when the signing device or interface is compromised, the numeric threshold of the multisig becomes meaningless. Notably, the same attack vector applies equally to multisig governance wallets in DeFi protocols, and the claim that "self-custody eliminates custody risk" must be re-examined in the face of supply-chain attacks. The stolen funds were then dispersed within the first 48 hours across dozens of wallet addresses each holding about 10,000 ETH and were further laundered in layers through decentralized exchanges, cross-chain bridges, and mixers [9], using decentralized exchanges to swap assets and evade freezing. Addresses associated with the Lazarus Group appear on the sanctions list of the U.S. Treasury's Office of Foreign Assets Control (OFAC), which poses a compliance challenge for the entire on-chain ecosystem; the Tornado Cash sanctions precedent shows that decentralized protocols that interact with sanctioned addresses may themselves face regulatory risk. This was the largest crypto theft up to that time, and its scale further confirms the structural fragility of the centralized-custody model: under this architecture, the defender must maintain a perfect defense against every attack, while the attacker need succeed only once to inflict a major, irreversible loss. However much an exchange invests in internal security, the very fact that a vast quantity of assets is concentrated

under the control of a single entity constitutes an ineliminable systemic risk.

Whether FTX's internal corruption or Bybit's external breach, the root cause points to the same conclusion: the risk of the function-bundling model is not a matter of a particular operator's moral failure or technical negligence but a structural property of the architecture itself. FTX's collapse exposed the fragility of the bundled architecture along the governance dimension, and Bybit's theft exposed the fragility of the same architecture along the technical dimension. The existence of two failure paths shows that even if a centralized exchange's governance system is sound, it still faces the single-point-of-failure risk at the technical level; conversely, even if its technical defenses are sound, a failure of internal governance can still destroy the entire system at the root. This repeated disappointment with the "trust an institution" model is precisely the fundamental force driving the market to explore alternatives more seriously. Those on-chain trading models that seek to rebuild the foundation of trust through publicly verifiable code and cryptography are analyzed in detail in Section 5.4.

5.4 On-chain trading models

On-chain perpetual futures trading has expanded rapidly over the past several years. By 2025, decentralized exchanges handled $6.7 trillion in perpetual futures volume, up 346% from the prior year and accounting for about 10% of the overall perpetual futures market [25] [26]. This growth reflects traders' persistent demand for alternatives to centralized exchanges. Decentralized exchanges, however, have not eliminated the risks inherent in financial markets; through cryptography and consensus mechanisms, they transform risk from one form into another. This section examines in depth the core mechanisms of on-chain perpetual futures trading and analyzes the new risk exposures it introduces in self-custody, execution models, and app-chain architecture.

5.4.1 Self-custody and atomic settlement

The core promise of decentralized-finance infrastructure is to reshape asset control and the trade-settlement process through cryptography. On a traditional centralized exchange, users must deposit assets into a wallet the platform controls, the platform records users' account balances in an internal database, and trades are booked in the matching engine. This model introduces extremely high centralized-custody risk: once the platform is hacked or funds are misappropriated internally, users' assets face direct loss. The Bybit theft of about $1.5 billion discussed earlier (Section 5.3.6) further demonstrates the fragility of the centralized-custody model [27].

On-chain perpetual futures trading eliminates this platform-custody risk through a self-custody mechanism. Under self-custody, the user controls assets on the blockchain directly through private keys, and a smart contract can operate on those assets only under specific conditions authorized by the user's cryptographic signature. This mechanism ensures that the platform cannot unilaterally misappropriate user funds, eliminating traditional centralized-custody risk at the root. On-chain trading also uses an atomic-settlement mechanism, completing trade matching and fund transfer indivisibly within the same blockchain transaction—if any step fails, the whole transaction

reverts—thereby eliminating settlement risk (see Chapter 1 for the discussion of atomic settlement).

The complete flow of on-chain perpetual futures trading includes connecting a wallet, depositing margin, submitting an order, on-chain matching and settlement, and withdrawing funds (Figure 5-9); throughout, assets remain under the control of the user's private keys, a smart contract can operate on funds only under the specific conditions authorized by a cryptographic signature, and matching and fund transfer complete atomically within the same blockchain transaction.

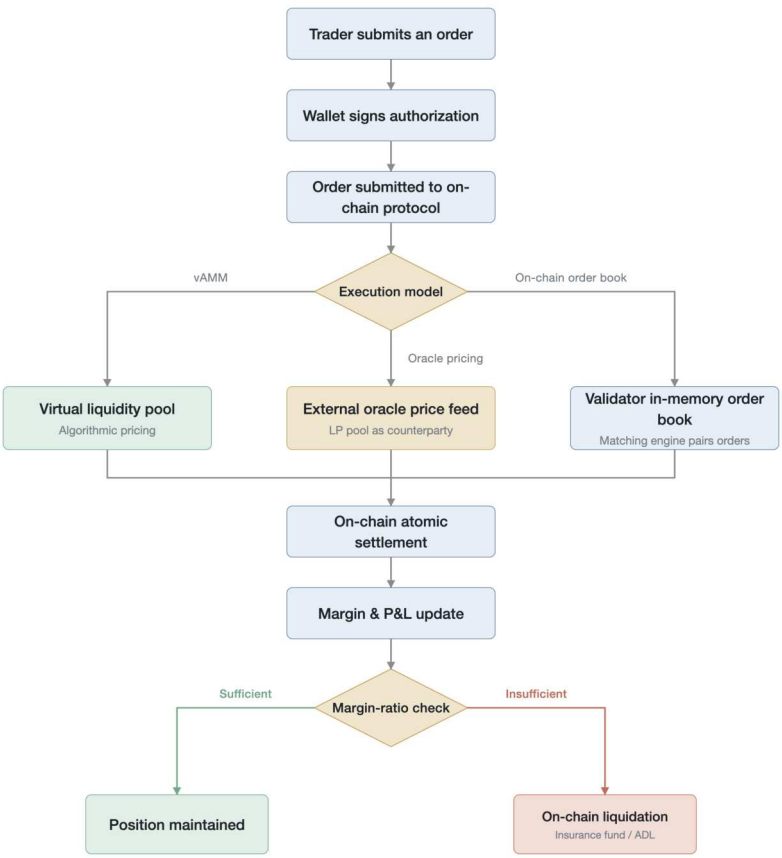

Figure 5-9. The on-chain perpetual futures trading flow (a schematic of the self-custody and atomic-settlement flow, not empirical data; Data source: protocol-architecture analysis based on the dYdX Foundation [28] and Nansen Research [29])

This elimination of risk, however, is not without cost; it essentially transforms institution-level systemic risk into user-level operational risk and protocol-level technical risk. Self-custody requires the user to assume full responsibility for protecting the private keys. Once a private key is lost or stolen, the assets face irreversible loss, and no centralized institution can provide a recovery service. Moreover, self-custody now faces tightening regulatory constraints: the EU's Transfer of Funds Regulation (TFR) requires crypto-asset service providers to apply additional identity verification

to transfers involving unhosted wallets, and the FATF Travel Rule likewise extends compliance requirements to self-custody users, which may in practice limit the convenience with which self-custody users interact with regulated services. In addition, when interacting with a smart contract, a user must authorize the contract to operate on the assets in the wallet. If the user inadvertently authorizes a malicious smart contract, or if a legitimate smart contract contains a vulnerability, an attacker can still drain the user's assets.

Against the backdrop of increasingly frequent cross-chain trading, cross-chain bridge contracts have become a new locus of concentrated systemic risk. To move assets between different blockchain networks, a user must lock the assets in a bridge contract on the source chain and mint an equivalent amount of wrapped assets on the destination chain. This mechanism makes bridge contracts high-value attack targets. As noted earlier, the cumulative losses from cross-chain bridge hacks have exceeded $2.5 billion, about 40% of the total value stolen across Web3 [11]; this shows that although on-chain trading eliminates the custody risk of a single exchange, the complexity of cross-chain infrastructure introduces smart-contract-vulnerability risk that is more insidious and far more destructive.

5.4.2 A comparison of three execution models

To achieve efficient derivatives trading in a decentralized environment, on-chain perpetual futures protocols have evolved three main execution models. Each makes a different trade-off among performance, decentralization, and transparency, and each exposes particular risk characteristics in actual operation.

The virtual automated market maker (vAMM) model is the archetypal design of early on-chain perpetual futures. This model borrows the constant-product formula of the automated market maker from spot markets, but the pool contains no real reserve assets; instead, it uses an algorithm to simulate liquidity depth and determine prices. After depositing collateral, users take long and short positions against one another in the virtual pool. The advantage of this design lies in its high degree of decentralization and its permissionless nature: anyone can create a new trading pair based on the algorithm. A vAMM, however, relies entirely on internal-algorithm pricing, and when the market experiences an extreme one-sided move, the virtual pool's price readily depegs severely from the external spot price. The first version of Perpetual Protocol once generated large amounts of bad debt because of price depegging, ultimately facing bankruptcy risk [30]. The specific consequences of depegging for traders include immediate unrealized losses for position holders at the moment of depegging, unreasonable forced liquidations triggered by a mark price that deviates from the true price, and funding rates that spike to abnormal levels because of an extreme imbalance in the long-short ratio.

The oracle-pricing model takes an entirely different approach. It abandons the internal price-discovery mechanism and instead relies on the spot prices of mainstream exchanges provided by an external oracle as the execution price. In this model, liquidity providers (LPs) pool their funds into a global liquidity pool that serves as the unified counterparty for all traders. Traders can enjoy a zero-slippage trading experience because the price is determined entirely by the external oracle. This design, however,

introduces fundamental oracle risk and LP-loss risk. Oracle risk can be systematically divided into four categories: manipulation risk, in which an attacker manipulates the price of the underlying asset in an illiquid external spot market and exploits the feed lag to perform risk-free arbitrage on the on-chain protocol; feed-latency risk, in which the oracle network's update frequency cannot fully match instantaneous market movements, creating a pricing window under extreme volatility; upstream data-source dependency risk, in which the oracle's aggregated price sources are concentrated in a few centralized exchanges, so that an interruption or error in the upstream data source transmits directly to on-chain pricing; and operator conflict-of-interest risk, in which, when the protocol's validators also serve as oracle nodes, the combination of pricing power and settlement power can create an incentive for self-dealing. In September 2022 and July 2025, leading oracle-pricing protocols such as GMX suffered repeated price-manipulation and reentrancy attacks of this kind, causing losses ranging from several million to tens of millions of dollars [31] [32].

The on-chain order-book model represents the latest direction in on-chain derivatives trading. This model seeks to rebuild on the blockchain the time-tested central limit order book (CLOB) mechanism of traditional financial markets. Early hybrid architectures placed order matching on off-chain centralized servers and submitted only the final fund settlement to the chain, trading this for higher throughput. But this compromise sacrificed the transparency and censorship resistance of the matching process. A new generation of on-chain order-book protocols instead builds a dedicated app-chain that embeds the matching engine, margin checks, and liquidation logic entirely within the blockchain's consensus layer. This model can deliver performance close to that of a centralized exchange while preserving deterministic trade ordering and full on-chain transparency.

Notably, the three models differ structurally in the design of their funding-rate mechanisms: the vAMM's funding rate is implicit in the curve shift of the virtual pool and is not calculated independently; the oracle-pricing model's funding rate is usually calculated explicitly on the basis of the long-short position ratio; and the on-chain order-book model's funding-rate calculation is closer to that of a centralized exchange, based on the deviation between the contract price and the mark price. These differences directly affect each model's contribution of the funding rate to the efficiency of price anchoring. The relative positions of the three models within the trilemma are shown in Figure 5-10.

Figure 5-10. A comparison of the positions of three DEX execution models within the trilemma (conceptual schematic; qualitative positions, not measured coordinates; placements reflect the author's judgment, not empirical data; Data source: Nansen Research [29])

As the figure shows, the chosen points of the three models form an evolutionary path extending from the decentralization vertex toward the performance vertex: the vAMM is closest to the decentralization and transparency vertices but farthest from the performance vertex; the oracle-pricing model occupies the middle ground, trading dependence on external infrastructure for higher capital efficiency; and the on-chain order-book model advances performance substantially through an app-chain architecture but moves correspondingly away from the decentralization vertex. This path reveals the core evolutionary logic of on-chain derivatives-trading execution models: while preserving on-chain transparency, they trade a gradual concession in decentralization for a performance experience approaching that of a centralized exchange.

5.4.3 App-chain architecture and validator centralization

As on-chain trading's demands for low latency and high throughput keep rising, the performance bottleneck of general-purpose blockchains has become increasingly apparent. To break through this limit, leading decentralized exchanges have begun migrating to an app-chain architecture. An app-chain is an independent blockchain tailored to a specific decentralized application, and its core idea is to bind the underlying consensus mechanism tightly to the upper-layer application logic.

In a hybrid architecture, a decentralized exchange is usually deployed on a general-purpose blockchain such as Ethereum or its layer-2 network. Although this architecture can share the underlying network's vast validator set and high degree of security, a general-purpose network must accommodate the execution of all kinds of smart contracts and cannot provide the deterministic low latency required for high-frequency trading. Moreover, a hybrid architecture relies on centralized infrastructure such as Amazon Web Services for off-chain matching, which not only introduces single-point-of-failure risk but also leaves the trade-ordering process without cryptographic verifiability

[28].

By contrast, an app-chain architecture achieves full-stack integrated control from the consensus layer to the application layer. In the case of a decentralized exchange that adopts an app-chain architecture, it usually customizes a Byzantine fault-tolerant (BFT) consensus algorithm optimized specifically for the throughput of financial messages. Under this architecture, order submission, cancellation, and matching, along with margin liquidation, all take place under the protection of on-chain consensus. Validator nodes are responsible not only for packaging blocks but also for running the order-book state machine directly in memory, ensuring that the execution order of every trade is network-wide consistent and tamper-proof. This deep customization allows an app-chain to achieve sub-second block-confirmation times and a throughput capacity of hundreds of thousands of orders per second (here, throughput refers to message throughput—the processing rate of messages such as order submissions and cancellations—and actual fill throughput is typically far lower than message throughput) [33] [34].

The core difference between the hybrid architecture and the app-chain architecture lies in where the components sit and in the corresponding trust assumptions. In a hybrid architecture, the matching engine runs on an off-chain centralized server and only final settlement is submitted to the chain, so users must trust the fairness of the off-chain components; in an app-chain architecture, the matching, margin checks, and liquidation logic are all embedded in the blockchain's consensus layer, and trade ordering is jointly determined by the validator set. This difference gives the two architectures different performance boundaries in latency, throughput, transparency, and censorship resistance (Figure 5-11), and the fundamental difference in their trust assumptions is that the former's trust rests on "whether the off-chain platform is fair," while the latter's shifts to "whether the validator set is honest."

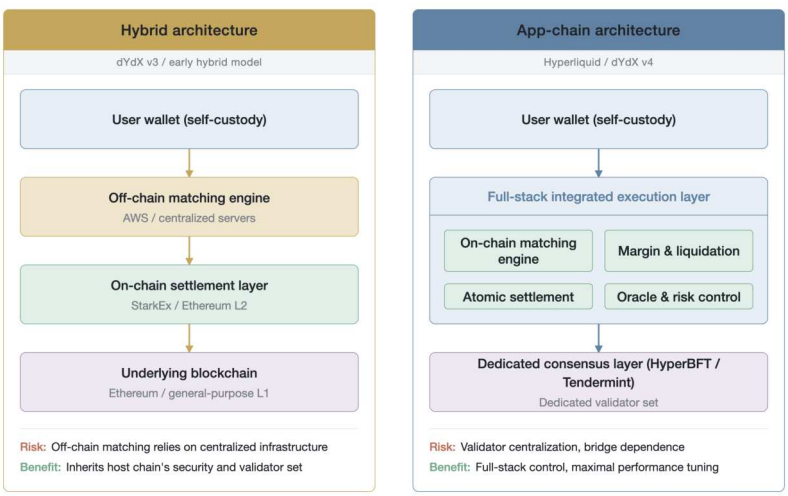

Figure 5-11. An architectural comparison of a hybrid DEX and an app-chain (conceptual architectural comparison, not empirical data; Data source: dYdX Foundation [28])

While gaining high performance, however, the app-chain architecture faces the significant cost of validator centralization. To maintain an extremely high network-synchronization speed, an app-chain can usually accommodate only a limited number of validator nodes. For example, in early 2025 Hyperliquid maintained network consensus with only about 16 validator nodes (later expanded to about 24), and the staked tokens were highly concentrated in the hands of early investors and the team [12] [35]. Beyond centralization risk at the governance level, the infrastructure concentration of validators also constitutes a significant operational risk: if most validators run on the same cloud provider or in data centers in the same geographic region, a single data-center failure or network partition can cause the network to lose liveness. Solana's multiple network-wide outages between 2021 and 2023 provide a precedent: during a network outage, all unsettled perpetual futures positions face the risk of not being liquidated, and the combination of extreme market conditions and network downtime can cause large-scale depletion of the insurance fund. This highly concentrated validator structure significantly weakens the blockchain's censorship resistance and its decentralized trust assumptions. When a few validators hold absolute control of the network, they can not only determine the ordering of trades but even change the protocol's core rules through a consensus upgrade. This concentration of power can cause an app-chain, under extreme conditions, to exhibit the arbitrary characteristics of a centralized institution, thereby departing from the original intent of decentralized finance.

5.4.4 Architecture audit and verifiability rating

Objectively assessing the security and degree of decentralization of an app-chain architecture requires a fact-based verifiability-rating framework. This framework does not rely on subjective scoring; instead, it performs a structured analysis by examining, for each dimension of the system, whether it is on-chain queryable, auditable, and under user control. Taking Hyperliquid, the current volume leader, as an example (other app-chain architectures such as dYdX v4 face similar trade-offs), one can conduct a deep audit of its architecture along four core dimensions.

On the dimension of custody and asset safety, this app-chain exhibits relatively high verifiability. Users' account balances are fully recorded in the on-chain state, and anyone can independently verify the authenticity of their assets by running a full node, without relying on financial statements the platform provides [36]. The platform does not hold users' private keys, and asset transfers require authorization by the user's cryptographic signature. On the withdrawal path, however, the system carries a partially restricted risk. Because this app-chain is an independent network, cross-chain asset transfers depend heavily on a cross-chain bridge contract controlled by a validator multisig. Although the bridge-contract code is publicly auditable, its security is ultimately anchored to the honesty of the validator set.

On the dimension of trade execution and matching, this system achieves fully on-chain execution of order matching. Unlike a hybrid model that relies on centralized servers, its consensus mechanism ensures deterministic trade ordering, and all matching logic runs openly in the validator nodes. The system's low latency and high throughput have been validated in actual operation. Hyperliquid's core node code long remained closed-

source and was only gradually opened after sustained scrutiny from the community [37]. In addition, on preventing MEV, the system currently lacks an independent third-party audit, and the fairness of trade ordering still largely depends on trust in the validators.

On the dimension of clearing and risk management, the system's margin checks and liquidation-engine logic both execute on-chain, and their trigger conditions and execution processes are fully public and queryable. The insurance fund's balance is likewise displayed transparently on-chain, and the rules of the auto-deleveraging mechanism are hard-coded into the protocol. The system's oracle price-feed mechanism, however, involves a significant compromise. In pursuit of the highest update speed, the system does not use a decentralized third-party oracle network but instead has its own validator set directly maintain the price oracle. Although this design reduces latency, it also gives validators both pricing power and settlement power, which can trigger serious conflicts of interest and manipulation risk under extreme conditions.

Combining the audit results across these four dimensions, this app-chain achieves relatively high on-chain verifiability in custody and trade execution, carries latent conflict-of-interest concerns in clearing and risk management because of the compromise of a self-built oracle, and, in governance and emergency response, exposes discretionary risk arising from validator centralization (Figure 5-12).

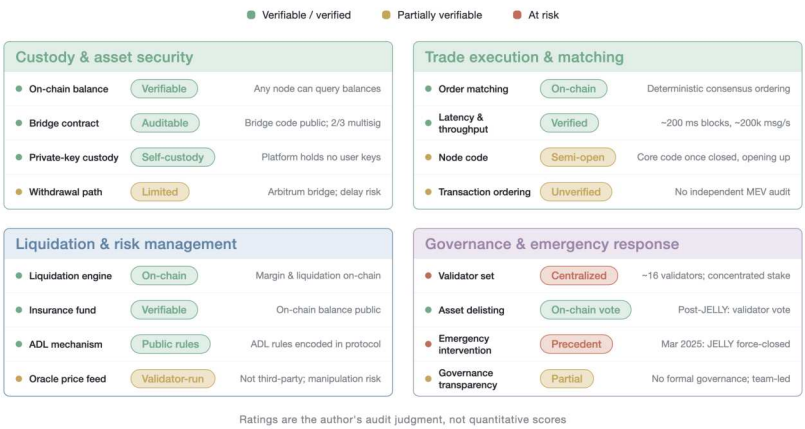

Figure 5-12. The verifiability-rating matrix from a four-dimensional architecture audit of the app-chain (the author's four-dimensional structured rating; ratings reflect the author's audit judgment and are ordinal, not quantitative scores, and not empirical data; the figure of about 16 validators reflects the genesis count as of early 2025, later expanded to about 24 [12][35]; the JELLY incident resolution [38][39]; the roughly 200,000 per second figure is message throughput—orders, cancellations, and similar messages, not fills—on a vendor basis [33][34]; architecture [28]; OneKey Blog is a secondary review [37])

On the dimension of governance and emergency response, this app-chain exposes the most obvious centralization risk. The validator set is limited in number and its stake is highly concentrated, so the system's governance lacks broad community participation. In responding to sudden events, this centralized structure grants validators extensive discretion.

The JELLY incident of March 2025 is an in-depth case of this governance risk [38] [39].

A trader opened a large short position in the low-liquidity token JELLY on Hyperliquid and then sharply pushed up the token's price in the external spot market. Because JELLY's spot liquidity was extremely thin, a small amount of capital could significantly move the oracle price feed, causing the Hyperliquid liquidity provider vault (HLP), as it passively absorbed the liquidated short, to face a peak unrealized loss of about $12 million (with exposure at one point reaching about $230 million); because the position was ultimately liquidated at the very low price of $0.0095, the HLP actually booked a small profit. This incident first exposed the fundamental risk of listing perpetual futures on low-liquidity tokens: when the oracle price feed can be manipulated with a small amount of capital, the leverage effect of perpetual futures amplifies the manipulation gains many times over.

The validator set's response to this crisis raised deeper questions of governance legitimacy. The validators rapidly reached consensus, decided to forcibly delist JELLY, and forcibly closed all related positions at a price of $0.0095, while the oracle quote at the time was about $0.50 (the on-chain delisting-vote mechanism was introduced only after this incident, and the handling at the time was in fact a rapid coordination among validators). The exercise of this price-setting power was in essence a product of off-chain coordination, and its basis of legitimacy was neither the automatic execution of code nor sufficient community deliberation. The Hyper Foundation subsequently promised to compensate affected users, but this compensation mechanism was itself an off-chain promise outside the protocol rather than a deterministic guarantee at the smart-contract level.

Viewed from the dimension of legal risk, the validators' unilateral forced liquidation at a price far below the market price could constitute market manipulation or a breach of fiduciary duty. The CFTC's enforcement precedent against Ooki DAO has shown that decentralized governance does not exempt participants from legal liability, and the narrative that "code is law" is fragile in the face of regulatory enforcement.

The implications of the JELLY incident for this chapter's theoretical framework are multidimensional. On the verifiability ladder, Hyperliquid has L3-level verifiability in normal operation, but the validators' governance override in a moment of crisis effectively downgraded it to L1, with the final enforcement of the rules depending on the discretion of a few rather than the determinism of code. Within the trilemma, the incident revealed a latent third dimension between decentralization and performance: when a crisis arrives, a limited validator set is forced to tilt toward centralized decision-making, sacrificing the predictability of the rules for the sake of protecting the system's solvency. The community's reaction to the incident also displayed a marked framing-effect split: some users viewed the intervention as a "responsible emergency response," while others viewed it as a "fundamental betrayal of the commitment to decentralization," and this narrative contest directly affected the market's repricing of trust in the protocol.

5.4.5 The on-chain risk waterfall

Sections 5.2.3 and 5.3.4 analyzed, respectively, the legally mandated default waterfall of the traditional central counterparty and the self-attested risk waterfall of the central-

ized exchange. The former manages systemic risk through a statutory, multi-layered loss-absorption mechanism whose parameters are public and subject to regulatory review; the latter mimics this structure in form but differs fundamentally along three key dimensions—transparency, legal constraint, and user protection.

Building on the experience of both models, on-chain perpetual futures protocols have constructed a distinctive on-chain risk waterfall, but the waterfall structure differs markedly across protocols. In the case of Hyperliquid, its risk waterfall in fact comprises four layers: the first layer is the trader's initial and maintenance margin; the second layer is the backstop liquidation of the HLP—that is, when routine liquidators fail to take over in time, the protocol-operated market-making vault passively absorbs the liquidated position; the third layer is the on-chain insurance fund (about $300 million to $500 million in size as of early 2025); and the fourth layer is auto-deleveraging. dYdX v4's waterfall differs: after margin is exhausted, the position is taken over by an external liquidator network, and if liquidation produces a shortfall loss, it is absorbed by the insurance fund (on the order of tens of millions of dollars in size), with ADL initiated after the insurance fund is exhausted.

The absolute sizes of these insurance funds differ from those of the traditional central counterparty by orders of magnitude. CME's total default resources (including the default fund and the statutory power to levy additional assessments on members) exceed $10 billion, of which the default fund itself is about $3 billion, whereas an on-chain protocol's insurance fund is usually only tens of millions to hundreds of millions of dollars and lacks a mandatory replenishment mechanism. Because of the blockchain's transparency, all margin balances and liquidation thresholds are publicly queryable, and any market participant can monitor the system's overall leverage level. When a user account's margin ratio falls below the maintenance level, the smart contract automatically triggers the liquidation logic. Unlike a centralized exchange, an on-chain protocol usually allows external liquidators to participate in the liquidation process and incentivizes them, through a liquidation discount, to take over high-risk positions in time, thereby using market forces to defuse risk. The reliability of the external liquidator network, however, has its own operational fragility. During "Black Thursday" in March 2020, MakerDAO's liquidation auctions saw the extreme situation of a liquidator winning bids at a price of zero: when a spike in Ethereum gas fees made the cost of a liquidation transaction higher than the gain from the liquidation discount, liquidators chose to withdraw, forming a "liquidator strike" that left the system exposed and unprotected.

The funding source of an on-chain insurance fund is usually a share of the trading fees the protocol collects, and its balance is fully visible on the blockchain [40]. This transparency lets the market assess the protocol's risk-bearing capacity in real time. When a protocol faces an extreme black-swan event and the insurance fund is breached, the auto-deleveraging rules are fully hard-coded into the smart contract. The system ranks accounts according to a preset algorithm, by leverage ratio and profit ratio, and executes deleveraging transparently and deterministically. In addition, in some app-chain architectures, as the JELLY incident in Section 5.4.4 shows, the validator set can also exercise emergency-intervention power through a consensus vote—for example, forcibly halting a market or modifying the settlement price.

The distinctive role the funding rate plays in the risk waterfall deserves separate discussion. The funding rate is in essence a continuously running risk-redistribution mechanism with no counterpart in the traditional central counterparty's default waterfall. Under normal market conditions, the funding rate maintains the anchoring of the contract price to the spot price by transferring payments between longs and shorts. Under extreme conditions, however, the funding rate can produce a positive-feedback effect: when the market rises sharply, the positive funding rate spikes, attracting short sellers to enter to earn the rate; if the uptrend persists, these short sellers are liquidated, further pushing up the price and the funding rate, forming a self-reinforcing loop of "high rate → attracts shorts → trend continues → shorts are liquidated → higher rate." This mechanism means that under extreme conditions the funding rate can turn from a stabilizer into an amplifier, constituting a distinctive risk-transmission channel in the on-chain risk waterfall that differs from traditional finance.

The three market structures display systematic differences across five key dimensions of the risk-management mechanism: the frequency of margin monitoring rises progressively from daily settlement to real-time on-chain checks; liquidation execution evolves from a closed internal engine toward an open external liquidator network; the transparency of the insurance fund moves from periodic audit reports to a real-time-queryable on-chain balance; the ultimate backstop mechanism shifts from statutory member assessments to algorithmically determined auto-deleveraging; and the guarantee of rule enforcement moves from legal constraint to cryptography and consensus. Table 5-2 lays out the comparison across these five dimensions. One evolutionary throughline runs across all dimensions: from the traditional central counterparty to on-chain protocols, margin monitoring moves from discrete periodic settlement to continuous real-time checking, liquidation execution moves from a closed membership system to an open liquidator market, and the insurance fund moves from periodic audit to real-time on-chain querying. This evolution takes gains in transparency and determinism as its benefit and takes declines in the depth of financial resources and the flexibility of crisis response as its cost.

Dimension of comparison	Traditional CCP	Centralized exchange	On-chain derivatives protocol
Margin monitoring	Daily or intraday settlement	Real-time risk engine	Real-time checks by on-chain smart contracts
Liquidation executor	Clearing members	Platform's internal engine	External arbitrageurs or protocol liquidators
Insurance fund transparency	Periodic audit reports	Opaque or partially disclosed	On-chain balance queryable in real time
Ultimate backstop mechanism	Member assessments	Auto-deleveraging (opaque)	Auto-deleveraging (algorithmically determined)
Rule-enforcement guarantee	Legal and regulatory constraints	Platform reputation and internal controls	Cryptography and consensus mechanisms

Table 5-2. A comparison of risk-management mechanisms across the three structures of derivatives markets (Data source: Harris [3], Paddrik & Zhang [5], CPMI-IOSCO [20])

On the whole, the on-chain risk-waterfall mechanism is markedly superior to the centralized exchange in transparency and the determinism of its rules, but it still falls short of the strictly regulated traditional central counterparty in the depth of financial resources and the flexibility of responding to extreme crises. The on-chain trading model has not eliminated the leverage risk and liquidity risk inherent in derivatives markets; instead, through cryptographically verifiable smart contracts and decentralized consensus, it transforms the management of risk from unverifiable internal operations into publicly auditable algorithmic execution. This transformation grants users greater rights to information and control, but it also demands of them a higher capacity for risk identification, in order to cope with new on-chain systemic risks such as smart-contract vulnerabilities, oracle failure, and validator consensus collusion.

5.5 Cross-architecture risk isomorphism

Many of the new problems of on-chain finance are, at a deeper level, the recurrence of old problems from traditional finance in a new technical environment. Recognizing this isomorphism helps strip away the technical shell to see the essence of a problem and to draw on traditional finance's two centuries of experience in solving it. At the same time, the on-chain versions of these new forms exhibit fundamental differences in speed, scale, and transmission mechanism, requiring market participants to reassess the boundaries of risk. This section analyzes, in turn, four core isomorphic mappings and characterizes the complete path of cross-modal risk transmission.

5.5.1 Adverse selection and impermanent loss

Adverse selection is the core dilemma facing market makers; in essence, a market maker is always trading against counterparties who hold more information than it does, and so it continuously incurs losses. Glosten and Milgrom (1985) [41] proved that under information asymmetry, even a risk-neutral market maker still posts a positive bid-ask spread, because the spread is the rational compensation for adverse-selection risk. In a traditional order-book market, the market maker manages this risk by adjusting the width of its quotes: when the share of informed traders rises, the spread widens to cover the higher adverse-selection cost; when market information is relatively uniform, competitive pressure forces the spread to narrow. Harris (2003) [3] treats adverse selection as the core issue of market-maker economics, noting that a market maker's profit comes from the liquidity demand of uninformed traders while its losses come from the informational advantage of informed traders.

In an automated market maker, the impermanent loss that liquidity providers face is essentially the on-chain version of the adverse-selection cost. When an asset's true price moves, arbitrageurs—acting as informed traders—use the pricing formula to trade against the liquidity pool until the price inside the pool aligns with the external market. In this process, arbitrageurs extract value while liquidity providers bear the loss. Milionis et al. (2022) [42] proposed the loss-versus-rebalancing (LVR) model, which rigorously proves that impermanent loss can be quantified as the cost to liquidity providers of being exploited by arbitrageurs for providing stale prices. The model's central conclusion is that the instantaneous LVR—the loss rate per unit time, with dimensions of

value per unit time—is proportional to the square of the underlying asset's price volatility, σ^2, and to the marginal liquidity at the price, $L(P)$; this form closely resembles the gamma-risk structure in Black-Scholes option pricing and applies to all constant function market makers (CFMMs). It should be noted that Black-Scholes assumes continuous hedging and constant volatility, whereas AMM rebalancing is constrained by the discreteness of block time, and under extreme volatility, price jumps within a block interval cause actual LVR losses to deviate substantially from the predictions of the continuous-time model. Whether in a traditional order book or an automated market maker, the underlying mechanism by which liquidity providers are systematically drained of value by the better-informed party is exactly the same; only the outward form changes, from passive fills against active quotes to active arbitrage against passive liquidity. The strategy spaces of the two structures do differ importantly: a traditional order-book market maker can adjust the width and depth of its quotes in real time in response to information events, whereas an AMM liquidity provider is bound by the mathematical structure of the pool and can only passively accept the new asset ratio when the price moves. This asymmetry implies that the adverse-selection cost in an AMM may be systematically higher in magnitude than in an active market-making environment. This isomorphism means that the theoretical tools and practical strategies developed in traditional finance to address adverse selection can, with appropriate adjustment, be applied directly to the risk management of on-chain liquidity provision. Chapter 19 will systematically analyze this continuum from the perspective of the "toxic flow spectrum."

5.5.2 Margin cascades and liquidation cascades

The positive feedback loop of leveraged systems is known in traditional finance as the *price accelerator*. Harris (2003) [3] notes that under a margin regime, a sharp market decline triggers margin calls, and if a trader cannot top up in time, the position is forcibly liquidated, generating fresh selling pressure that causes further declines and more forced liquidations, forming a self-reinforcing positive feedback loop. The 1929 stock market crash is the classic case of this mechanism: the widely used margin loans of the time triggered a wave of large-scale forced liquidations as the market fell, turning a market correction into a systemic collapse. In the nearly one hundred years since, traditional finance has developed a series of buffering mechanisms—including price limits, circuit breakers, and the central counterparty clearing system—to break the positive feedback loop.

The liquidation cascade of perpetual futures markets is the extreme amplification of this old problem in an on-chain environment. Because the market broadly offers extremely high leverage and trades around the clock, chained liquidations can transmit rapidly across platforms via oracles. Ali (2025) [43] conducted a quantitative analysis of the October 2025 crypto market flash crash, finding that under a macroeconomic shock, $19 billion in open interest was wiped out within just 36 hours, the volatility-persistence coefficient was close to 0.90, and the cross-asset contagion intensity was about 20% higher than the spillover effect during the 2018 trade war. Compared with the day-scale transmission of traditional finance, the on-chain version of the liquidation cascade is two orders of magnitude faster ("orders of magnitude" here refers to the cross-market

spillover time window: in traditional finance it is measured in days, whereas on-chain liquidation completes cross-platform transmission at the minute scale through oracles and arbitrage mechanisms) and has a distinctive cross-platform transmission mechanism. Moreover, the transparency of the on-chain environment gives the liquidation cascade a behavioral-contagion dimension that does not exist in traditional finance: large liquidation events are fully visible on-chain, propagate in real time through block explorers and social media, and turn a mechanical liquidation process into a "panic signal" for market participants. Social media compresses the timescale of panic propagation from the hour scale of traditional finance further to the minute scale, and the behavioral-level panic selling and the mechanism-level forced liquidation reinforce each other, potentially making the risk structure of an on-chain liquidation cascade structurally higher than that of a traditional margin cascade. After a large-scale liquidation on one decentralized exchange causes the price to deviate, arbitrageurs quickly transmit the shock to other platforms, triggering broader liquidations. The time buffer that settlement cycles and margin-call notices provide in traditional finance barely exists in an on-chain environment, so the risk-control system must respond within a second-scale time window. Chapter 20 will provide a formal analysis of the full dynamics of the liquidation cascade through the reflexivity triangle model.

5.5.3 Market fragmentation and cross-chain fragmentation

Trading the same asset on multiple exchanges disperses liquidity, increases transaction costs, and makes the price-discovery process more complex. In traditional finance, market fragmentation has long been a core concern of regulators and scholars, its main driver being competition among different trading venues. After the 2005 Regulation National Market System took effect, U.S. equity trading volume was dispersed across more than ten exchanges and dozens of dark pools, and the consolidation of the best bid and offer relied on complex market-data infrastructure.

In on-chain finance, the coexistence of multiple public blockchains has produced cross-chain fragmentation. Liquidity is dispersed across different decentralized exchanges on different chains such as Ethereum, Solana, and Arbitrum, and a user seeking the best price must resort to cross-chain bridges and aggregators, which not only raises transaction costs but also introduces an entirely new security dimension. In a Bank for International Settlements working paper, Shin (2026) [44] points out that the congestion and high-fee structure that public chains create in order to incentivize validators structurally drive user dispersion, making fragmentation an endogenous feature of decentralized economies rather than the result of external competition. An empirical study of Uniswap by Lehar et al. (2023) [45] finds that high-fee pools attract 58% of liquidity supply but execute only 21% of trading volume, indicating that fixed transaction costs produce a systematic stratification of liquidity providers.

Cross-chain fragmentation exposes the system to extremely high security risk. Data from Chainalysis (2022) [46] show that in just the first eight months of 2022, about $2 billion in crypto assets was stolen in 13 separate cross-chain bridge hacks, 69% of the total stolen that year. The cumulative losses from cross-chain bridges have reached the scale of billions of dollars (the DefiLlama data compiled by Chainlink put the figure

at more than $2.5 billion) [11]. The failure of a cross-chain bridge not only causes direct fund losses but can also destroy all downstream derivatives positions collateralized by bridged assets: when bridged WETH or WBTC depegs because the bridge contract is breached, all perpetual futures positions using these assets as margin face simultaneous liquidation, forming "collateral-level contagion." The on-chain version of fragmentation is not merely an economic problem of reduced price-discovery efficiency but a technical problem that threatens the security of the entire ecosystem. Traditional finance's fragmentation can be mitigated through regulatory coordination and market-data consolidation, whereas the solution to on-chain fragmentation must address the dual challenge of economic efficiency and technical security at once.

5.5.4 Closing gaps and low-liquidity amplification

Information accumulated during a traditional financial market's closure is usually released at the open in the form of a price gap. To digest overnight information and smooth the price shock, traditional exchanges introduced mechanisms such as the call auction to provide a price-discovery window before formal continuous trading begins. This discrete closure-open rhythm creates a discontinuity in information release, but it also provides market participants a time window to reassess positions and adjust risk-control parameters.

On-chain finance's around-the-clock trading eliminates the discrete closure period, but liquidity displays marked periodic variation across different time windows. Hansen et al. (2024) [47] find that cryptocurrency volatility and volume exhibit systematic intraday and intraweek patterns, and that these patterns strengthen over time, possibly driven by algorithmic trading and futures-market settlement schedules. During Asian hours or on weekends, market liquidity falls significantly, and the impact of large orders is extremely amplified. Makarov and Schoar (2020) [48] document persistent, sizable arbitrage opportunities across cryptocurrency exchanges, with price deviations especially pronounced across national exchanges and widening further during periods of rapid price increase. Research by Mourey et al. (2025) [49] further confirms a "weekend effect" in crypto markets, noting that negative weekend returns and high volatility can even predict weak Monday equity-market performance, and that this effect became more pronounced after the 2022 LUNA collapse.

Because they lack the closure-period shock absorber of traditional finance, the continuous impact of information during low-liquidity windows replaces the concentrated release at the open, raising the market's intrinsic volatility. This poses distinctive challenges for service providers. The risk-control system must respond in real time while the market is running and cannot, like a traditional futures exchange, perform system maintenance and parameter adjustments after the close. Market makers must bear higher inventory risk and widen their spreads during low-liquidity windows, and any system vulnerability can cause an irreversible loss before the operations team can intervene. Chapter 22 will analyze the implications of 24/7 volatility in depth, and Chapter 23 will examine the distinctive mechanism of volatility clustering in a market without shock absorbers.

5.5.5 The cross-modal risk transmission path

The risk transmission between centralized and decentralized architectures forms a tightly coupled cyclical system whose transmission speed far exceeds the cross-market contagion of traditional finance. This transmission path can be characterized precisely in four steps. In the first step, large-scale liquidation on the centralized-exchange side causes a sharp price drop, and highly leveraged positions are forcibly liquidated, generating concentrated selling pressure. In the second step, the oracle network collects the centralized exchange's price data and passes it to the mark-price system of the on-chain decentralized exchange, so that the on-chain price reflects the centralized market's decline almost synchronously. In the third step, the update of the decentralized exchange's mark price triggers on-chain liquidations, and the liquidation flow hits the liquidity pool or order book, further depressing the on-chain price. In the fourth step, arbitrageurs buy low on the decentralized exchange and sell on the centralized exchange, adding to the centralized exchange's selling pressure and causing the price to fall further, thereby completing one positive-feedback cycle. This theoretical arbitrage loop, however, can be blocked in extreme conditions by a key execution friction: a centralized exchange may freeze withdrawals during a crisis. As an "emergency circuit breaker," a withdrawal freeze has a double-edged effect: while it stops risk from transmitting from the centralized market to the chain, it also stops users from moving assets to the safe option of self-custody, and it can cause a persistent cross-venue price divergence, because arbitrageurs cannot execute the cross-platform convergence trade.

It should be noted that the four-step linear cycle above is a simplified model. Actual cross-modal transmission is a nonlinear network structure containing multiple feedback loops operating in parallel (such as the funding-rate feedback, the liquidity-withdrawal feedback, and the collateral-value feedback). These loops may behave as negative feedback (self-stabilizing) under normal market conditions, but under certain conditions—such as when multiple loops switch to positive feedback simultaneously—they can produce a resonance effect that amplifies systemic risk far beyond the predictions of a linear model.

Moreover, cross-modal transmission is not confined to an internal loop within crypto markets. Macro-financial factors such as the U.S. dollar liquidity cycle constitute an important external trigger for systemic shocks in crypto markets. The macro backdrop of FTX's collapse was the repricing of global risk assets caused by the Federal Reserve's aggressive rate hikes in 2022; a tightening of dollar liquidity transmitted to the crypto-derivatives market through common holders (institutional investors holding both traditional risk assets and crypto assets), triggering deleveraging and selling. This bidirectional macro-crypto transmission means that a systemic-risk assessment of perpetual futures markets cannot be confined to the crypto ecosystem alone but must also incorporate global macro-liquidity conditions.

This transmission process is amplified by three key factors. The immediacy of the oracle keeps prices in the centralized and decentralized markets nearly synchronous, eliminating the cross-market risk buffer that settlement delay provides in traditional finance. Around-the-clock trading means transmission can occur at any time, including the low-liquidity hours of the early morning, making the shock effect more severe. High

leverage ensures that every price drop can trigger fresh liquidations, accelerating the positive feedback loop.

Naifar and Makni (2025) [50] provide empirical evidence of cross-modal contagion in their analysis of the FTX collapse. The study finds that after the extreme event, Bitcoin's outward directional connectedness jumped from 67.00 to 82.21, and the intra-group spillover among DeFi tokens likewise strengthened significantly, with Uniswap's risk reception doubling from 14.89 to 30.92. These data indicate that shocks in the centralized market transmit efficiently to the decentralized ecosystem through oracles and arbitrage mechanisms, and that the two modes are tightly linked at the macro-risk level by the same underlying price. Each platform's risk-control system can set parameters only from a local perspective and cannot assess the systemic risk level of the whole market, and this information asymmetry constitutes a systemic-risk hazard in the current perpetual futures market.

The four isomorphic mappings above share a common feature: the underlying economic mechanism remains unchanged, but the on-chain environment introduces fundamental differences in transmission speed, scale amplification, and security dimension. Adverse selection changes from passive fills against active quotes to active arbitrage against passive liquidity; the margin cascade accelerates from day-scale transmission to the minute scale; market fragmentation expands from an economic-efficiency problem to a technical-security problem; and the closing gap changes from a discrete release at the open to a continuous impact during low-liquidity windows. Table 5-3 lays out these four mappings and their shared underlying mechanisms, and the fourth column marks where each is analyzed in depth in later chapters. As the table shows, the third column of each mapping—the "core isomorphic mechanism"—points to the same underlying logic: whether adverse selection or the margin cascade, the driving mechanisms of information asymmetry and leverage amplification are essentially the same across different technical environments; only the transmission speed and scope of impact change by orders of magnitude because of the characteristics of the on-chain environment.

Old problem in traditional finance	New form in on-chain finance	Core isomorphic mechanism	Deeper analysis in later chapters
Adverse selection: market makers face informed traders	Impermanent loss: AMM liquidity providers face arbitrageurs	Liquidity providers are systematically drained of value by the better-informed party	Chapter 19
Margin cascade: margin calls trigger forced liquidations	Liquidation cascade: high leverage triggers chained liquidations that propagate across platforms via oracles	Self-reinforcing positive feedback in leveraged systems; two orders of magnitude faster on-chain	Chapters 20 and 22
Market fragmentation: the same asset trades on multiple exchanges	Cross-chain fragmentation: liquidity is dispersed across chains and cross-chain bridges are weakly secured	Dispersed liquidity reduces price-discovery efficiency; on-chain adds a security dimension	Chapter 14
Closing gap: information accumulated during the closure is released at the open	Low-liquidity amplification: in 24/7 continuous trading, shocks are amplified in the early morning and on weekends	A timing mismatch between information release and liquidity supply	Chapters 22 and 23

The four steps of this transmission cycle—liquidation on the centralized exchange triggering a price drop, the oracle transmitting the price on-chain, on-chain liquidation generating fresh selling pressure, and arbitrageurs transmitting the shock back to the

centralized market—form a closed positive-feedback loop, and three factors, the immediacy of the oracle, around-the-clock trading, and high leverage, together amplify the transmission efficiency of this loop (Figure 5-14).

The four-step cyclical path of cross-modal risk transmission (a schematic of the cross-modal transmission mechanism, not empirical data; a simplified model—the actual structure is a nonlinear multi-loop network, as detailed in the text; the connectedness values from [50] appear in the text; Data source: Naifar and Makni [50])

5.6 Effects on market microstructure

Differences in service-provider architecture ultimately transmit systematically to the core dimensions of market microstructure. Four dimensions—price-discovery efficiency, the mode of liquidity supply, the structure of transaction costs, and the distribution of systemic risk—together determine the operating quality of a market. This section builds, for each dimension, a causal chain of "architecture choice affects microstructure," identifying the core variables and transmission paths; detailed quantitative analysis will follow in the corresponding later chapters.

5.6.1 The reconstruction of price discovery

Price discovery is the process by which a market aggregates dispersed information about an asset's fundamental value into a single price. In centralized exchanges and on-chain central limit order books, price forms through the bidding contest between buyers and sellers, following the traditional supply-and-demand-driven pattern. Market makers' quoting behavior, the distribution of limit orders, and the impact of market orders together determine the path of price formation. In a decentralized exchange that relies

on oracle pricing, by contrast, the platform outsources pricing entirely, becoming a price taker rather than a price discoverer. Research by Chen et al. (2024) [51] shows that in oracle-based decentralized exchanges, traders tend to react to external price sources rather than contribute new price information through their own trading. This design may cause price-discovery lag, but it also avoids the price distortion that would arise from insufficient in-house liquidity. A comparative study by Barbon and Ranaldo (2024) [52] finds that decentralized exchanges may offer more competitive execution costs on large trades, but the presence of gas fees creates persistent arbitrage opportunities that interfere with the efficiency of price discovery.

In perpetual futures markets, the funding rate constitutes a distinctive dimension of price discovery. The funding rate is not only the mechanism that maintains the anchoring of the contract price to the spot price; it is itself a key indicator of market sentiment and of the balance of long and short forces. Differences in settlement frequency across service providers directly affect the speed of price convergence: centralized exchanges usually settle every 8 hours, whereas some app-chains achieve hourly or even more frequent settlement, and a higher settlement frequency means faster price convergence and smaller basis fluctuations. Specifically, under an 8-hour settlement cycle, the basis can accumulate to a significant level within the settlement interval, offering basis arbitrageurs an ample window to operate; hourly settlement compresses this window, reducing basis fluctuation but also raising the sensitivity of arbitrage strategies to latency; and continuous settlement (such as the per-block settlement achieved by some app-chains) compresses, in theory, the basis-arbitrage space to the block-interval level, rendering traditional funding-rate arbitrage strategies economically more marginal. Differences in the funding rate across platforms create cross-platform arbitrage opportunities that objectively promote the convergence of the global price, but they also expose arbitrageurs to several entirely different risk frameworks simultaneously—the counterparty risk of the centralized exchange, the smart-contract risk of the on-chain protocol, and the cross-platform settlement-timing risk all act on the arbitrageur's position portfolio at once. Chapters 13 through 15 will systematically develop the analysis of price discovery.

5.6.2 The evolution of liquidity supply

The mode of liquidity supply under different architectures reflects a trade-off between barriers to access and professional risk-management capability. A centralized exchange's liquidity is provided mainly by professional market makers, who use high-frequency algorithms and complex inventory-management models to control risk and can provide extremely deep liquidity, but from highly concentrated sources. Harris (2003) [3] defines a market maker as "a trader who provides immediacy to the market," whose profit comes from the bid-ask spread as compensation for the liquidity demand of uninformed traders. In a centralized exchange, a market maker's barriers to entry include technical infrastructure, capital scale, and a cooperative relationship with the exchange, and these barriers concentrate liquidity supply in the hands of a few professional institutions.

Automated market makers lower the barrier to liquidity supply to the minimum, al-

lowing any asset holder to become a liquidity provider. A passive liquidity provider, however, must bear the full adverse-selection cost, and capital efficiency under the constant-product model is generally low, with a large amount of capital allocated to price ranges that will in fact never be used. Although the concentrated-liquidity design raises capital utilization by several orders of magnitude, it essentially turns passive supply into a position that requires active management, placing higher demands on the professional ability of ordinary users. Research by Milionis et al. (2022) [42] shows that in a concentrated-liquidity environment, the behavior pattern of liquidity providers is closer to that of a traditional market maker than to that of a passive asset holder, and their returns depend on the quality of range selection and rebalancing strategy. On-chain order books, in turn, seek a balance between low barriers and professional risk management, usually combining professional market makers with protocol-level market-making vaults to maintain liquidity, so that professional institutions and ordinary users can participate in liquidity supply in different ways within the same market. Chapter 19 will develop the full analysis of market-making economics.

5.6.3 Structural differences in transaction costs

The structure of transaction costs differs fundamentally across architectures and can be analyzed at three levels: explicit costs, implicit costs, and architecture-specific costs. Explicit costs mainly comprise trading fees and network gas fees. Centralized exchanges usually offer the lowest fees and grant tiered discounts to large traders, whereas a decentralized exchange's explicit costs are affected by the congestion of the underlying network, and gas fees on Ethereum mainnet can make small trades uneconomic, although the development of layer-2 networks and app-chains is significantly lowering this cost.

Implicit costs are often more important than explicit costs. Because of concentrated liquidity, a centralized exchange has relatively small slippage and price impact, and large orders can be executed within a narrower price range. In an automated market maker, slippage constitutes the main implicit cost, its size depending on the ratio of trade size to the depth of the liquidity pool. In addition, different architectures have their own distinctive cost types. A centralized exchange operator has a global view of all order flow and could in theory abuse this information; this cost is hard to observe and quantify but can have a systematic effect on users' actual execution quality. On-chain markets, by contrast, face MEV costs. Adams et al. (2024) [53] find that when trading volatile assets, the probability of encountering adversarial slippage is 80% higher than when trading mature assets, and MEV-extraction behavior such as sandwich attacks constitutes a significant implicit cost for on-chain traders. Wu et al. (2025) [54] tracked 19 months of CEX-DEX arbitrage activity and found that just 19 major searchers extracted $233.8 million in value through more than 7.2 million arbitrage events, with the top three searchers accounting for three-quarters of the total value extracted, indicating a highly concentrated trend in MEV extraction. An app-chain architecture, by imposing order-ordering rules at the consensus level, can reduce certain types of MEV from the base layer to some extent—a structural advantage that general-purpose-chain decentralized exchanges struggle to achieve. Although a precise cross-venue cost comparison is limited by data availability and the continual change

in market conditions, order-of-magnitude estimates offer a reference: for a $1 million BTC-PERP trade, the total transaction cost (fees plus slippage) at a leading centralized exchange such as Binance is about 2 to 4 basis points; at an on-chain order book such as Hyperliquid, about 3 to 6 basis points; and the explicit cost (fees plus price-impact fee) of an oracle-pricing model such as GMX, about 6 to 10 basis points, though its zero-slippage feature may make it competitive on very large trades. These values fluctuate with market liquidity and volatility, but the order-of-magnitude differences reflect the structural differences in execution efficiency across architectures.

5.6.4 The distribution of systemic risk

Systemic risk takes markedly different distributional forms across architectures, and this difference directly affects the design of regulatory strategy and risk-management frameworks. The risk of the centralized-exchange model is highly concentrated in a few entities. Dell'Erba (2025) [55] points out that the crypto-derivatives market is replicating the "too big to fail" (TBTF) structure of traditional finance, with a few leading exchanges concentrating the vast majority of trading volume and user assets. In traditional finance, however, the TBTF problem is accompanied by an implicit government guarantee: systemically important institutions can obtain central bank liquidity support and fiscal bailouts in a crisis, whereas centralized entities in crypto markets enjoy no safety net, and FTX's actual collapse proves that they are in essence "too big and will fail." This distinction means that the systemic consequences of concentration in crypto markets may be more severe than in traditional finance. Similar concentration risk is also forming at the on-chain-protocol level: if a leading protocol such as Hyperliquid dominates most of the trading volume of the on-chain perpetual futures market, its failure would not only cause direct user losses but could also destroy the market's trust in the entire on-chain derivatives model, producing an ecosystem-contagion effect far beyond the scope of a single protocol. FTX's collapse is an extreme expression of concentration risk: the failure of a single institution directly caused enormous fund losses and triggered a broad crisis of industry trust. Research by Jalan and Matkovskyy (2023) [56] argues that the FTX episode was in essence a failure of corporate governance and regulation rather than a defect of crypto assets themselves, and that the systemic risk of crypto markets actually peaked in 2021 because of China's regulatory tightening.

The on-chain model disperses risk across multiple independent protocols, and the failure of a single protocol usually does not directly cause the system to collapse. The composability of decentralized finance, however, constitutes an efficient channel for risk contagion. A report by the Financial Stability Board (2023) [40] emphasizes that the mutual nesting and dependence among protocols allow the risk of one protocol to transmit rapidly to the entire ecosystem, its main vulnerabilities being operational fragility, liquidity and maturity mismatch, leverage, and interconnectedness. In the Terra/LUNA episode, the depegging of the algorithmic stablecoin triggered a downward spiral that caused chained liquidations across multiple lending protocols, with a lasting negative impact on the entire decentralized-finance ecosystem. The cross-modal contagion mechanism (as described in Section 5.5.5) further links the centralized and decentralized markets tightly, together forming a complex and fragile risk network. The Financial Stability Board (2023) [40] also notes that although the 2022 crypto-market

turmoil and FTX's collapse had a limited impact on the traditional financial system, spillover effects could strengthen significantly in the future as the ties between the two systems deepen. Chapter 20 will provide a formal analysis of cross-dimensional contagion through the reflexivity triangle model, and Chapter 25 will build a comprehensive evaluation framework for market quality.

5.7 Chapter summary

From traditional finance to centralized exchanges and then to on-chain protocols, the evolution of the service-provider ecosystem is not a linear process of progress but a continuous transformation of the risk surface. Each new architecture, while dissolving the core risks of its predecessor, necessarily introduces a set of new risks of a different nature. Understanding this dynamic is the prerequisite for making a rational service-provider choice.

The five theoretical tools proposed in this chapter provide a systematic analytical framework for this understanding. The risk substitution theorem shows that no zero-risk architecture exists, only a choice among types of risk, and that the criterion for the choice is not which architecture is absolutely safer but which risk is more manageable and more hedgeable for a particular user. The service provider's trilemma reveals the inherent conflict among performance, transparency, and decentralization that cannot all be had at once; any service provider can only choose its own position within the triangle, and although frontier technologies such as zero-knowledge proofs are trying to expand the area of the triangle, they cannot eliminate the constraint of the triangle itself. The concept of the bundling tax reveals the hidden cost of a centralized exchange's efficiency: while enjoying ultra-fast trading and a convenient experience, users pay the price of opacity, conflict of interest, and single points of failure—which forms, with the trust tax that traditional finance pays to achieve functional separation (discussed in Chapter 1), the two ends of the same trade-off. The verifiability ladder makes trust cost concrete: the five-level standard from fully unverifiable to fully verifiable shows that every increase in verifiability comes at the cost of a higher cost of technical understanding. And the old-problems-in-new-forms perspective reminds us that many of on-chain finance's challenges are essentially the technical recurrence of traditional finance's old problems: adverse selection, the margin cascade, and market fragmentation appear in the on-chain environment as impermanent loss, the liquidation cascade, and cross-chain fragmentation, and although their transmission speed and scale change fundamentally, the underlying mechanisms remain isomorphic.

The purpose of these theoretical tools is not to judge which service provider is superior but to give market participants a framework for rational choice grounded in understanding rather than faith. A mature trader should combine multiple service providers according to personal risk preference, technical ability, and trading needs, so as to achieve the best balance of risk and return. For users with lower risk tolerance and limited technical ability, a regulated centralized exchange may be the more reasonable starting point; for users who pursue asset self-sovereignty and possess the ability to understand the technology, on-chain protocols offer a transparency and verifiability that a traditional architecture cannot achieve.

This chapter has conducted a static analysis of the current service-provider ecosystem. One trend worth watching is that the boundary between the centralized and decentralized models is blurring: some centralized exchanges are beginning to migrate the settlement layer on-chain to improve transparency, while some on-chain protocols are moving closer to centralized platforms at the user-experience layer to lower the barrier to use. Chapter 6 will shift from static analysis to dynamic analysis, examining how the three paradigms evolve through competition, how price-discovery power shifts among different architectures, and whether this convergence trend will produce a hybrid model combining the strengths of both or instead create new systemic risks.

The Evolution and Trade-offs of Perpetual Futures Market Structure

A single 10x-leveraged long position in ETH perpetual futures traverses markedly different execution paths on a centralized exchange (CEX), a general-purpose public-chain decentralized exchange (DEX), and an application-chain DEX. On a centralized exchange, the order is matched within 500 milliseconds at fees as low as 0.02%, yet the margin is held in the exchange's centralized wallet; what the user holds is merely a claim recorded in a database, the order-sequencing process is entirely opaque to outsiders, and the 2022 collapse of FTX—which exposed a customer-fund shortfall of roughly $8.7 billion—revealed the systemic risk inherent in this custodial structure [1]. On a general-purpose public-chain DEX built on Ethereum, the user retains sovereignty over assets through a self-custodial wallet, but trading intent is exposed in the public mempool, where a sandwich attack can convert 0.3% of slippage into profit for maximal extractable value (MEV) searchers [2], so the price of asset sovereignty is an implicit *transparency tax*. On an application-chain DEX, the user obtains sub-second matching and near-zero slippage while retaining on-chain self-custody, yet the underlying network may be maintained by only a dozen or so validator nodes, and the risk of validator collusion becomes a new trust assumption.

These three execution paths epitomize the structural transformation now under way in crypto derivatives markets, which grew rapidly in 2025. CEX perpetual futures volume reached approximately $86.2 trillion, up 47.4% year over year [3]. The more striking change, however, occurred in decentralized markets: DEX perpetual futures volume grew 346% year over year in 2025, reaching approximately $6.7 trillion [3]. The ratio of DEX to CEX perpetual futures volume climbed from 2.1% in early 2023 to 11.7% by November 2025—roughly one DEX trade for every nine CEX trades at that ratio [4]. Within this shift, application-chain DEXs led by Hyperliquid at one point captured roughly 60% of the on-chain perpetual futures market, with annualized volume rivaling that of established CEXs such as Coinbase [5].

These figures reflect a deep transformation in the market's fundamental structure. The migration of volume from CEXs to DEXs is not merely a reallocation of market share; it signals that the market's basic rules are being redefined. How prices form, how participants compete, how risk is distributed, and how fairness is defined are all undergoing

fundamental change. Drawing on the market-microstructure methodology of Harris (2003) [6], this chapter builds an analytical framework that dissects how each structure shapes the economic activity and power relations within it, rather than simply judging which is superior.

This chapter argues that the evolution of market structure is not a linear replacement of CEXs by DEXs but a paradigm shift in the mode of competition. The object of competition migrates from *latency* to *information* and then to *mechanism*, and each migration redefines who wins and who loses. Beginning with the micro-level trade lifecycle, the chapter advances a competition-mode migration thesis, examines the rise of strategic MEV in depth, explores the price-discovery migration hypothesis, analyzes the evolution of risk distribution, and finally considers the convergence and endgame of the three paradigms.

6.1 The trade lifecycle

The execution path of a trade—from order submission through matching to final settlement—is far more than a technical distinction. It fundamentally determines how information flows, how power is allocated, and how costs arise. Chapter 5 performed a *static dissection* of the internal components and risks of the three architectures from the service provider's perspective; this section shifts the vantage point, tracing a trade's complete journey through the three architectures from the trade's own point of view. This complementary perspective reveals the sharply different trade-offs that centralized exchanges, general-purpose public-chain DEXs, and application-chain DEXs make among performance, transparency, security, and cost, providing a solid factual basis for the competition-mode analysis in Section 6.2.

Figure 6-1 compares the essential differences among the three paradigms across four stages: order submission, matching, settlement, and asset custody.

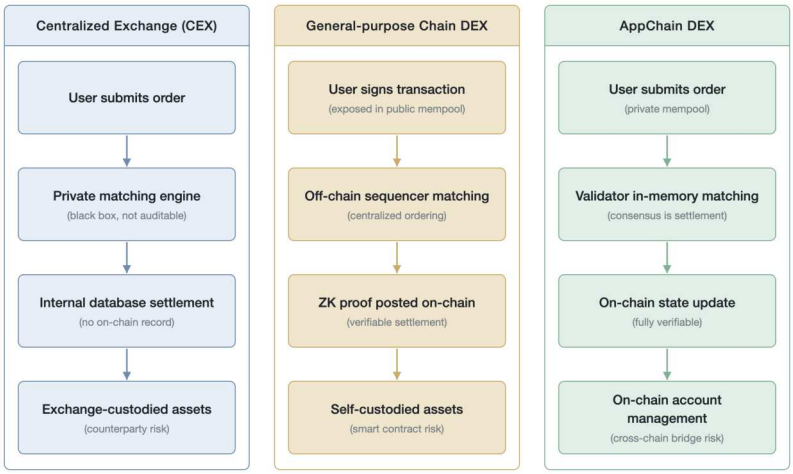

Figure 6-1. Comparison of the trade execution flow across the three perpetual futures market-structure paradigms (a conceptual process comparison, not empirical data; drawn by the author, based on Harris [6])

6.1.1 Centralized exchanges

A centralized exchange is operated by a single entity whose private, centralized servers maintain the order book, match trades, and custody user assets. A user's trading records are merely entries in an internal database, interacting with the blockchain only at deposit and withdrawal. The core advantage of this architecture is high performance: the internal latency of top-tier matching engines has reached the sub-millisecond and even sub-100-microsecond range, while end-to-end response latency from API submission to confirmation is typically between 1 and 10 milliseconds, with throughput exceeding a million orders per second—a level no on-chain solution can currently match.

Order submission stage. A user submits a limit order or market order to the exchange's private servers through an API or web front end. From that moment, the trade enters an execution environment entirely opaque to the outside world. The user cannot verify which internal systems the order passes through before matching, cannot confirm whether sequencing strictly follows price-time priority, and cannot know whether the exchange itself or its affiliates enjoy some privilege in the order flow. This opacity is the structural root of information asymmetry in CEX markets. The exchange holds real-time order-flow data for all users, data of extremely high value for anticipating short-term price movements. This informational advantage creates structural room for potential unfairness. The flow of benefits between FTX and its affiliated trading firm, Alameda Research, is an extreme manifestation of this structural risk [1].

Matching stage. The high-performance matching engine scans the order book at microsecond speed, pairing buy orders with market makers' sell orders under price-time priority. It is here that the core game of the CEX paradigm—the adverse-selection game—unfolds. Market makers sustain market liquidity by quoting on both the bid and ask sides, earning their profit from the bid-ask spread. Their greatest risk, however, is being exploited by better-informed traders: when the market is about to move directionally, informed traders quickly hit the stale quotes that market makers have not yet updated, inflicting losses on the market makers.

Facing adverse-selection risk, market makers have two basic responses. The first is to widen the bid-ask spread, compensating for expected adverse-selection losses with a higher margin, though this reduces the competitiveness of their quotes. The second strategy has come to dominate in practice: increase speed, updating or withdrawing stale quotes faster than informed traders can act. This logic of *speed as survival* has driven a continuous arms race around infrastructure latency. Institutions with colocation services place their servers in the same physical space as the exchange's data center to minimize network latency; some deploy custom hardware such as field-programmable gate arrays (FPGAs) to accelerate trading logic at the physical layer, or use microwave communication networks in pursuit of a microsecond-level speed edge. This latency race, which has run for decades in traditional financial markets, is now replicated in full in crypto CEXs. As a result, market-making profits are highly concentrated among a handful of institutions with top-tier infrastructure, such as Wintermute, Jump Trading, and Cumberland.

The CEX fee structure further reinforces this competitive landscape. The mainstream maker-taker model rebates fees to makers who provide liquidity and charges higher

fees to takers who consume it. Institutional market makers, as the primary makers, enjoy fee discounts or even negative fees, whereas retail traders, as takers, pay higher transaction costs. Seen this way, the fee structure is itself an institutionalized cost-transfer mechanism, shifting the implicit cost of sustaining liquidity from market makers onto ordinary traders.

Settlement stage. Once matching succeeds, settlement completes instantly on the exchange's internal ledger. This is essentially just an update of database account balances, involving no blockchain operation. Although extremely fast and cheap, what the user holds is not a genuine on-chain asset but a liability the exchange owes the user. The safety of assets depends entirely on the exchange's solvency and operational integrity. The 2022 collapse of FTX exposed a customer-fund shortfall of roughly $8.7 billion (per the debtors' estimate and the August 2024 court restitution order) [1][53], and the $1.5 billion security incident suffered by Bybit in February 2025 [7] both plainly reveal the systemic risk embedded in this centralized custodial structure. Notably, these two events belong to entirely different categories of operational risk: FTX was a governance and fraud failure, whereas the Bybit incident was a supply-chain attack in which the attacker—attributed to the Lazarus Group—manipulated the signing-ceremony interface of the Safe{Wallet} front end to induce multisig holders to sign a malicious transaction. This UI-layer attack vector is not unique to CEXs; any system relying on multisig approval—including DEX treasury management, cross-chain-bridge operator multisigs, and application-chain governance wallets—faces the same class of risk. In enjoying peak performance, the user in effect entrusts the entire security of their assets to an unauditable third party.

Risk management. The liquidation engine monitors the margin level of every account in real time. When the mark price (typically computed as the index price across multiple exchanges plus a funding-rate basis smoothed by an exponential moving average, or EMA) drives an account's margin ratio below the maintenance-margin requirement, the system automatically triggers forced liquidation. This mark-price methodology differs fundamentally from the oracle-based mark price used in DEXs, a design difference analyzed further in the discussion of oracle manipulation in Section 6.3.2. If a shortfall arises during liquidation—that is, if the liquidation proceeds are insufficient to cover the loss—the loss is borne by the exchange's insurance fund. Should the insurance fund be exhausted in extreme conditions, the remaining loss is allocated by rule to traders on the profitable side through an auto-deleveraging mechanism. The entire risk-control process, from margin calculation through liquidation execution to the use of the insurance fund, runs inside a *black box* that outsiders cannot independently audit. Users can neither verify the fairness of liquidation prices nor confirm the true size and use of the insurance fund.

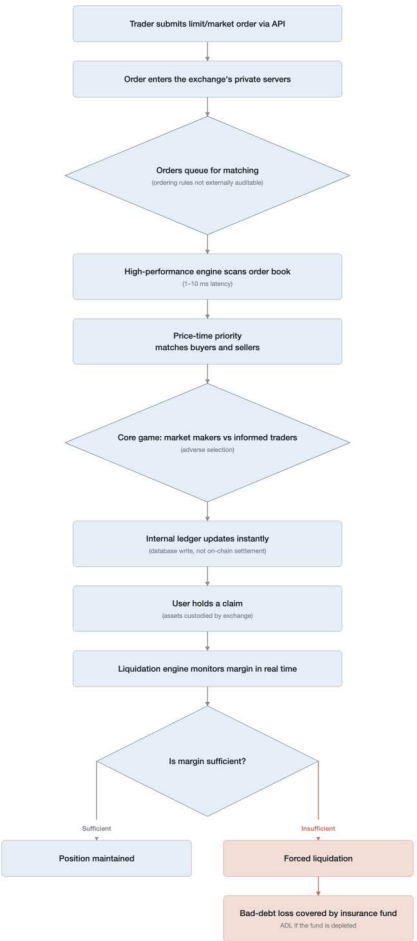

Figure 6-2. The trade lifecycle on a centralized exchange (from order submission to settlement and risk control, completed entirely within the exchange's private servers; a mechanism-process schematic in which the 1-to-10-millisecond figure refers to end-to-end response latency, not empirical data; drawn by the author, based on Harris [6])

6.1.2 General-purpose public-chain DEXs

A general-purpose public-chain DEX deploys its core settlement logic on a public blockchain while executing some functions—such as order-book maintenance and matching—off-chain. This hybrid model of *off-chain matching, on-chain settlement* seeks a balance between the security of the blockchain and the performance of trading. Representative general-purpose public-chain DEXs today include GMX v2 and Vertex on Arbitrum. Notably, the early architecture typified by dYdX v3 (built on StarkEx) has undergone a major transformation: dYdX v4 migrated to a standalone application chain based on the Cosmos SDK at the end of 2023 and, under this chapter's taxonomy, now falls within the application-chain DEX category—a migration that is itself strong evidence for the competition-mode migration thesis in Section 6.2. Its typical

architecture is based on ZK-Rollup technology, with an off-chain sequencer handling high-speed matching and on-chain smart contracts handling final state verification and asset custody.

Order submission stage. A user cryptographically signs the trade with a self-custodial wallet. Before the trading intent is finally confirmed and packed into a block, it is typically exposed in the public mempool. The public mempool is the cornerstone of blockchain transparency: it ensures that all pending transactions are visible to every participant in the network, safeguarding the system's auditability. Yet this same transparency makes pending transactions highly vulnerable to MEV extraction. MEV searchers continuously scan the mempool with specialized algorithms, and once they spot a large order, they extract value from it through a variety of strategies.

The most common forms of MEV attack include the following. Front-running: after detecting a large buy order, the searcher buys ahead of it at a lower price and sells for a profit once the large order pushes the price up. The sandwich attack: the searcher inserts a buy and a sell transaction, respectively, before and after the target transaction, capturing a risk-free profit from the target's price impact. And liquidation sniping: the searcher monitors the margin status of on-chain positions and, when liquidation conditions are about to trigger, front-runs the liquidation to capture the reward the protocol offers. The common feature of these attacks is that they all rely on the trading-intent information exposed by the public mempool.

The MEV value chain and the multi-tier auction. The competitive relationship in a general-purpose public-chain DEX is fundamentally different from that in a CEX. In a CEX, the core game plays out between market makers and informed traders and centers on the asymmetry of price information. In a general-purpose public-chain DEX, the core game plays out between active MEV searchers and passive ordinary traders and centers on the speed and strategic depth with which public information is exploited.

MEV extraction forms a layered value chain. Ordinary traders are the source of value; their trading intent is exposed in the mempool. MEV searchers capture arbitrage opportunities through algorithmic scanning and send carefully constructed *arbitrage bundles*, together with a bribe fee, to block builders. Block builders select the profit-maximizing combination from the bundles submitted by many searchers, assemble a complete block, and submit it to validators. Validators select the highest-bidding block to propose and confirm. The total cost of this multi-tier auction is ultimately borne by ordinary traders, while the profit is distributed among searchers, builders, and validators according to the equilibrium of the game.

In a thematic report released in July 2025, the European Securities and Markets Authority (ESMA) noted that MEV searchers typically pay the vast majority of their revenue—roughly 85% to 93%—to block proposers, making the right to order transactions an extremely scarce resource [2]. ESMA further noted that MEV poses a potential threat to market fairness and investor protection, marking the problem's formal entry into the field of view of global financial regulators. This judgment bears a deep structural resemblance to traditional financial markets' regulatory concerns about high-frequency trading; both involve the systematic exploitation of an informational advantage and the fairness issues that result.

Matching and settlement stage. Orders are sent to an off-chain sequencer for matching. The sequencer packages a batch of matched trades, generates a zero-knowledge proof (such as a ZK-STARK), and submits it to a smart contract on the Ethereum mainnet for verification. The core advantage of this design is that it guarantees the correctness of settlement at the mathematical level: even if the sequencer tries to forge trade results or tamper with account balances, the on-chain zero-knowledge-proof verification mechanism can detect and reject the invalid state transition. Users need not trust the sequencer's honesty—only the correctness of the mathematics.

Nevertheless, the centralization of the sequencer itself remains a risk worth attention. A sequencer outage means the entire exchange halts, and users cannot execute any trades or adjust positions during that time. On top of this, the sequencer could in theory selectively delay or reject transactions, though such behavior can be detected after the fact. To mitigate this risk, most Layer-2 designs include a *forced-exit* mechanism that lets users withdraw assets directly through the mainnet contract when the sequencer fails, ensuring assets cannot be permanently locked.

Risk management. In sharp contrast to the *black-box* risk control of a CEX, the liquidation logic of a general-purpose public-chain DEX is hard-coded into on-chain smart contracts. Anyone can monitor the margin status of on-chain accounts and, when liquidation conditions trigger, call the contract function to perform the liquidation and capture the reward the protocol offers. This permissionless, open liquidation market greatly enhances the system's overall stability, because liquidation no longer depends on the risk-control capacity of a single entity but is maintained jointly by participants across the entire network. Yet this mechanism brings both benefit and risk: in extreme conditions, all participants can see in real time which positions are about to be liquidated, which can produce a *liquidation cascade*—a large number of liquidations triggering at once, further depressing the price, triggering still more liquidations, and forming a vicious cycle. In addition, code vulnerabilities in the smart contracts themselves are a risk source that cannot be ignored; once a contract is attacked, losses can be catastrophic and hard to reverse.

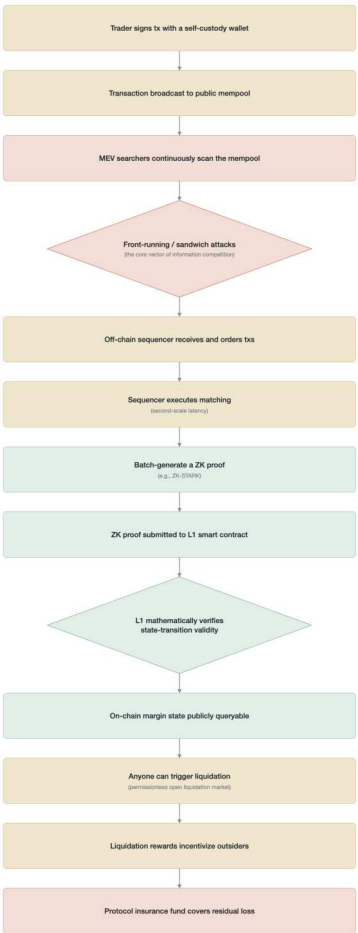

Figure 6-3. The hybrid execution path of a general-purpose public-chain DEX (after the trade is exposed in the public mempool, it is matched by an off-chain sequencer and finally settled on the mainnet via a ZK proof; a conceptual process schematic, not empirical data; drawn by the author, based on ESMA [2] and Harris [6])

6.1.3 Application-chain DEXs

The application-chain DEX represents a third direction in the evolution of market structure. It builds the entire exchange—order book, matching engine, settlement, and risk management—as an independent, sovereign blockchain deeply optimized for trading. For application-chain protocols typified by dYdX Chain (built on the Cosmos SDK) and Hyperliquid, the core idea is this: the architecture of a general-purpose public chain cannot provide sufficient performance or room for customization for high-frequency trading, so a dedicated chain must be purpose-built for the exchange [5].

Full-stack control and extreme performance optimization. Unlike a general-purpose public-chain DEX, which deploys smart contracts only at the application layer, an application-chain team holds full-stack control, spanning the application layer (ex-

change logic), the consensus layer (the validator network), the network layer (node communication), and the data layer (state storage). This full-stack control creates room for high-performance optimization. In a traditional blockchain architecture, a transaction must pass through several steps—mempool broadcast, block packing, and consensus confirmation—before it can finalize. In an application chain, these steps are deeply integrated and optimized: the order book is maintained directly in validators' memory, and matching logic is embedded in the consensus process itself. Take Hyperliquid's HyperBFT consensus protocol: matching and confirmation complete in the same step, achieving sub-second confirmation latency and giving users an experience close to that of a CEX. The operational risk of Byzantine fault-tolerant (BFT) consensus, however, cannot be ignored: when the leader node goes offline, the protocol must perform a view change (leader rotation), during which no blocks are produced and no transactions are confirmed. For a perpetual futures exchange, a consensus interruption of several seconds amid volatile conditions can prevent users from adjusting margin or closing positions, thereby triggering passive liquidation.

Order submission and matching stage. A user's signed order is sent directly to validator nodes and enters a private mempool. In sharp contrast to the public mempool of a general-purpose public-chain DEX, trading intent in a private mempool is not broadcast network-wide and is visible only to the validator currently responsible for producing the block. This design structurally and substantially weakens external searchers' sandwich attacks and front-running, because searchers can hardly scan pending transactions, making these traditional forms of MEV technically very difficult. The private mempool does not eliminate MEV, however; it concentrates MEV-extraction capability, moving it from a group of openly competing searchers to the leader validator currently responsible for producing the block, creating a monopolistic window for MEV extraction. In the absence of verifiable ordering rules—such as first-in-first-out (FIFO) ordering enforced by a ZK proof—a validator can freely order transactions during its leader round, and the covert nature of this MEV behavior makes it harder to detect and quantify than MEV in a public mempool.

In an application chain, validators play a dual role: they are participants in consensus (voting to confirm blocks) and operators of the matching engine (maintaining the order book in memory and executing matching). After orders are matched at high speed in a validator's memory, the result is proposed to other validators as part of a block for consensus confirmation. Here, *consensus is settlement*: once a block receives confirming signatures from enough validators, the trade completes matching and settlement simultaneously, with no need to wait for the additional on-chain verification step required by a general-purpose public-chain DEX.

New trust assumptions and validator MEV. Even as the application-chain architecture eliminates one class of risk, it introduces a new trust assumption. Because validators control the right to order transactions, they can in theory perform self-preferential ordering—for example, inserting their own buy order ahead of a user's large buy order, or delaying the processing of certain transactions. This *validator MEV* is more covert than MEV in a public mempool, because it occurs inside a validator's internal systems and is hard for outsiders to detect and quantify in real time.

The degree of decentralization of the validator network and the cost of misbehaving therefore become key variables for the system's fairness. If validators are numerous enough and broadly distributed geographically and in their interests, the payoff to a single validator from misbehaving will be far smaller than the cost of having its staked tokens slashed, forming an effective economic deterrent. But some application chains had very few validators in their early stages. Hyperliquid had only 16 validators early on [5]. Although Ethereum has roughly 1 million validator nodes, large staking pools such as Lido control about 28% of the staked share, so the number of effective independent operators is far below the nominal node count. A more appropriate comparative metric is the Nakamoto coefficient—the minimum number of independent entities needed to control 33% or 51% of the staking weight—rather than the raw node count. Even so, Hyperliquid's validator set remains far inferior to Ethereum's on this metric. This limited validator set makes the possibility of node collusion a hidden danger that cannot be ignored. Although the staking-slashing mechanism provides economic-level security, if a small number of validators control the majority of the network's staking weight, the potential payoff from collusion may exceed the cost of slashing, weakening the system's security assumptions.

Risk management and on-chain governance. An application chain's core risk-control mechanisms—liquidation parameters (such as the maintenance-margin ratio and the liquidation-penalty rate) and the rules governing use of the insurance fund—are determined by on-chain governance. This means all rules are public and transparent, and any participant can know in advance under what conditions which risk-control action will trigger. This predictability is a major improvement over the *black-box* risk control of a CEX.

Governance itself, however, is also a complex arena of play. Large token holders can, through their votes, profoundly influence protocol parameters that bear on the interests of all traders. For example, adjusting the liquidation-penalty rate directly affects the incentives of liquidators and the losses of those being liquidated; adjusting the insurance fund's replenishment mechanism affects the profit distribution of all LPs. Where governance power is highly concentrated, the interests of a few large holders may take priority over those of the community as a whole. In addition, depositing assets into an application chain usually requires a cross-chain bridge, and the security of cross-chain bridges has historically been among the more fragile links in DeFi. According to public tallies from the DeFiLlama and Rekt databases (data as of 2025, with figures varying by how cross-chain bridges are defined and how incidents are classified), cross-chain-bridge attacks caused more than $2.5 billion in asset losses between 2021 and 2025 (the larger individual incidents include Ronin at roughly $625 million, Wormhole at roughly $320 million, and Nomad at roughly $190 million) [8]; and for an application-chain DEX, nearly all user funds must be deposited through the bridge, making the bridge the single largest attack surface. Before a user's assets enter the application chain, they must bear the smart-contract risk and relay-node risk of the bridging process.

The integrated trade flow of an application-chain DEX (orders enter validator memory for matching through a private mempool, and consensus and settlement complete in the same step; a conceptual process schematic, not empirical data; drawn by the author, based on Coinage Media [5] and Eco.com [9])

6.1.4 Structural comparison

Having traced the complete trade lifecycle, the table below systematically compares the essential differences of the three paradigms at their key junctures along eight dimensions: order visibility, matching mechanism, settlement path, asset custody, the core game, opacity risk, risk-control transparency, and the liquidation mechanism. These differences are not a simple ranking of *which is better* but structural trade-offs made under different constraints.

Dimension	Centralized exchange	General-purpose public-chain DEX	Application-chain DEX
Order visibility	Visible only to the exchange; inside a *black box*	Present in the public mempool; globally visible	Present in the private mempool; visible only to validators
Matching mechanism	Centralized high-performance engine (internal sub-millisecond; end-to-end 1–10 ms)	Off-chain sequencer matching (sub-second); settlement finality depends on L1 (seconds to minutes)	In-memory matching by validators (sub-second latency)
Settlement path	Internal database-ledger update; no on-chain operation	ZK proof submitted to the mainnet for verification	Consensus and settlement merged into one
Asset custody	Centralized exchange custody; the user holds a claim	Self-custodial wallet; managed by smart contracts	On-chain self-custody; depositing relies on a cross-chain bridge
Core game	Market makers vs. informed traders (adverse selection)	MEV searchers vs. ordinary users (information exploitation)	Mechanism exploiters vs. protocol LPs (the mechanism game)
Primary opacity risk	The exchange uses its informational advantage for self-preferential treatment	MEV extraction is public, but ordinary users cannot escape it	Validator MEV is covert and hard for outsiders to detect
Risk-control transparency	Fully opaque; not externally auditable	Smart contracts are public; anyone can verify	On-chain governance sets parameters; rules are transparent
Liquidation mechanism	Executed internally by the exchange; the insurance fund is opaque	Permissionless, open liquidation market	Protocol-level liquidation engine; parameters are adjustable

Table 6-1. Structural comparison of the trade lifecycle across the three paradigms (Data source: compiled by the author)

The comparison in Table 6-1 reveals a deep structural insight: each of the three paradigms selects a different resting point within the *impossible triangle* of performance, transparency, and decentralization. The centralized exchange chooses high performance, sacrificing transparency and control over assets, and its core game centers on latency. The general-purpose public-chain DEX chooses absolute transparency and decentralization, accepting a compromise in performance and the affliction of MEV, and its core game centers on information exploitation. The application-chain DEX tries to find an optimum between performance and transparency through a customized architecture, but it introduces new trust assumptions, and its core game centers on understanding and exploiting protocol mechanisms.

Market structure also systematically shapes trader behavior at the micro level. For example, on oracle-priced DEXs, a mechanically lower slippage and adverse-selection risk on the long side [11] has given rise to a systematic long bias [10], showing that different pricing mechanisms, fee structures, and risk-management rules regularly incentivize or suppress specific types of trading behavior—a shaping effect detailed in Section 6.4.4.

Each structural choice creates a different form of competition and gives rise to a different

dimension of *unfairness*. In a CEX, unfairness manifests in the capital threshold of hardware and in the exchange's informational privilege; in a general-purpose public-chain DEX, it manifests in the systematic extraction of value from ordinary users by MEV searchers; in an application-chain DEX, it manifests in validators' implicit informational advantage and the possibility that protocol mechanisms are strategically exploited. Section 6.2 systematically analyzes how these forms of competition migrate as market structure evolves, and what that migration means for market participants and regulators.

6.2 The competition-mode migration thesis

In Chapter 5, we performed a static dissection of the three service-provider architectures, analyzing how their internal components operate and how risk is distributed in each. Markets, however, are not static structures but arenas of intense, real-time competition. Different market structures create not only different risks but also fundamentally different modes of competition. Across this evolution, the focus of competition, its weapons, its battlegrounds, and the very definition of *fairness* all undergo a profound migration.

This section advances the *competition-mode migration thesis*, arguing that the evolution of market structure is not a simple, linear replacement of centralized exchanges by decentralized exchanges but a paradigm shift in the focus of competition. In this shift, the object of the game migrates from traditional *latency* (whose hardware is faster) to *information* in general-purpose public-chain DEXs (who can exploit transparent data faster) and finally evolves, in application-chain DEXs, into a contest over *mechanism* (who understands the protocol's rules more deeply). Each migration redefines who wins, who loses, and what fairness means.

6.2.1 Latency competition in CEXs

As described in Section 6.1.1, the core game market makers face in a CEX is adverse selection [11][12]; their main response is to increase speed rather than widen spreads, which drives an arms race around microsecond-level latency waged with colocation and custom hardware as weapons [6].

Budish, Cramton, and Shim (2015) argued at the theoretical level that the design of the continuous limit order book inevitably produces mechanical arbitrage opportunities; competition does not eliminate these opportunities but merely raises the speed threshold needed to capture them [13]. The empirical data of Aquilina, Budish, and O'Neill (2022) further show that the most common latency-arbitrage races in traditional markets last only 5 to 10 microseconds [14]. In digital-asset markets, high-frequency trading firms likewise pursue double-digit-microsecond *tick-to-trade* performance [15]. The pattern of latency competition that ran for decades in traditional finance is replicated in full in crypto CEXs [16].

The consequences of latency competition are multidimensional. First, it greatly raises the barrier to market entry, and market-making profits are highly concentrated among a handful of institutions with top-tier infrastructure. Second, as described in Sec-

tion 6.1.1, the maker-taker fee model, as an institutionalized cost-transfer mechanism, further entrenches the advantage of leading institutions [17]. Finally, the CEX architecture inherently contains structural information asymmetry: the exchange holds the order-flow data of all users, while the entire matching process runs in a *black box* that outsiders cannot audit; the flow of benefits between FTX and Alameda Research is precisely an extreme manifestation of this structural unfairness [1]. Under the CEX competition paradigm, the exchange's own informational advantage is an absolute structural unfairness that transcends hardware capital.

6.2.2 Information competition in general-purpose public-chain DEXs

As DeFi matured, DEXs on general-purpose public chains set out to eliminate the CEX *black-box* problem through thoroughgoing transparency. On DEXs built on public chains such as Ethereum, every trading intent is exposed in the public mempool before it is finally confirmed and packed into a block. This fundamental architectural change migrated the focus of competition from *latency* to *information exploitation*. The transparency paradox discussed in Chapter 1 is fully displayed here: transparency removes the privilege of centralized institutions, but it also enables technically capable participants to extract value systematically from ordinary users.

At this stage, MEV became the primary vehicle of information competition. The public mempool makes all pending transactions visible to everyone, so competition is no longer about *whose hardware is faster* but about *who can analyze and exploit this public information faster and more precisely*. The three basic forms of MEV (front-running, the sandwich attack, and liquidation sniping) and their layered value chain and multi-tier auction structure were detailed in Section 6.1.2 and are not repeated here; the total cost of this multi-tier auction is ultimately borne by ordinary traders, while the profit is distributed among searchers, builders, and validators.

MEV has a broad impact on the integrity of DeFi markets, and its negative externalities have drawn close attention from regulators [2]. The actual data show that the scale of this information competition is enormous. For example, daily MEV extraction on the Ethereum mainnet has long stayed on the order of hundreds of thousands of dollars; and over the 30 days from late 2025 to early 2026, MEV profit extracted on Ethereum reached nearly $24 million [18]. In addition, sandwich attacks targeting private transaction pools occur frequently and cause significant user losses [19].

Under the information-competition mode, the market's definition of *fairness* changed. The threshold of competition shifted from hardware-capital investment to algorithmic and technical capability. MEV searchers' profit comes from their ability to process public information faster and more intelligently than ordinary users. Although technically anyone can run a searcher node and compete, in practice this capability is likewise highly concentrated among a handful of institutions with top-tier algorithm teams.

Everyone can see, but only the fastest and smartest can exploit—this is precisely the economic embodiment of the transparency paradox. While enjoying self-custody of assets and on-chain verifiability, ordinary users are forced to pay an implicit *transparency tax*. The MEV figures above (over $500,000 per day on Ethereum) reflect total MEV extraction across the entire Ethereum ecosystem, spanning spot DEX swaps, lending

liquidations, and many other scenarios. The effective *transparency tax* that perpetual futures traders actually bear must be assessed independently and varies significantly across different Layer-2 environments.

6.2.3 Mechanism competition in application-chain DEXs

To solve the performance bottleneck and severe MEV problems of general-purpose public chains, the application-chain architecture emerged. Application-chain DEXs typified by Hyperliquid deeply integrate order-book maintenance, the matching engine, and the consensus mechanism by building an independent blockchain purpose-optimized for trading. More importantly, they typically adopt a private-mempool design, so that a user's trading intent is not exposed on the public network before it is formally packed into a block.

This architectural change effectively suppresses traditional atomic MEV (such as front-running and sandwich attacks), because searchers lose the ability to observe pending transactions in advance. Competition, however, does not disappear; it evolves toward a deeper and more covert level. Notably, although the mempool is private, an application chain's API exposes real-time order-book state at low latency, so sophisticated traders who colocate servers near validators can conduct *statistical MEV*—informed trading based on observable order-flow patterns. This to some extent reintroduces, at the application-chain level, a shadow of latency competition. On this basis, a deeper *mechanism competition* emerges. In this mode, the focus of competition is no longer hardware latency, nor is it simply scanning the mempool, but rather a deep understanding and strategic exploitation of the protocol's own economic mechanisms. This is precisely the concretization, at the market-structure level, of the *mechanism parasitism* phenomenon defined in Chapter 4.

In mechanism competition, attackers or advanced traders no longer seek to extract tiny value at the millisecond scale or within a single block; instead, they turn to complex, cross-cycle, cross-market games. This section formally defines this as *strategic MEV*. Unlike atomic MEV, which relies on reordering transactions, the core features of strategic MEV are its non-atomicity, its cross-cycle nature, and its compound exploitation of the protocol's inherent economic vulnerabilities (such as liquidation thresholds, insurance-fund design, and leverage limits).

A series of events on Hyperliquid in March 2025 provides a textbook empirical case of this new mode of competition. On March 12, a whale trader known as *0xf3F* built a long position of more than $300 million in ETH with 50x leverage on Hyperliquid. When the position generated a large unrealized profit, the trader did not choose to close it on the open market but instead began strategically withdrawing margin from the account. This maneuver artificially raised the position's liquidation price until it finally triggered the protocol's forced liquidation [20].

The logic behind this *strategic self-liquidation* is a precise economic calculation. Fifty-times leverage corresponds to a 2% initial-margin ratio, meaning a $300 million notional position requires only about $6 million of initial margin. The trader realized that closing such a huge position directly on the order book would incur enormous slippage losses; estimated from the position's size and the order-book depth at the time, the market-

impact cost of a normal close was far higher than the liquidation penalty the protocol specified. In this way, the trader successfully locked in more than $1.86 million in profit while transferring the enormous market-impact cost of closing the position onto the protocol's liquidity providers. In Hyperliquid's liquidation cascade, a liquidated position is first taken on by backstop liquidators attempting to close it on the open market; if that fails within the time window, the position is transferred to the Hyperliquidity Provider (HLP) vault as the taker of last resort. In this incident, because the position was too large, the intermediate liquidation mechanisms failed to absorb it effectively, and the HLP vault was forced to take on the entire remaining position as the de facto central counterparty, ultimately bearing roughly $4 million in slippage losses [20].

Just two weeks later, on March 26, Hyperliquid suffered the mechanically more complex *JELLY attack*—three coordinated attackers used mutually hedged, huge long and short positions to induce forced liquidation, forcing the HLP vault to take on a low-liquidity position and ultimately eliciting the team's highly controversial centralized delisting and forced-liquidation intervention (the case is detailed in Section 6.3.2) [20].

These events profoundly reveal the essence of mechanism competition: the *weapon* of competition has shifted from engineering (code and hardware) to economics and game theory. Every on-chain operation by the attacker complies with the protocol's rules, and the profit comes from understanding the economic implications of those rules far more deeply than the protocol's designers do. This is a paradigm shift from *who is faster* to *who thinks more deeply.* In the application-chain era, the definition of *fairness* evolves further: the cognitive threshold becomes the new barrier to entry, and protocol liquidity providers and ordinary users who do not understand the deeper implications of the mechanisms become the ultimate bearers of this *mechanism tax.*

6.2.4 A unified comparison of the competition modes

To understand more clearly the essential differences among these three competition modes, we can construct a systematic comparison matrix. As described in Section 6.1.4 (and in Chapter 5), the three paradigms each select a different trade-off within the *impossible triangle.* The table below systematically compares the three competition modes along six dimensions: the focus of competition, core weapons, principal participants, the battleground, the definition of fairness, and the manifestation of unfairness.

Dimension	CEX latency competition	General-purpose public-chain DEX information competition	Application-chain DEX mechanism competition
Focus of competition	Hardware latency (microsecond matching speed)	Information exploitation (trading intent in the public mempool)	Mechanism understanding (strategic exploitation of the protocol's economic rules)
Core weapons	Colocation, custom FPGA hardware, microwave communication networks	MEV search algorithms, block-building optimization, gas-bidding strategies	Cross-cycle position building, exploitation of the liquidation mechanism, cross-market manipulation
Principal participants	High-frequency market makers (Wintermute, Jump Trading, etc.)	MEV searchers, block builders	Strategic traders, protocol-mechanism researchers
Battleground	Physical distance inside the exchange's data center	The public mempool and block-space auctions	The protocol's liquidation engine, insurance fund, and oracle mechanism
Definition of fairness	Capital threshold: who can invest more hardware capital	Technical threshold: who has superior algorithmic capability	Cognitive threshold: who understands protocol economics more deeply
Manifestation of unfairness	Hardware-capital barriers plus the exchange's informational privilege	Systematic value extraction from ordinary users by MEV searchers	Validators' implicit ordering power plus the transfer of losses to protocol LPs by strategic MEV

Table 6-2. A unified comparison matrix of the three competition modes (Data source: compiled by the author)

As Table 6-2 shows, the focus of competition—from physical latency in the CEX, to information exploitation in the general-purpose public-chain DEX, to mechanism understanding in the application-chain DEX—displays a progressive abstraction from hardware engineering to algorithmic technology and then to economic cognition. Corresponding to this is a migration in the definition of fairness: unfairness in the CEX is determined mainly by hardware-capital investment, in the general-purpose public-chain DEX by algorithmic capability, and in the application-chain DEX by the depth of one's understanding of protocol economics. The migration of the competition mode not only changes the rules of the game but also profoundly reshapes the role and situation of each class of market participant. A role that occupies a central position in the CEX paradigm may be marginalized in the on-chain paradigm, and vice versa. From the perspective of six core participants—retail traders, institutional market makers, high-frequency traders, MEV searchers, validators/nodes, and protocol governors—Table 6-3 analyzes the changing opportunities, challenges, and game positions each role faces across the three paradigms.

Participant role	CEX paradigm (latency competition)	General-purpose public-chain DEX paradigm (information competition)	Application-chain DEX paradigm (mechanism competition)
Retail traders	Enjoy the best experience and lowest latency but bear very high custodial risk and the information-asymmetry risk of the black box, passively accepting market makers' spreads.	Gain self-custody of assets and global transparency but must bear the cost of MEV extraction (the transparency tax), gas-fee volatility, and smart-contract risk.	Gain a near-CEX experience and the advantage of self-custody but face cross-chain-bridge risk. MEV extraction is partly mitigated by protocol design, but they may bear an implicit mechanism tax.
Institutional market makers	Hold a central position, earning spreads by providing liquidity. Must invest heavily in low-latency infrastructure to counter adverse selection and enjoy fee subsidies.	Role is weakened (replaced by algorithms under the AMM model). Under the order-book model, they face intense competition from MEV searchers and must adapt to high on-chain latency.	Role revives. They return to the center under a high-performance order book, may gain an informational advantage by running validator nodes, and face competition from protocol-native market-making mechanisms.
High-frequency traders	A traditional area of advantage; they gain a millisecond edge through hardware and network investment and execute latency-arbitrage and statistical-arbitrage strategies.	Advantage is greatly diminished; on-chain second-level latency renders traditional HFT strategies ineffective, but some can transform into professional MEV searchers.	Becomes a new arena. Sub-second latency makes some strategies viable again, and running a validator node may become the *colocation* of the application-chain era.
MEV searchers	Do not exist; information asymmetry and ordering privilege are sealed inside the exchange's black box.	A core role; they continuously scan the public mempool and drive a complex multi-tier auction market.	Role is constrained; the private mempool limits traditional scanning strategies. But strategic MEV targeting protocol-mechanism vulnerabilities becomes a new, higher-order form of play.
Validators/nodes	Not applicable (centralized servers).	An indirect role; as consensus maintainers of the underlying chain, they capture most of the risk-free MEV revenue through mechanisms such as proposer-builder separation.	A core role, simultaneously bearing the triple duties of consensus confirmation, order matching, and transaction ordering. They hold the ultimate informational advantage but face the constraint of staking slashing.
Protocol governors	Not applicable; decision-making power rests entirely with corporate management.	Participate through the DAO and governance tokens, usually facing the dilemma of low retail participation and decision-making dominated by large holders.	On-chain governance is decisive. Validators and large token holders wield significant influence over core mechanisms such as liquidation parameters, determining the protocol's economic security.

Table 6-3. The game matrix of six core participants across the three paradigms (Data source: constructed by the author)

Table 6-3 reveals a noteworthy pattern in the evolution of roles: institutional market

makers hold a central position in the CEX, are weakened in the general-purpose public-chain DEX, and regain a central position in the application-chain DEX; MEV searchers, in turn, go from nonexistent in the CEX to a core role in the general-purpose public-chain DEX, and then to being structurally constrained in the application-chain DEX while pivoting to higher-order strategic MEV. Accompanying this, the transmission path of information asymmetry also evolves from the closed form of the CEX, through the transparent form of the general-purpose public-chain DEX, to the semi-transparent form of the application-chain DEX (see Figure 6-5).

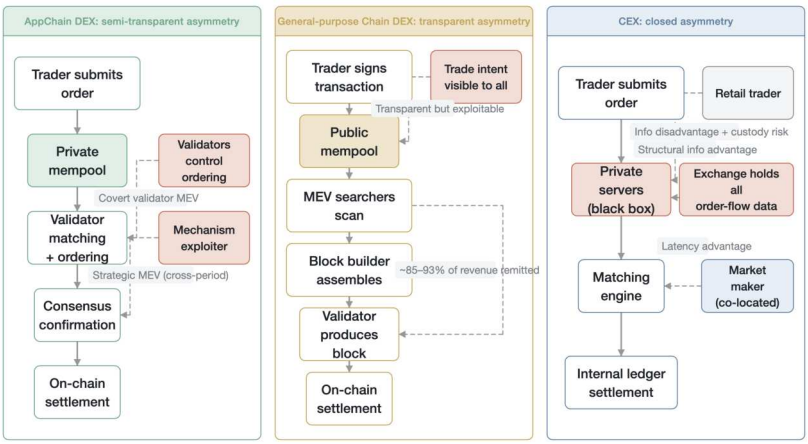

Figure 6-5. The transmission path of information asymmetry across the three paradigms (from the CEX *black box* to the general-purpose public chain's *public mempool* and then to the application chain's *private mempool plus validator matching*, the way an informational advantage is obtained changes fundamentally; a conceptual mechanism schematic, not empirical data; the roughly 85%–93% of revenue remitted follows ESMA [2]; drawn by the author, additionally based on Harris [6])

6.2.5 The drivers of competition-mode migration

Figure 6-6 decomposes the three migrations of the competition mode into three stages and labels the core driver of each: the diminishing returns of latency competition, the revaluation of transparency after the FTX collapse, and the application chain's recombination of performance and transparency within the *impossible triangle*.

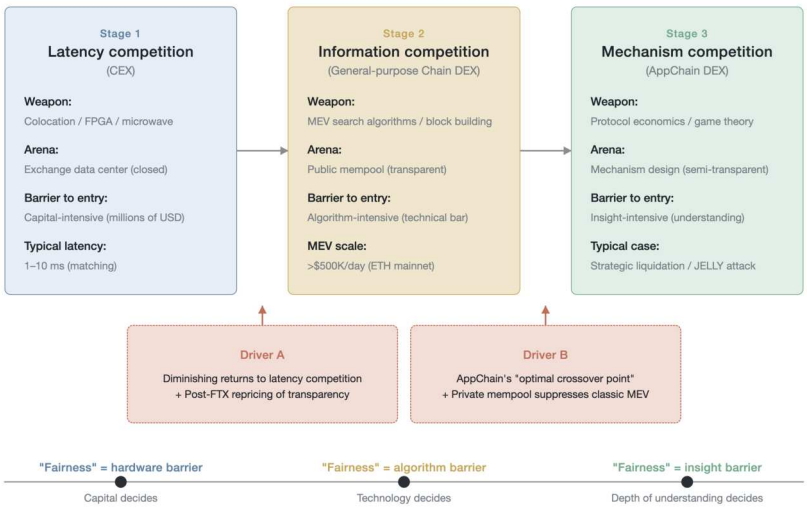

Figure 6-6. The three-stage migration of the competition mode (a mechanism-evolution schematic, not empirical data; the daily MEV figure of over $500,000 follows EigenPhi [18], on the late-2025-to-early-2026 basis; drawn by the author, based on Budish, Cramton, and Shim [13] and ESMA [2])

As Figure 6-6 shows, each migration corresponds to the economic return of the prior competition mode approaching zero: the diminishing marginal returns of latency competition in CEXs pushed capital toward on-chain information competition, while the high cost and poor user experience of MEV extraction on general-purpose public chains in turn drove the market toward the mechanism competition of application chains.

The starting point of the migration is the diminishing returns of latency competition. In CEXs, the arms race around microsecond latency has approached physical limits. To gain even a one-microsecond speed advantage, an institution must invest exponentially growing capital (for example, laying a straighter microwave link or developing more advanced FPGA chips), yet the excess profit such marginal investment can bring is rapidly approaching zero. This has become a zero-sum arms race in which participants keep investing merely to maintain their existing competitive position rather than to create new economic value [13]. When traditional hardware competition ceases to be economically attractive, capital and technical talent naturally turn to areas of competition with higher returns.

Even as the returns to latency competition diminished, the 2022 collapse of FTX triggered a fundamental reappraisal of transparency. After this event, market participants' valuation of *verifiability* rose sharply. Institutional investors and advanced retail traders came to realize that the high efficiency of CEXs was built on one-sided trust and an extremely high single-point-of-failure risk. They became increasingly willing to pay a certain efficiency cost for the ability to *independently verify asset safety and trade execution*. This fundamental shift in risk preference became a powerful underlying driver pushing capital and volume to migrate from CEXs to on-chain models. Behavioral finance, however, offers a competing explanation: availability bias and narrative contagion may lead participants to systematically overestimate the probability of sim-

ilar events after a salient catastrophe, causing an excessive flight from all custodial structures. Lo's (2004) adaptive markets hypothesis [21] predicts that such behavioral overreaction may partially reverse as the FTX event fades from collective memory. This means that in assessing the migration trend, one must distinguish its structural component (a genuine rise in demand for verifiability) from its behavioral amplification component (a panic-driven narrative shift), the durability of the latter being uncertain.

Nevertheless, although general-purpose public-chain DEXs offer transparency, their high gas fees, second-level confirmation latency, and large-scale MEV extraction make them ill-suited to carry high-frequency perpetual futures trading. It is against this backdrop that application chains try to find a more commercially viable optimal intersection within the *impossible triangle*. Through a customized consensus mechanism and in-memory matching, application chains achieve sub-second latency, meeting the performance needs of the vast majority (roughly 95%) of trading strategies; through a private mempool, they structurally suppress the worst atomic MEV; and at the same time they still preserve the baseline of self-custody of assets and on-chain verifiability of core logic. This *performance plus transparency* combination explains why an application chain like Hyperliquid could grow rapidly in 2025 and at one point capture roughly 60% of the on-chain perpetual futures market.

In sum, the migration of the competition mode from latency to information and then to mechanism is an evolutionary process driven jointly by technical bottlenecks, risk events, and economic incentives. In the sections that follow, we examine the highest expression of this mechanism competition—strategic MEV—and analyze how the dominance of price discovery shifts over the course of this evolution.

6.3 Strategic MEV

MEV has been a core issue throughout the development of decentralized finance. Early MEV mainly took the form of technical arbitrage, such as sandwich attacks based on transaction ordering or simple cross-DEX arbitrage. As complex financial derivatives such as perpetual futures have become widespread on-chain, however, the form of MEV is undergoing a profound evolution. This section elevates *strategic MEV* from an observation in the competition-mode discussion of Section 6.2 to a formally defined conceptual category; it systematically argues how strategic MEV differs in nature from traditional atomic MEV, analyzes its three typical forms in the perpetual futures setting, and explores paths for defending against it at the mechanism-design level and for institutionalizing MEV. This concept is the concretization, at the market-structure level, of the *mechanism parasitism* theory of Chapter 4.

6.3.1 Atomic MEV and strategic MEV

To understand the essence of strategic MEV, one must be clear about how it differs from traditional atomic MEV. This difference lies not only in the mode of execution but, more deeply, in the economic logic and risk characteristics behind it. The difference between the two is a leap in kind, not a gradual change in degree.

Traditional atomic MEV relies mainly on a structural feature of blockchains' decen-

tralized architecture: the absence of a unified, tamper-proof transaction timestamp. "Decentralization means there is no pipeline that creates a single queue, nor any natural time-based ordering of transactions as in traditional finance" [2]. On smart-contract platforms such as Ethereum, miners or validators (and, with the introduction of MEV-Boost, block builders) hold the privilege of deciding the order of transactions within a block. Searchers monitor the public mempool, identify profitable trading intent, and compete for block space by submitting transaction bundles that include a higher priority fee. The core feature of this MEV is its *atomicity*: the entire operation (such as the front transaction, the target transaction, and the back transaction) is executed within a single atomic transaction in the same block. If any link fails, the entire transaction is rolled back, and the extractor bears no execution risk, paying only a small gas fee [2][22].

By contrast, strategic MEV is no longer confined to micro-level transaction ordering within a single block; it extends to the macro level of economic gamesmanship. Extractors of strategic MEV exploit not only information in the mempool but also, more deeply, the structural design features of DeFi protocols (especially perpetual futures protocols) in their margin models, liquidation engines, or oracle mechanisms. This MEV is often a continuous operation spanning multiple blocks or even several days, requiring the extractor to commit substantial capital and bear real market-execution risk [23]. This book gives the following formal definition of strategic MEV:

> Strategic MEV: Unlike atomic MEV, which relies on reordering transactions within a single block, the core features of strategic MEV are its non-atomic, cross-cycle, cross-domain, compound attacks. It involves an attacker, over a longer time horizon, exploiting a protocol's inherent economic mechanisms (leverage, liquidation thresholds, insurance-fund design) and market structure (order-book transparency, cross-market liquidity imbalances) to construct, through a series of seemingly independent operations, a final high-value profit or loss-avoidance scenario. The goal of strategic MEV is typically not to extract value from a single transaction but to actively plan and trigger a larger market event, or to externalize a personally incurred loss onto the entire protocol system.

The two differ in nature across several key dimensions. In terms of the information source and profit basis, the profit of atomic MEV comes from the pending transactions of other users in the public mempool; in essence, it exploits users' slippage tolerance. The profit of strategic MEV, however, comes from the protocol's systemic design—especially the insurance fund or the liquidity providers' capital pool—as the extractor, by actively planning a market event (such as manipulating the price of a low-liquidity asset), forces the protocol to execute operations under rules unfavorable to it, thereby achieving a value transfer. In the conceptual framework of Chapter 4, atomic MEV corresponds to the behavioral pattern of the *economic bot*, whereas strategic MEV is the market-structure version of *mechanism parasitism*: the attacker does not violate the rules but understands the economic implications of the rules more deeply than their designers do.

This difference extends further to the dimensions of risk characteristics and capital requirements. Atomic MEV is risk-free arbitrage; the extractor uses the atomicity of smart contracts to guarantee an *all-or-nothing* execution result. Strategic MEV, by

contrast, is a risky investment with directional exposure; the extractor must build a real position, faces the market risk of price movements, and often needs to deploy millions or even hundreds of millions of dollars to drive the market price or exhaust the protocol's liquidity. Correspondingly, the party that bears the loss changes fundamentally: the victim of atomic MEV is usually a single attacked trader, whose loss is local and quantifiable; the loss caused by strategic MEV is often socialized, with the protocol's insurance-fund loss ultimately borne by all liquidity providers and possibly even spreading, through the auto-deleveraging mechanism, to all profitable traders. This socialization of losses makes strategic MEV far more destructive to the protocol ecosystem than atomic MEV.

A direct consequence of these differences is that the suite of technical defensive tools already developed against atomic MEV—such as private transaction pools (Flashbots Protect), the proposer-builder-separation (PBS) mechanism, and order-flow auctions—is nearly useless against strategic MEV [2]. These mechanisms protect ordinary users by hiding trading intent or redistributing MEV profit, but strategic MEV exploits the protocol's economic rules themselves rather than information asymmetry or transaction ordering. Defending against strategic MEV must return to the starting point of mechanism design—achieved by refining margin requirements, optimizing liquidation logic, and strengthening system resilience.

Dimension	Atomic MEV (technical arbitrage)	Strategic MEV (economic game)
Information source	Public mempool pending transactions	Protocol mechanism design structural flaws
Execution horizon	Within one block (seconds)	Across blocks / days (hours to days)
Capital requirement	No large capital needed (atomic arbitrage)	Millions to hundreds of millions in real capital
Risk profile	No execution risk (atomicity guarantee)	Bears execution risk (non-atomic)
Who bears the loss	The single targeted trader	Protocol insurance fund LPs / all participants
Defense	Private order flow PBS / MEV-Share	Mechanism redesign makes exploit infeasible

Qualitative comparison, not quantitative (cells encode categorical differences, not magnitudes)

Figure 6-7. A multidimensional comparison of atomic MEV and strategic MEV (a conceptual comparison matrix along qualitative dimensions, with no empirical data; Data source: ESMA [2]; Daian et al. [22]; Gramlich et al. [23])

As Figure 6-7 shows, the two types of MEV display a leap in kind across six dimensions—information source, execution cycle, capital requirement, risk characteristics, the party bearing the loss, and defensive means (the six-dimensional comparison is detailed in the figure). Between the two, *multi-block MEV* is drawing researchers' attention as an intermediate form: block builders may coordinate strategies across consecutive blocks, and under the PBS framework, where the top two or three builders produce over 90% of

Ethereum's blocks, this concentration may give rise to new strategic vectors unforeseen by traditional PBS design. In short, this leap from *risk-free technical arbitrage* to *risky economic gamesmanship* means that existing technical-layer defensive tools are nearly useless against strategic MEV, and the focus of defense must shift to the protocol's mechanism-design layer.

6.3.2 Typical forms

Because of their high-leverage nature and complex liquidation mechanisms, perpetual futures markets have become a high-risk domain for strategic MEV. The presence of leverage multiplies the precision and destructive power of an attack: under 50x leverage, the initial-margin ratio is only 2%, meaning an adverse price move on the order of 2% is enough to bring a position close to liquidation, which creates an extremely low cost threshold for a carefully planned attack. Several leading on-chain perpetual futures platforms have recently suffered such attacks, exposing deep vulnerabilities in protocol design. In the perpetual futures setting, strategic MEV mainly takes three typical forms. The three forms below each exploit, in different ways, a compound of the economic vulnerabilities described earlier (liquidation thresholds, insurance-fund design, and leverage limits); the relationship is many-to-many rather than one-to-one.

In *strategic self-liquidation*, the attacker exploits the passive-takeover mechanism of the protocol's liquidation engine, transferring the market-impact cost of closing its own huge position onto the protocol's insurance fund or liquidity providers. Its economic logic can be stated succinctly: when the slippage cost of a normal close exceeds the penalty incurred from being liquidated, a rational attacker will choose to *be liquidated* rather than *close the position itself*, thereby externalizing the difference onto the protocol system.

In March 2025, the *JELLY token attack* suffered by the decentralized derivatives exchange Hyperliquid was a textbook case of this technique. In this incident, the attacker used three coordinated accounts to carry out a complex market manipulation. One account (0xde9) built a short position of roughly $4.1 million in the JELLY token on Hyperliquid, while two other accounts (0x20e and 0x67f) built a total of roughly $4.05 million in long positions [20]. Through this *hedged* operation, the attacker controlled both the long and short sides while keeping a market-neutral exposure. Subsequently, as the price of the JELLY token swung violently (partly triggered by the attacker's own spot operations), the margin ratio of the short position fell rapidly, triggering forced liquidation.

Because of the design of Hyperliquid's liquidation mechanism, when a user's position is liquidated, the protocol's HLP vault is forced to take on these huge positions as the central counterparty. JELLY, however, is a low-liquidity meme coin, and its market depth simply could not absorb such a huge closing order. When the HLP vault tried to close these short positions on the market, it produced extremely severe slippage; the peak unrealized loss during the incident once exceeded $10 million, and the widely reported vault loss was roughly $13.5 million (a peak-unrealized-loss figure, not a realized loss; the HLP vault recorded a small profit of about $700,000 after the incident was finally settled) [37]. Facing potential insolvency, the HLP vault simultaneously encountered

panic withdrawals by LP participants, a chain of behavior that exhibited classic bank-run dynamics, further intensifying the liquidity crisis and very likely constituting the direct trigger for the team's forced resort to centralized intervention. The Hyperliquid team ultimately took the highly controversial step of centralized intervention, forcibly closing the position at $0.0095 and delisting the token, containing the loss within a certain range; but the incident starkly exposed the systemic risk of the liquidation engine acting as a passive taker [24]. "The same group of people build and control the protocol, operate the HLP pool, issue the HYPE token, and run the validator nodes; for the sake of the network, they decided to delist JELLY and make everyone whole except the attacker"—this incident reveals the structural contradiction that a decentralized exchange, in extreme circumstances, must resort to centralized intervention [24].

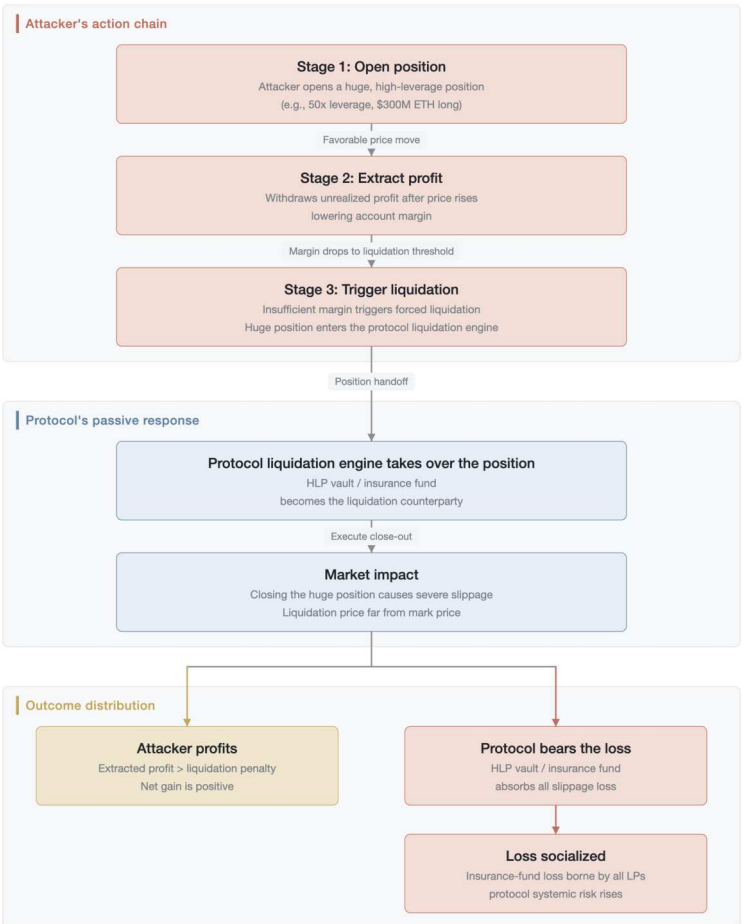

Figure 6-8. The self-liquidation attack flow and value-transfer mechanism in strategic MEV (a mechanism-process schematic, not empirical data; the illustrative $300 million ETH position at 50x leverage refers to the March 2025 whale self-liquidation incident [20]; drawn by the author, based on Arkham Intelligence [20] and Talos [24])

As Figure 6-8 shows, the core logic of the self-liquidation attack is this: the attacker withdraws unrealized profit when the price moves favorably, deliberately renders the ac-

count under-margined, and forces the protocol's insurance fund to take on the position under extremely unfavorable conditions, thereby socializing private risk.

The second form of strategic MEV is *cross-market liquidation manipulation*, which can be seen as an upgraded version of the self-liquidation attack, with the attacker extending the scope of operations from a single platform to multiple markets. The core strategy is this: build a huge position on a perpetual futures platform, then manipulate the underlying asset's price on the spot market (usually a low-liquidity DEX), thereby influencing the oracle price feed on which the perpetual futures platform depends, and finally triggering the liquidation of one's own or others' positions for profit.

The economic essence of this attack is cross-market arbitrage: as long as the cost of manipulating the spot market is lower than the profit obtained from perpetual futures liquidation, the attack is profitable. Because a perpetual futures protocol's oracle typically relies on price data from on-chain DEXs, whose liquidity is often far lower than that of centralized exchanges, the manipulation cost can be kept relatively low. A case in point is the market-manipulation attack Hyperliquid suffered on the POPCAT and HYPE tokens in November 2025: the attacker used only about 3 million USDC to build a buy wall on the spot market, which triggered a chain of liquidations on the perpetual futures market and cost the protocol vault nearly $4.9 million [25]. This kind of cross-market attack means the risk-control measures of a single platform cannot cover the entire attack surface, highlighting the severity of cross-protocol risk transmission in on-chain financial systems.

Compared with the first two forms, *insurance-fund arbitrage* is the most covert variant of strategic MEV. The attacker carefully constructs a fully hedged portfolio of positions and exploits logical flaws in the protocol's liquidation mechanism to trigger *pseudo-liquidations* that defraud the protocol of liquidation rewards, thereby systematically extracting value from the insurance fund. Unlike the first two forms, insurance-fund arbitrage often does not trigger violent market swings; instead, it siphons off protocol funds continuously and gradually. Reportedly, the same November 2025 manipulation of the POPCAT and HYPE tokens on Hyperliquid also exhibited the characteristics of insurance-fund arbitrage: through the interplay of hedged positions and the liquidation mechanism, the attacker caused the protocol a loss of roughly $4.9 million [25] (this is a different facet of the same incident described above under cross-market liquidation manipulation, not a second, independent loss), and the protocol became aware of the anomaly only after the incident had persisted for some time.

The three forms above share a profound common feature: every on-chain operation by the attacker complies with the protocol's rules, and the profit comes from the depth of understanding of the rules' economic implications rather than from violating them. *On-chain protocol compliance*, however, must be clearly distinguished from *legality under the law*: the CFTC's anti-manipulation framework (Commodity Exchange Act §9(a)(2)) and Article 91 of the EU's Markets in Crypto-Assets (MiCA) Regulation may both apply to coordinated cross-market manipulation strategies, regardless of whether the on-chain transactions are technically valid—a legal dimension explored in Chapter 26. This means that defending against strategic MEV cannot rely on *punishing the actor* but only on *fixing the mechanism vulnerabilities that make the behavior profitable.* This

marks the transformation of MEV from passive opportunity discovery to active strategy construction, a qualitative change from technical arbitrage to economic gamesmanship.

6.3.3 Defending against strategic MEV

In the face of increasingly frequent strategic MEV, traditional defenses based on technology and cryptography (such as encrypted mempools and batch auctions) prove inadequate, because strategic MEV does not exploit information asymmetry or network latency but the public, transparent economic rules themselves. Defending against strategic MEV must therefore begin with the protocol's mechanism design rather than a mere speed race. The table below systematically compares the defensive means and their effectiveness against the two types of MEV at four levels: the transaction layer, the ordering layer, the profit layer, and the mechanism layer.

Defense level	Defense against atomic MEV	Defense against strategic MEV
Transaction layer	Private transaction pools (hide trading intent)	Ineffective (strategic MEV does not depend on single-transaction information)
Ordering layer	PBS (separating builders and proposers)	Partly effective (reduces validator MEV but does not affect cross-cycle strategies)
Profit layer	MEV-Share (returns part of the profit to users)	Ineffective (strategic MEV profit comes from protocol mechanisms, not transaction ordering)
Mechanism layer	Not applicable	The core line of defense: redesigning the liquidation, insurance-fund, and margin mechanisms

Table 6-4. A comparison of the effectiveness of defenses against the two types of MEV at different levels (Data source: compiled by the author)

As Table 6-4 shows, the mature transaction-, ordering-, and profit-layer defensive tools for atomic MEV are either inapplicable or only partly effective against strategic MEV; only a redesign at the mechanism layer constitutes an effective line of defense, a judgment that directly determines the three core defensive directions below. The first defensive direction is to reshape the margin and dynamic-leverage model. To compete for market share, many perpetual futures platforms early on offered excessive high leverage and lowered initial-margin requirements, which gave strategic MEV ample leverage room. Introducing a dynamic, risk-based margin model (similar to the SPAN margin model of the Chicago Mercantile Exchange in traditional finance) is the core means of addressing this problem. But the SPAN analogy has clear limits for long-tail crypto assets: SPAN presupposes a well-behaved return distribution and deep liquidity for the underlying asset, whereas a meme coin like JELLY may experience volatility exceeding 1,000% within hours, fundamentally violating SPAN's statistical assumptions. Margin requirements must be dynamically linked to an asset's liquidity, historical volatility, and the concentration of a user's positions [24]. Hyperliquid's actual response after the JELLY incident (imposing open-interest caps and sharply reducing the maximum

leverage on long-tail assets) took a more direct path than dynamic margining, reflecting that under extreme liquidity conditions, coarse-grained position-size limits may be more operationally feasible than a fine-grained dynamic-margin model. This direction receives a deeper, engineering-oriented discussion in the liquidation-mechanism design of Chapter 11.

Above the margin layer, the design of the liquidation engine itself also needs fundamental optimization. Protocols need to introduce tiered liquidation and auto-deleveraging mechanisms: when market liquidity is insufficient to absorb a huge liquidated position, the system should not forcibly dump it on the market and cause a shortfall, but should instead trigger auto-deleveraging (ADL), forcibly closing counterparty positions against the most profitable traders on the opposite side of the liquidated position [26]. Although this harms the experience of some profitable traders, it protects the protocol's overall solvency. Paired with this is risk isolation of the insurance fund: high-risk assets (such as long-tail tokens) should have a separate isolated-margin pool, so that their liquidation losses are borne only by the liquidity providers participating in that pool, preventing the collapse of a single asset from triggering a systemic spread. Chapter 12 provides a detailed analysis of this from the perspective of insurance-fund governance.

The third level of defense concerns oracle resilience. To defend against oracle manipulation, a protocol must adopt a composite oracle mechanism that is multi-source and time-weighted or median-weighted, reducing the impact of an anomalous swing in any single spot market. At the same time, a *price circuit breaker* should be introduced: when the on-chain oracle price deviates significantly from the prices of multiple centralized exchanges, or when volatility exceeds a threshold within a short time, the opening and liquidation functions for that trading pair are automatically suspended to await a return to normal. But the circuit breaker itself can also become an attack surface: an attacker can deliberately trigger the circuit breaker during a genuine market crash to freeze the protocol and block the execution of legitimate liquidations, essentially constituting a denial-of-service vector disguised as a safety mechanism. The engineering implementation of these measures is given in concrete form in the clearing and settlement architecture design of Chapter 29.

6.3.4 The path toward institutionalizing MEV

The existence of MEV is an endogenous property of blockchains' decentralized architecture and cannot be eradicated. Although MEV causes wealth transfer and unfair treatment for ordinary users, some forms of MEV (such as cross-market arbitrage and timely liquidations) objectively improve the pricing efficiency and market liquidity of DeFi protocols [2]. The long-term direction of the industry should therefore not be a futile attempt to eradicate MEV but the institutionalization and standardization of MEV, moving it from disordered extraction toward an orderly economic mechanism.

The institutionalization of atomic MEV has begun to show results. In the Ethereum ecosystem, through the proposer-builder-separation mechanism promoted by Flashbots, the process of MEV extraction has been modularized and made market-based. As the most widely adopted implementation of PBS, MEV-Boost currently covers roughly 85% to 95% of Ethereum's block production [2]. Under this system,

searchers submit arbitrage bundles to block builders through sealed-bid auctions, and builders assemble them into complete blocks and pass them, via relays, to block proposers. Because of the fierce bidding competition among searchers, the vast majority of the profit MEV generates (roughly 85% to 93%) is ultimately forced to be paid to block proposers (that is, Ethereum's validator nodes) [2]. In addition, the MEV-Share protocol further returns part of the MEV profit to the original traders, while application chains' protocol-layer ordering rules (such as first-in-first-out, FIFO) reduce the room for certain forms of MEV to occur at the architectural level.

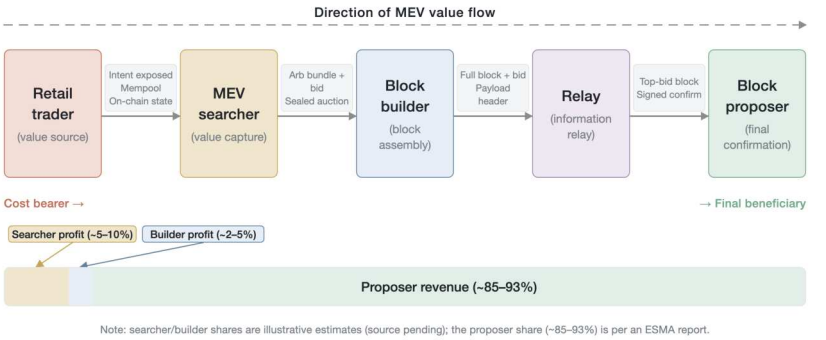

Figure 6-9. The value flow and profit-distribution architecture of the MEV supply chain (a value-distribution schematic, not empirical data; the 85%-to-93% figure for proposers follows ESMA [2], while the searcher and builder shares are the author's estimates; Data source: ESMA [2]; Flashbots Documentation)

As Figure 6-9 shows, value in the MEV supply chain flows out from ordinary traders, is captured by searchers and packaged by builders, and is finally passed, via relays, to block proposers, objectively subsidizing the security-consensus cost of the underlying blockchain. Yet even as the PBS mechanism reduces the risk of validator centralization, it also changes the incentive structure of the block-building market, driving it to evolve toward *generating and capturing more MEV*, which may increase total MEV and thus cause greater potential harm to ordinary users [27].

The institutionalization of strategic MEV is still in an early, exploratory stage. For application-layer protocols such as perpetual futures, institutionalizing MEV means *internalizing*, through mechanism design, the value that external extractors would otherwise seize for free, turning it into protocol revenue or user welfare. Concrete directions include: protocol-level position-size limits and a redesign of the liquidation mechanism (making strategic exploitation economically infeasible); governance-driven dynamic parameter adjustment and emergency-response mechanisms (as when Hyperliquid, after the JELLY incident, sharply tightened the leverage ceiling and position limits on long-tail assets); and cross-platform sharing of risk-control information (although this direction still faces enormous coordination challenges in a decentralized environment).

The structural resemblance between institutionalizing MEV and traditional financial regulation. The process of institutionalizing MEV bears a deep structural resemblance to the regulation of high-frequency trading in traditional finance. Both face

the same core problem: how, when information competition cannot be eliminated, to make it fairer and more transparent through institutional design. The market-fairness issues MEV raises correspond directly, at the conceptual level, to front-running prohibitions in traditional finance, but the decentralized nature of blockchains makes traditional regulatory enforcement hard to apply directly [2]. Regulators are gradually stepping into this area, exploring how to map traditional finance's principles of *best execution* and market-manipulation prevention onto the DeFi environment. In its 2023 DeFi policy recommendations, the International Organization of Securities Commissions (IOSCO) already explicitly required *responsible persons* to identify, disclose, and, where feasible, manage and mitigate the impact of MEV strategies [2]. Yet in a sufficiently decentralized protocol, identifying the *responsible person* is itself an unresolved enforcement problem, and IOSCO itself acknowledged in its 2023 report that when a protocol is governed by a token-based DAO, its recommended framework may lack a clear enforcement target.

In the long run, the evolution of strategic MEV will force the maturation of on-chain financial infrastructure. Only when protocol design can find a balance between openness and security, and when the value distribution of MEV can reconcile efficiency and fairness, can decentralized derivatives markets truly build institutional-grade trust and achieve larger-scale growth.

The evolution of MEV's forms and the process of its institutionalization directly affect the market's informational efficiency and pricing quality. Large-scale extraction of atomic MEV raises the implicit cost of on-chain trading and lowers informed traders' willingness to express information on-chain, which may suppress the price-discovery function of on-chain markets. Conversely, the effective institutionalization of MEV (reducing searchers' rent-seeking room through mechanisms such as PBS and MEV-Share) helps improve on-chain execution quality and creates conditions for the migration of price discovery from CEXs to on-chain venues. This logic forms an important premise for the discussion of the price-discovery migration hypothesis in the next section.

6.4 The price-discovery migration hypothesis

Market structure determines not only the distribution of risk and the mode of competition; its more far-reaching influence lies in reshaping the pricing power over assets. In the perpetual futures ecosystem, *price discovery*—the process by which new information is incorporated into asset prices—is a core topic of market-microstructure research. This section advances the *price-discovery migration hypothesis*: there is a structural trend indicating that the dominance of price discovery is gradually shifting from centralized exchanges to application-chain decentralized exchanges. This trend is not an incidental fluctuation in liquidity but a systematic change driven by deep economic forces. In theory, once this migration reaches a *critical mass*, the network effects of liquidity may render it irreversible. As Section 6.4.3 will argue, however, the current market evidence is not yet sufficient to confirm that the migration has crossed an irreversible critical point, and the analysis in this section should be regarded as a research hypothesis awaiting empirical testing.

6.4.1 Structural drivers

The trend of price discovery migrating from CEXs to on-chain venues does not stem from an ideological call but is driven by three mutually reinforcing structural forces. Before analyzing these drivers, one important confounding variable deserves attention: the 346% year-over-year growth in DEX perpetual futures volume must be read against the CEX growth rate of 29% and against the macro environment of the same period (the Federal Reserve's rate-cutting cycle, the approval of spot Bitcoin ETFs, and a general recovery in risk appetite). DEX volume may have a higher beta to risk-appetite sentiment, because in a bull market new retail traders disproportionately enter through DeFi channels. Part of the growth may therefore reflect a cyclical rising-tide effect rather than a purely structural advantage. Acknowledging this confounding variable, the following three structural forces remain identifiable.

The most fundamental of these forces is the trust premium of verifiable liquidity. In the black-box architecture of a CEX, the depth of the order book cannot be independently verified by outsiders. This opacity not only masks potential wash trading but, in extreme market conditions, also deprives participants of confidence in the authenticity of liquidity. The collapse of FTX (see Section 6.1.1) became a landmark event, and market participants came to grasp the fundamental gap between *paper liquidity* and *real liquidity* [28]. By contrast, every resting order on an on-chain central limit order book is a genuine on-chain commitment that anyone can independently audit cryptographically. As institutional investors and high-frequency trading firms increasingly value the verifiability of liquidity, this transparent liquidity acquires a significant trust premium. This premium is continuously pushing capital to migrate from CEXs to on-chain architectures. As the left panel of Figure 6-10 shows, the ratio of DEX to CEX perpetual futures volume climbed from 2.1% in the first quarter of 2023 to 11.7% in November 2025, with the trust crisis after the FTX collapse markedly accelerating this trend.

On top of the trust premium, the efficiency gains of protocol-level market making constitute the second driver of the migration. Traditional CEX market making relies heavily on a few professional institutions with top-tier infrastructure (such as Wintermute, Jump Trading, and Cumberland), and this high entry threshold leads to market-making profits being monopolized by a handful of institutions. Application-chain DEXs, however, are breaking this monopoly through protocol-level innovation. Take Hyperliquid's HIP-3 mechanism and its HLP vault: market making shifts from the privilege of a few institutions to an open, protocol-driven public service. Any capital holder can participate in market making by injecting funds into the HLP vault, and the protocol automatically manages quoting strategies and risk exposure. This architecture attracts broader capital participation in liquidity provision and significantly increases order-book depth. Data made public by the Hyperliquid team in early 2026 show that the cumulative resting-order depth of its Bitcoin perpetual futures at certain price levels has approached twice that of Binance, with bid-ask spreads comparable to those of top-tier CEXs [29]. Note, however, that these data come from a self-report by an interested party; the potential bias and the need for independent cross-validation are detailed in Section 6.4.3. More fundamentally, assessing liquidity quality requires distinguishing *resilient depth* from *fragile depth*: orders provided by independent, profit-

driven market makers are usually actively replenished after being filled, constituting *resilient depth*; whereas the liquidity provided by the HLP vault—a single, concentrated, protocol-driven LP—may freeze or be withdrawn under stress as participants panic-withdraw, constituting *fragile depth*. The JELLY incident already demonstrated the structural fragility of HLP's concentrated liquidity provision. This efficiency gain directly strengthens the on-chain market's ability to absorb large orders and reflect new information, which is precisely the core function of price discovery.

The on-chain migration of traditional financial institutions has further accelerated this process. Professional trading firms are moving their technical capabilities and capital from CEXs to on-chain markets. Market makers and proprietary trading firms from Wall Street have already begun deploying strategies on-chain [30]. For example, Jump Trading invested in Firedancer, a high-performance validator client for Solana, while Cumberland became a core data provider for the Pyth oracle network. These moves reflect deep institutional conviction in the price-discovery potential of on-chain markets. The inflow of institutional capital brings not only deeper liquidity but, more importantly, more efficient information processing: professional market makers possess sophisticated pricing models and risk-management systems, and their participation directly improves the speed and accuracy with which on-chain markets incorporate new information into prices. As the right panel of Figure 6-10 shows, annual DEX perpetual futures volume grew from roughly $0.3 trillion in 2022 to roughly $6.7 trillion in 2025, a compound annual growth rate exceeding 180%, with accelerating institutional participation an important driver of this growth.

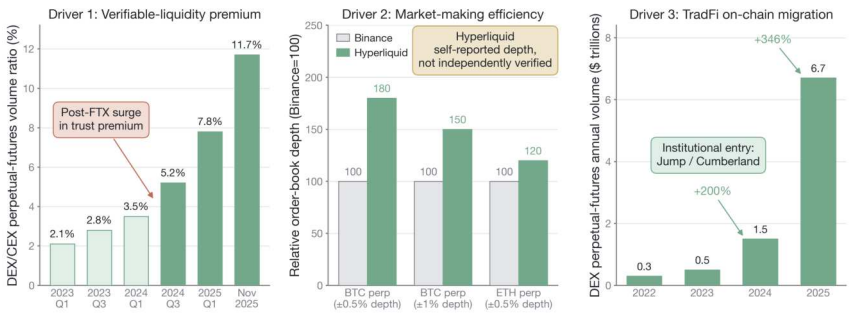

Figure 6-10. The three structural drivers of the price-discovery migration and the current evidence (the left panel shows the ratio of DEX to CEX perpetual futures volume, through November 2025 [4]; the middle panel shows Hyperliquid's self-reported resting-order depth [29], for a specific price level and time window, not cross-validated against independent data sources such as Kaiko and Amberdata; the right panel shows annual DEX perpetual futures volume [3], with +200% and +346% on a year-over-year basis; Data source: CoinGecko [4], DeFiLlama, The Block [3], and Hyperliquid team public data [29])

The three panels of Figure 6-10 together sketch the current progress of the price-discovery migration across three dimensions: market share, liquidity depth, and absolute scale. As the next subsection will argue, however, these data are not yet sufficient to prove that the migration has crossed an irreversible critical mass.

6.4.2 Critical mass and network effects

The liquidity of financial markets has powerful, self-reinforcing network effects. As classic theory in financial economics reveals, liquidity attracts liquidity. In perpetual futures markets, this network effect manifests as a clear positive feedback loop: deeper liquidity leads to narrower bid-ask spreads; narrower spreads attract more traders; the gathering of traders brings more order flow; abundant order flow further attracts more market makers; and the increase in market makers in turn provides deeper liquidity (see Figure 6-11).

This mechanism means that if the liquidity of application-chain DEXs can persistently surpass that of CEXs on certain core assets, this positive feedback loop may make the migration of price discovery irreversible. For once a certain *critical mass* is crossed, any effort to pull liquidity back to the traditional architecture must overcome the same enormous network-effect barrier. This closely resembles the competitive dynamics among exchanges in traditional finance: once an exchange gains an overwhelming liquidity advantage in a particular asset class, competitors find it nearly impossible to reclaim market share in that asset.

Assessing the current state of the migration, however, demands extreme rigor. Empirical research shows that the current crypto market still exhibits a clear two-tiered structure: CEXs remain dominant in price discovery, with a price-integration measure about 61% higher than that of DEXs [31]. The specific methodology behind this figure (information share, the Gonzalo-Granger decomposition, or another price-discovery measure), the sample period, and the range of assets analyzed all significantly affect the estimate. Such estimates are highly sensitive to the sampling frequency and the lead-lag specification, and given the rapid change in DEX market share, even recent research may already be partly outdated. New information is reflected in prices at the CEX first and only then transmitted to DEXs through the funding rate and arbitrage mechanisms. This finding shows that although the direction of the migration trend is clear, and it has already completed the stage-transition from *impossible* to *observable*, it remains a considerable distance from the *irreversible* critical mass.

Figure 6-11 assesses the current state of the price-discovery migration across five key dimensions: liquidity depth (for some assets, such as BTC perpetual futures, this has approached or even surpassed the CEX) is the dimension closest to critical mass, whereas on the price-discovery-contribution (information-share) dimension, the CEX is still about 61% higher, the strongest evidence that the migration is incomplete; trading-volume share, institutional participation, and the persistence of liquidity after incentives are withdrawn are the key variables that will determine whether the migration can move from *observable* to *irreversible*.

6.4.3 A cautious reading of the current evidence

Regarding the price-discovery migration hypothesis, we must maintain a cautious scholarly stance and recognize several key limitations in the current market evidence.

Potential bias in data sources. Some of the prominent data currently supporting the migration hypothesis (such as order-book-depth comparisons at specific price levels)

come from public statements by application-chain team members or from reports by interested parties. Although these data have reference value, they carry an inherent conflict of interest. For example, the depth data made public by the Hyperliquid team selected the price levels and time windows most favorable to itself and may not reflect true conditions across all hours and all market states. These data need to be cross-validated through independent academic research and third-party microstructure data (from professional data providers such as Kaiko and Amberdata).

Snapshot versus norm. A depth snapshot at a single point in time or under a specific market environment cannot represent the market's persistent norm. Liquidity may temporarily surpass the CEX in certain periods (such as the peak of protocol token incentives, the anticipation phase of an airdrop, or when market sentiment is extremely optimistic) but may fall back significantly after incentives end or sentiment shifts. Assessing the true progress of the migration requires examining the retention rate of liquidity after a complete market cycle (including bull markets, bear markets, and extreme volatility events). "Incentives are highly effective at attracting volume but ineffective at retaining risk. Fee rebates and points programs can rapidly mobilize activity, but they do not by themselves generate durable open interest. Risk does not stay where it is subsidized; it stays where it is safely held." [32]

Depth does not equal price-discovery quality. Order-book depth is only one dimension of market quality. The quality of price discovery depends more on informational efficiency (the speed and accuracy with which new information is incorporated into prices) and on market resilience (the speed at which prices recover after being hit by a large order). A market with an extremely deep order book but slow information transmission may have lower price-discovery quality than a shallower market that reacts to information far more quickly. These multidimensional assessments require more precise microstructure tools—such as the Hasbrouck information share [33] and the Gonzalo-Granger permanent-transitory decomposition—for empirical testing, which is taken up in Chapters 13 through 15.

The role of seigniorage in liquidity formation. The perpetual futures DEX market is at a critical juncture in the transition from *subsidy-driven* to *market-structure-driven* [32]. The year 2025 is the first in which multiple perpetual futures DEXs began to pass this test at scale. Yet the liquidity of many emerging platforms still relies heavily on token-inflation incentives (seigniorage). Only when the main source of on-chain liquidity substantively shifts from token incentives to genuine trading demand and sustainable market-making profits can this migration of price discovery be considered truly sustainable.

> Conclusion: The directional judgment of the migration hypothesis is well-founded, but it is currently still at the stage of *a trend that is identifiable but not yet irreversible*. Chapters 13 through 15 will use more precise microstructure tools to assess this judgment.

The positive feedback loop of liquidity network effects and the current-state assessment of the price-discovery migration (a positive-feedback-loop schematic overlaid with the author's migration scores, where 0 to 100 is the author's composite assessment, not a single quantitative metric; the only external empirical data are the 11.7% volume share, November 2025 [4], and the CEX price-information share being about 61% higher [31]; Data source: CoinGecko [4], Zhivkov [31], and Hyperliquid public data [29])

6.4.4 The shaping of trader behavior

The migration of price discovery is not merely a reallocation of macro market share; at the micro level it profoundly shapes traders' behavioral patterns. Market structure is by no means a passive *backdrop* to trading behavior but an active *shaper* of it. Understanding this has a decisive influence on assessing the quality of price discovery under different architectures.

Empirical research on the behavioral differences between CEX and DEX traders reveals the concrete impact of this shaping effect [10]. That study systematically compared the behavioral differences of traders on CEXs and DEXs and found a striking phenomenon: on CEXs, traders' behavioral patterns are closer to those of traditional financial markets, showing a relatively balanced response to price signals in both directions—roughly symmetric sensitivity to good news and bad news. On oracle-priced DEXs, however, uninformed traders respond significantly more strongly to positive news than to negative news, producing a systematic long bias.

The root of this behavioral difference lies in the design of the underlying mechanism. Oracle-pricing models (such as the virtual automated market maker, or vAMM, and oracle-based synthetic assets) structurally reduce the slippage and adverse-selection risk a trader faces when building a long position. When a trader goes long on an oracle-priced DEX, the execution price is determined directly by the external price the oracle provides and is not constrained by local order-book depth, so a large long order does not push up the execution price the way it would in a traditional central limit order book. This mechanical asymmetry regularly incentivizes going long and suppresses going short.

To present these behavioral differences systematically, Table 6-5 compares the behavior of CEX traders and oracle-priced DEX traders across four key dimensions and traces the mechanism root behind each difference.

Behavioral dimension	CEX traders	Oracle-priced DEX traders	Mechanism root of the behavioral difference
Response to positive news	Moderately increase long positions	Significantly increase long positions	Oracle pricing lowers long-side slippage
Response to negative news	Moderately increase short positions	Relatively muted response	Shorting still faces liquidity constraints
Leverage propensity	Fairly evenly distributed	Skewed toward higher leverage	Low slippage encourages more aggressive positions
Holding period	Relatively short (mostly intraday)	Relatively long	Lagging oracle-price updates may systematically depress the deviation between the mark price and the index price, thereby lowering the absolute value of the funding rate and the cost of holding a position (a hypothetical explanation, awaiting further empirical testing)

Table 6-5. Behavioral differences between CEX and oracle-priced DEX traders and their mechanism roots (Data source: compiled by the author based on Chen, Ma, and Nie [10])

Table 6-5 shows that these behavioral differences are not random but correspond systematically to the underlying pricing mechanism—the structural weakening of long-side slippage under oracle pricing simultaneously incentivizes a long bias, higher leverage, and longer holding periods across all four dimensions. Beyond the mechanistic explanation, a behavioral perspective offers a complementary understanding: the amplifying effect of social media (narrative contagion in Crypto Twitter and Telegram groups) creates a powerful long-direction herding effect that superimposes on and reinforces the structural incentives of oracle pricing. This systematic long bias has reflexive implications: deviation from the CEX funding rate creates a predictable arbitrage flow, and the arbitrage flow itself becomes a source of distortion in the cross-CEX-DEX price signal. This finding shows that different pricing mechanisms, fee structures, and risk-management rules regularly incentivize or suppress specific types of trading behavior, thereby systematically affecting the direction and efficiency of price discovery; it also provides the macro background for the deeper discussion of order-book microstructure and mechanism design in later chapters (Chapters 7 and 8): every adjustment of a protocol parameter is not merely optimizing system performance but redefining the game matrix of market participants and thereby shaping the price-discovery characteristics of the entire market.

6.5 The evolution of risk distribution

The evolution of market structure has changed not only the mode of competition and the pricing mechanism but also, fundamentally, the distribution of systemic risk. In assessing the migration from centralized to decentralized architectures, a common error is to seek a simple binary conclusion: *Is on-chain safer than a centralized exchange?* This way of framing the question is itself flawed, because it presupposes that risk can be compared along a single dimension. This section advances the *risk visibility-manageability proposition*, arguing that the evolution from CEXs to on-chain architectures is essentially not a simple increase or decrease in the total quantity of risk but a structural transformation in the character of risk—from *invisible but occasionally explosive* to *continuously visible but manageable*. This framework is a dynamic extension of the *risk substitution theorem* of Chapter 5 and is of a piece with the concept of *risk-surface transformation* advanced in Chapter 1.

6.5.1 The risk visibility-manageability proposition

A core axiom in the theory of financial risk management is this: risk that cannot be observed and measured cannot be effectively managed. This axiom runs through the entire body of risk-management knowledge, from the Basel Accords to modern portfolio theory. On this basis, we advance the risk visibility-manageability proposition.

> Proposition: The visibility of risk is a necessary but not sufficient condition for its manageability. Invisible risk cannot be accurately quantified and therefore cannot be effectively hedged or managed ex ante; it can only be dealt with passively, after the fact, when a crisis erupts. Yet visibility alone does not guarantee manageability; the effective management of risk also depends on adequate loss-absorption capacity, appropriate circuit-breaker mechanisms, and a tiered liquidation system.
> Corollary: The evolution from CEXs to on-chain architectures marks a substantial improvement in the visibility of systemic risk. This does not mean the absolute level of risk falls; rather, it means the nature of risk changes fundamentally, from tail-risk events that are *unmanageable but occasionally require enduring catastrophic consequences* [34] to a normalized challenge that is *manageable but requires the continuous investment of resources for monitoring and protection*. The JELLY incident provides an important boundary-condition test of this proposition: the attack was fully visible on-chain in real time, and the community completed a diagnosis of the attack vector within hours—visibility did indeed accelerate identification of the problem. Yet the protocol could not manage this risk through automated mechanisms and ultimately still required centralized intervention (unilateral delisting and forced liquidation), which at the operational level is equivalent to the CEX behavior this chapter criticizes. This shows that, above visibility, the *manageability* of risk may still depend on residual centralized power, a tension especially pronounced in application chains with limited decentralization.

Under the CEX paradigm, risk exhibits the characteristics of *low-frequency, invisible, and occasionally catastrophic*. In day-to-day operations, the user experience is usually extremely smooth: trades execute fast, the interface is friendly, and customer service responds promptly. Risk is hidden inside the black box of centralized servers, and the safety of a user's assets rests entirely on one-sided trust in the exchange's solvency

and internal governance. Yet once this invisible risk accumulates to a critical point, it often erupts in an extremely destructive way. The customer-fund losses caused by the FTX collapse and its bankruptcy proceedings, which lasted more than two years (see Section 6.1.1) [28]; the $1.5 billion security incident suffered by Bybit in February 2025 [35]; and the loss of roughly 850,000 BTC by Mt. Gox in 2014 (on the basis of the bankruptcy-trustee / civil-rehabilitation proceedings) [54], with its legal-recovery process stretching over nearly a decade, are all textbook cases of this pattern. Their common feature is that, before the disaster, external market participants had almost no warning, and the social cost was extremely high.

By contrast, risk under an on-chain architecture exhibits the characteristics of *high-frequency, visible, and manageable*. In a general-purpose public-chain or application-chain DEX, the MEV game plays out in real time in the public mempool, the logic and potential vulnerabilities of smart contracts are open to all auditors, and every parameter and trigger condition of the liquidation process is clearly queryable on-chain. Users and institutions can intuitively *see* these risks every day. Precisely because of this continuous visibility, market participants can build real-time monitoring systems, early-warning mechanisms, and hedging strategies. Take the JELLY attack Hyperliquid suffered in March 2025: the attacker exploited a design flaw in the liquidation mechanism, and the protocol vault consequently faced a peak unrealized loss of roughly $13.5 million (not a realized loss; the HLP vault recorded a small profit after final settlement—see the detailed analysis of this incident in Section 6.3.2); but the protocol-level response completed within hours: the token was delisted, positions were settled at the mark price, and parameters were tightened [36]. This pattern of *rapid exposure, rapid repair* stands in sharp contrast to the CEX pattern of *long concealment, sudden collapse*.

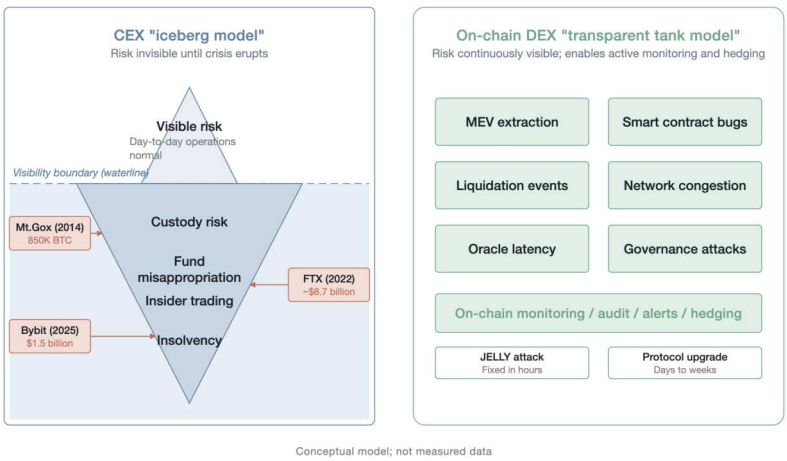

Figure 6-12. A visualization of the risk visibility-manageability proposition (a CEX's tail risks—custodial risk, misappropriation of funds, insolvency—are invisible in daily operation until a crisis erupts; on-chain DEX risk types—MEV extraction, smart-contract vulnerabilities, liquidation events—are continuously visible, supporting active monitoring and hedging; a conceptual-model schematic, not empirical data; the roughly $8.7 billion FTX figure is on the debtors' customer-shortfall / August 2024 court restitution-order basis, Bybit's $1.5 billion [7], and JELLY's within-hours repair [36]; drawn by the author)

In assessing the merits of these two patterns, the lessons of financial history repeatedly prove a profound truth: invisible risk is not absent risk; it means only that when it erupts, the system will be utterly unprepared. One root of the 2008 global financial crisis was precisely that complex structured financial products hid the risk of subprime loans within multiple layers of securitization, leaving regulators and market participants unable to accurately assess the true scale of systemic risk. The collapse of FTX is the crypto market's version of the same lesson. Therefore, the systemic destructive power of a tail-risk event far exceeds the economic cost of sustaining continuous security investment. The evolution of risk toward a visible state is a necessary condition for a market's maturation.

6.5.2 Statistical properties of risk

To characterize this evolution more precisely, we need to systematically compare the statistical properties of risk across the three service-provider architectures. This is not only a dynamic extension of the *risk substitution theorem* of Chapter 5 but also a concretization of the concept of *risk-surface transformation* of Chapter 1, providing an analytical framework for quantitatively assessing market quality.

Dimension	Centralized exchange	General-purpose public-chain DEX	Application-chain DEX
Frequency of risk events	Low (roughly five catastrophic events with single losses exceeding $1 billion between 2022 and 2025, including FTX and Bybit; the total is significantly higher if bankruptcies such as Celsius, BlockFi, and Voyager and mid-sized security incidents are included)	High (per EigenPhi data, daily MEV extraction on Ethereum exceeds $500,000 [18])	Medium (in 2025, Hyperliquid experienced three strategic attacks on the order of tens of millions of dollars)
Single-shock magnitude	Extremely high (FTX roughly $8.7 billion, on the debtors' customer-shortfall basis [1]; Bybit $1.5 billion [35])	Low to medium (a single MEV extraction is usually thousands to tens of thousands of dollars; a contract-vulnerability attack can reach millions)	Medium (the three 2025 incidents were roughly $4 million, $13.5 million, and $4.9 million, respectively [20][37][25])
Ex ante predictability	Extremely low (operates inside a black box; not externally observable)	High (on-chain data and the mempool are globally traceable)	Medium to high (traceable on-chain, but strategic attacks have a degree of covertness)
Crisis-recovery path	Lengthy legal and bankruptcy proceedings (FTX about 2 years, Mt. Gox about 10 years)	Smart-contract repair and deployment (on the order of days to weeks)	Governance votes and protocol-level emergency upgrades (Hyperliquid's JELLY incident about 6 hours [36])

Table 6-6. A comparison of the statistical properties of risk across the three paradigms (Data source: compiled by the author based on [1][18][20][25][35][36][37])

The comparison in Table 6-6 presents a clear frequency-versus-shock-magnitude trade-off: the CEX has the lowest frequency of risk events but the highest single-shock magnitude (on the order of billions of dollars), whereas on-chain architectures have more frequent risk events but relatively controllable single losses (on the order of millions to tens of millions of dollars). The difference in the crisis-recovery path is especially striking: CEX bankruptcy recovery is measured in years, while on-chain protocol repair is measured in hours to weeks—an order-of-magnitude gap that directly corroborates the core assertion of the risk visibility-manageability proposition. Looking at the distribution of specific risk types, the three paradigms present markedly different profiles, echoing the risk substitution theorem of Chapter 5: rather than eliminating risk, different architectures substitute one form of risk for another.

Beyond the macro trade-off between frequency and shock magnitude, the three paradigms also present markedly different profiles in the distribution of specific risk types. From seven core risk categories—custodial/counterparty risk, smart-contract

risk, MEV/information leakage, liquidation/shortfall, economic security, cross-chain bridges, and regulation/compliance—Table 6-7 compares, one by one, the degree of exposure and the manifestation of each risk in the three architectures.

Risk type	CEX paradigm	General-purpose public-chain DEX paradigm	Application-chain DEX paradigm
Custodial/counterparty	Extremely high: assets are custodied by the exchange, facing theft, misappropriation, and bankruptcy risk	Extremely low: self-custodial wallet, managed by smart contracts	Low: on-chain account management, but the cross-chain bridge is the weak link
Smart contract	None: no on-chain smart contracts involved	High: contract vulnerabilities can cause fund losses	Medium: core logic embedded at the protocol layer, with a smaller attack surface
MEV/information leakage	Implicit: information asymmetry exists inside the exchange	Explicit and high: the public mempool exposes trading intent	Controllable: the private mempool mitigates traditional MEV, but validator MEV is a new risk
Liquidation/shortfall	Socialized sharing by the insurance fund; in extreme cases, transferred via ADL	Managed by the protocol insurance fund; the liquidation process is public and transparent	Managed by the protocol insurance fund; governance can adjust liquidation parameters
Economic security	None: does not depend on a token-economic model	Low: inherits the economic security of the underlying blockchain	Medium to high: relies on its own token's market capitalization to maintain network security
Cross-chain bridge	None: no cross-chain operations involved	Low: the official L2-to-L1 bridge has relatively strong security guarantees	Medium to high: assets must pass through a cross-chain bridge to enter the application chain
Regulation/compliance	High: a regulated entity, facing license revocation and asset freezes	Medium: decentralization raises the difficulty of enforcement, but the front end can be regulated	Medium: between a CEX and a pure DEX, with an as-yet-unclear regulatory status

Table 6-7. A comparison of the distribution of seven core risks across the three architectures (Data source: compiled by the author)

Table 6-7 clearly displays the concrete paths of risk substitution: the CEX's custodial/-counterparty risk is largely eliminated in on-chain architectures, but it is replaced by smart-contract risk and cross-chain-bridge risk; the implicit information asymmetry of the CEX turns into explicit MEV extraction in the general-purpose public-chain DEX and then evolves into the more covert validator MEV in the application-chain DEX. No architecture achieves the absolute elimination of risk; what differs is only the form of risk exposure and the degree to which it is manageable.

Figure 6-13 integrates Tables 6-6 and 6-7 into four complementary visual perspectives: (a) a frequency-versus-shock-magnitude scatter plot, (b) a radar chart of the seven risk types, (c) a comparison of recovery-path times, and (d) a visibility-manageability quadrant chart, intuitively presenting the overall direction of risk evolving from *low-frequency, high-shock, unmanageable* to *high-frequency, low-shock, manageable*. Here, the order-of-magnitude gap between recovery paths measured in years (CEX: FTX about 2 years, Mt. Gox about 10 years) and those measured in hours to weeks (on-chain: JELLY about 6 hours) is the most intuitive corroboration of the risk visibility-manageability proposition.

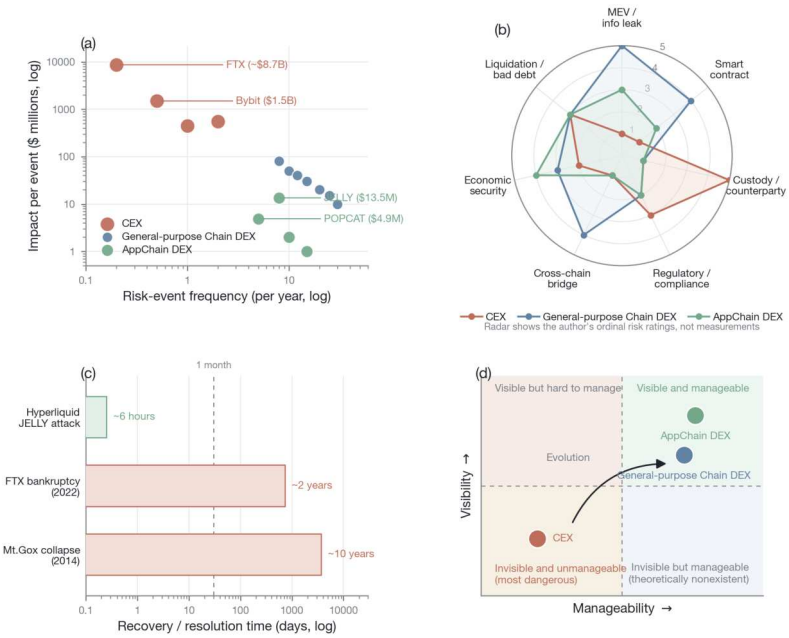

Figure 6-13. The evolution of risk distribution across the three paradigms: a frequency-versus-shock-magnitude scatter plot, a radar chart of the seven risk types, a comparison of recovery-path times, and a visibility-manageability quadrant chart (panels a and c use public event data, sourced event by event: FTX roughly $8.7 billion, on the debtors' customer-shortfall / restitution-order basis; Bybit $1.5 billion [7]; POPCAT roughly $4.9 million [25]; JELLY roughly $13.5 million, peak unrealized loss [37], recovered within hours [36]; panels b and d use the author's ordinal risk ratings, not quantitative measurements; Data source: public event records, 2014 to 2025; the DEX/CEX volume ratio additionally follows CoinGecko [4])

6.5.3 Cross-paradigm risk transmission

Although the three paradigms differ significantly in architectural design and risk distribution, they are not systems that operate in isolation. In the current crypto ecosystem, they are tightly connected by the price of the same underlying asset, constituting a complex financial system of *communicating vessels*. While this interconnection improves overall market efficiency (eliminating price gaps through cross-market arbitrage), it also creates a lethal path for cross-paradigm risk transmission. Beyond the oracle-mediated price-transmission channel detailed below, the stablecoin liquidity channel constitutes

another equally critical but more covert cross-paradigm transmission path. DEX perpetual futures use USDT and USDC as their principal collateral, and the credit basis of these stablecoins derives from off-chain fiat reserves and short-term Treasury portfolios. In a macro-stress scenario (as demonstrated by the USDC depeg event triggered by the collapse of Silicon Valley Bank in March 2023), transmission occurs not through the oracle price but through the collateral layer itself: a stablecoin confidence crisis would simultaneously impair the collateral quality of all three paradigms, triggering correlated liquidations. This channel bypasses all oracle-based circuit-breaker designs and constitutes one of the hardest-to-defend systemic risks in the current market structure.

In extreme market volatility, this transmission usually completes within minutes, and its typical cyclical path is shown in Figure 6-14. Because CEXs aggregate large numbers of highly leveraged retail traders, when the market suffers a sudden shock, the CEX is the first to trigger large-scale forced liquidations, causing prices to fall sharply. This negative feedback loop of *forced liquidation → price decline → more liquidations* is precisely the crypto-market realization of the *loss spiral* that Brunnermeier and Pedersen (2009) formalized in *Market Liquidity and Funding Liquidity*, in which the mutually reinforcing decay of market liquidity and funding liquidity is sharply amplified in a high-leverage environment [38]. Subsequently, the oracle network rapidly transmits the CEX crash price on-chain, triggering a chain of liquidations of highly leveraged DEX positions; on-chain liquidation flow strikes market makers' liquidity pools or order books, causing the DEX price to deviate significantly from the CEX; cross-market arbitrageurs then buy on the lower-priced DEX and sell to hedge on the CEX, transmitting new selling pressure back to the CEX and thereby potentially opening a new round of the negative feedback loop.

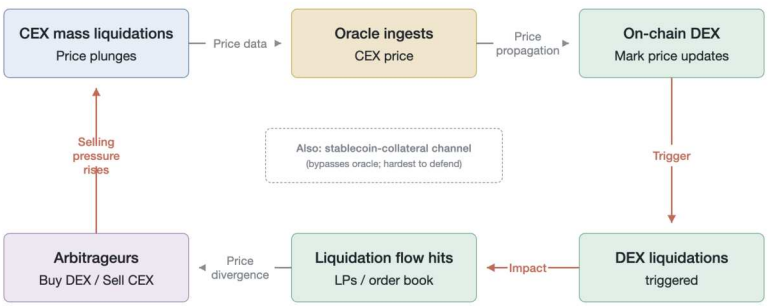

Figure 6-14. The cyclical path of cross-paradigm risk transmission (the price shock triggered by CEX liquidations is transmitted on-chain to DEXs via the oracle, triggering a chain of liquidations, and arbitrageurs' cross-market operations feed selling pressure back to the CEX; a conceptual-cycle schematic, the oracle-mediated channel, not empirical data; drawn by the author, based on FTI Consulting [39])

There are two key amplifiers in this transmission mechanism. The immediacy of the oracle is one. In traditional finance, the settlement delay between different markets often serves as a buffer—for example, the daily settlement mechanism of futures markets gives participants a time window to adjust positions. In the crypto market, however, oracle networks differ fundamentally in architecture: Chainlink uses a push-based heartbeat-

plus-deviation-threshold model (updating automatically when the price moves more than, say, 0.5% or after N minutes), while Pyth uses a pull-based model (consumers request the latest price on demand). This difference has different effects on the speed of cross-paradigm transmission; a pull-based oracle may in fact amplify the transmission effect, because liquidators actively pull the latest, most unfavorable price to trigger liquidations and capture rewards. Regardless of the model, oracles typically reflect price changes at second-level frequency, eliminating the settlement buffer of traditional finance, so that a price crash on the CEX side can be transmitted within seconds to all on-chain protocols relying on that oracle, triggering synchronized chain liquidations. Superimposed on the immediacy of the oracle is the blind spot of each platform's local perspective: whether it is a CEX's liquidation engine or a DEX's protocol parameters, their risk-control mechanisms can only make decisions based on local data from their own platform, and no single platform can assess the systemic leverage level of the entire market. A CEX's risk-control system cannot know how large a leveraged position the same batch of traders holds on an on-chain DEX, and vice versa. This *locally reasonable but globally inadequate* parameter setting (such as the liquidation-penalty rate, the maintenance-margin ratio, and the auto-deleveraging trigger conditions) is extremely fragile in the face of a cross-market resonant shock.

The crypto-market flash crash of October 2025 provides a vivid empirical illustration of this transmission mechanism. According to FTI Consulting's analysis, Bitcoin fell roughly 14% within hours, and the visible notional value of forced liquidations across CEXs and DEXs exceeded $19 billion within about 24 hours. The wave of CEX-side liquidations erupted first, and the on-chain DEX liquidation wave followed close behind, with the lag between them only a few minutes, during which the price deviation of major oracles at one point reached over 1% [39]. High leverage, shrinking order-book depth, the brief failure of oracles, and cross-platform auto-deleveraging mechanisms together constituted a severe liquidity crisis. In that event, the liquidation engines of multiple platforms triggered large-scale forced liquidations within the same time window, while each platform's risk-control system saw only its own internal risk exposure and could not assess the systemic leverage level of the entire market. This cross-paradigm risk transmission is the most severe systemic challenge facing today's perpetual futures market and a core problem that future regulatory frameworks and protocol engineering must confront head-on. Chapter 20 provides a formal analysis of this cross-paradigm transmission from the liquidity perspective, and Chapter 22 from the volatility perspective.

6.6 The paradigm endgame

After a systematic dissection of the competition modes, MEV forms, and risk distribution of the three paradigms—centralized exchanges, general-purpose public-chain decentralized exchanges, and application-chain DEXs—a core macro question must be addressed: Where are these three paradigms headed? Does the evolution of market structure necessarily follow the one-way, linear logic of *decentralization replacing centralization*, or will it display a more complex dynamic pattern?

The analysis in this section shows that the three paradigms will not converge on an

endgame of *one model rules them all*; instead, they will coexist over the long term amid competition and converge on one another through mutual borrowing. The key uncertainty is where the terminal state of this convergence will land, and whether advances at the technological frontier can effectively expand the area of the *impossible triangle* and thereby redefine the boundary of what is possible for market structure. At the same time, two fundamental unresolved problems—the effectiveness boundary of decentralization and the dual effect of transparency in a high-leverage environment—will continue to shape the evolutionary direction of the next generation of market structure.

6.6.1 Coexistence and the competitive landscape

Although decentralized exchanges have grown rapidly over the past few years, the market data clearly reveal a multipolar coexistence rather than a simple relationship of replacement. Over the full year of 2025, the top ten perpetual futures exchanges (spanning both CEXs and DEXs) handled as much as $92.9 trillion in volume, up 64.6% year over year [40]. Within this volume growth, DEX perpetual futures volume surged 346% to a record high of $6.7 trillion, and the ratio of DEX to CEX perpetual futures volume climbed further to 11.7% (for the starting point and trajectory of this ratio, see this chapter's introduction and Section 6.4) [40]. This does not mean, however, that CEXs are being comprehensively replaced; in absolute terms, CEXs still hold roughly 85% or more of market share.

This coexistence pattern arises because the three paradigms each occupy an irreplaceable niche. The centralized exchange remains the venue of choice for extremely latency-sensitive high-frequency market-making strategies, for retail investors with limited technical ability, and for institutional capital that depends on deep fiat on- and off-ramps. Through millisecond-level matching engines and internal-ledger settlement, CEXs offer the highest capital efficiency and liquidity depth achievable under current technical conditions. General-purpose public-chain DEXs (such as protocols deployed on Ethereum or its general-purpose Layer-2s), although unable to rival CEXs in performance, satisfy DeFi-native strategies with a strong demand for *composability*; on these platforms, perpetual futures can interact seamlessly with lending protocols and yield aggregators to form complex structured products. Application-chain DEXs (such as Hyperliquid) and the neighboring application-specific ZK-Rollups that anchor finality to Ethereum's settlement layer (such as Lighter, which strictly speaking does not have independent consensus—see Section 6.6.3) are opening a new battlefield that balances performance and verifiability. By building a dedicated Layer-1 blockchain, Hyperliquid achieved sub-second trade confirmation and throughput of roughly 200,000 orders per second, and in 2025, with $2.9 trillion in annual volume, leapt to become the world's seventh-largest perpetual futures exchange, even surpassing established CEXs such as Coinbase International [40].

From four dimensions—core user base, core advantage, market share, and representative platforms—Table 6-8 summarizes the niche each of the three paradigms occupies. This comparison helps explain why a simple *replacement thesis* cannot describe the market's true state, because each paradigm serves different user needs and trading scenarios, and

its core advantage cannot yet be fully replicated by the others under current technical conditions.

Dimension	CEX	General-purpose public-chain DEX	Application-chain DEX
Core user base	High-frequency market makers, retail, institutions	DeFi-native strategists	Mainstream traders, institutions
Core advantage	Low latency, fiat channels, liquidity depth	Composability, permissionless innovation	The optimal intersection of performance and verifiability
2025 market share	Roughly 85%+	Roughly 3%–4% (perpetual futures)	Roughly 8%–9% (perpetual futures)
Representative platforms	Binance, OKX, Bybit	GMX, Synthetix	Hyperliquid, Lighter

Table 6-8. The core niche differences among the three paradigms (Data source: compiled by the author)

Table 6-8 shows that the market-share distribution of the three paradigms corresponds closely to the size and capital volume of their core user bases. The criterion distinguishing a *general-purpose public-chain DEX* from an *application-chain DEX* in the classification above is whether the platform has an independent blockchain and consensus mechanism; for example, after dYdX v4 migrated from a general-purpose public chain (v3 on StarkEx) to an independent Cosmos-based application chain, it was reclassified from the former to the latter. In addition, the volume metric may be inflated by wash trading or incentive-driven exchanges, and open interest (OI) is a more robust indicator of genuine risk-bearing and price-discovery contribution; but because the availability of DEX OI data is limited, volume remains the primary comparison dimension here. The market may ultimately consolidate to one or two dominant platforms in each segment [41]. This means the future competitive landscape may evolve into a bipolar competition between *the top CEX and the top application-chain DEX*, while general-purpose public-chain DEXs continue to play their distinctive role in the composability niche. The coexistence of the three paradigms may constitute a long-term equilibrium of market structure, but this judgment must be treated with caution: the current coexistence may be sustained in part by user habits, platform lock-in effects, and switching costs, which makes it closer to a focal equilibrium sustained by behavioral inertia than to a Nash equilibrium in the strict sense. Should a major CEX regulatory crackdown occur, a technological breakthrough eliminate the application chain's performance advantage, or the liquidity network effect of one paradigm break through a critical point, the current tripolar coexistence could be disrupted.

6.6.2 Convergence dynamics

The evolution of market structure is not a static standoff but a dynamic process of mutual borrowing and fusion. The fundamental driver of this convergence is precisely the competitive compression of the trust tax that we examined in Chapter 1 (Section 1.4.3, *the layered hybrid of the three trust paradigms*) and Chapter 3 (the *institutional*

convergence thesis). To attract and retain liquidity, both CEXs and DEXs strive to make up for their own structural shortcomings, moving toward a middle ground of *lower trust tax and higher verifiability*.

The trend of CEXs moving closer to on-chain models accelerated markedly after the FTX collapse. To rebuild market trust, mainstream CEXs widely introduced cryptography-based proof of reserves, seeking to add a layer of verifiability outside their opaque internal ledgers. After the FTX event, proof of reserves (PoR) became standard practice for leading CEXs, but current PoR implementations have several known limitations: most are point-in-time snapshots rather than continuous audits, usually cover only the asset side without liability information, and cannot prevent *window dressing*—that is, an exchange temporarily borrowing assets before the snapshot to meet the proof requirement. The analysis of Vidal-Tomas (2025) further points out that in the absence of independent audit verification, the information content of PoR may be far lower than the market expects [42]. A deeper transformation is reflected in the evolution of asset-custody models: between 2024 and 2025, Binance actively promoted its keyless, seedless, multi-chain-supporting Web3 self-custodial wallet, allowing users to seamlessly access CEX liquidity while retaining control over their assets [43]. Institutional-grade custody services (such as Coinbase Prime) are exploring hybrid-custody and on-chain-settlement mechanisms, seeking to move toward the *transparency* axis within the impossible triangle. The essence of these moves is that CEXs, without giving up their performance advantage, are actively absorbing the verifiability elements of the on-chain ecosystem.

At the same time, DEXs are moving closer to institutional structure. As the scale of on-chain trading has grown and regulatory scrutiny has intensified, the fully *permissionless* ideal is giving way to an *orderly open market*. Protocols such as dYdX have begun implementing geo-fencing at the front end to restrict access by users from sanctioned regions [44]. In February 2026, Hyperliquid formally established a policy center, marking the beginning of leading on-chain protocols' active participation in exploring and shaping compliance frameworks [45]. Whether front-end geo-fencing is legally sufficient to avoid jurisdiction, however, remains fundamentally in doubt: the position of the SEC and the CFTC is that a protocol remains within their jurisdiction as long as users can access it through a VPN or by interacting directly with the smart contract. The CFTC's 2023 enforcement action against Ooki DAO established an important precedent: a DAO can be held legally liable as an *unincorporated association*. More subtly, the ability Hyperliquid demonstrated in the JELLY incident to unilaterally delist an asset and force liquidation can itself be cited by regulators as evidence that the protocol has centralized control and therefore needs to register. These legal issues are analyzed in depth in Chapter 26. At the on-chain-monitoring level, tools such as AMLBot have already extended to the Hyperliquid blockchain, providing the protocol with anti-money-laundering capabilities. At the protocol layer, DEXs have also begun introducing stricter position-size limits and governance of risk-control parameters, evolving from *fully permissionless* toward an *orderly open market* to prevent systemic collapse under extreme market conditions.

This two-way convergence is not merely a fusion of technology and products but a deep blending of two ecosystem cultures. The CEX ecosystem, originating in traditional

finance, emphasizes efficiency, liquidity, and top-down innovation, presenting a pyramidal participant structure; the DEX ecosystem, originating in the crypto community, prizes transparency, asset sovereignty, and bottom-up evolution, presenting a flatter participant structure. As traditional financial institutions participate deeply in on-chain market making (Jump Trading invested in Firedancer, a Solana validator client, and Cumberland became a data provider for the Pyth oracle) and CEXs continuously absorb on-chain elements, the boundary between the two is blurring.

> Both are moving toward a middle ground of *lower trust tax plus higher verifiability*. The driver of convergence is the competitive compression of the trust tax (Chapters 1 and 3). The ultimate result may be a *hybrid model*, in which different trust paradigms are chosen at different functional layers—precisely the *layered hybrid* predicted in Section 1.4.3, for which Chapter 28 will design a target architecture.

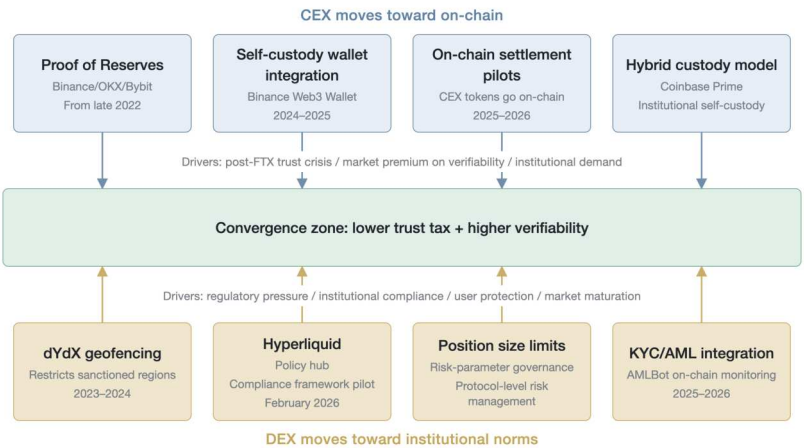

Figure 6-15. The two-way convergence trend of the CEX and DEX ecosystems (a conceptual convergence timeline, with event points through 2024 to 2026, not empirical data; Data source: Binance [43], AInvest [45], and dYdX Terms of Use [44])

Figure 6-15 presents the concrete paths of this two-way movement: the upper half shows the four paths by which CEXs move toward on-chain verifiability—through proof of reserves, self-custodial wallets, and the like—while the lower half shows the four paths by which DEXs move toward institutional compliance—through geo-fencing, policy centers, and the like—with the two sets of paths meeting in the middle ground of *lower trust tax and higher verifiability*. This convergence trend indicates that the next generation of market structure may no longer be a simple either-or choice between CEX and DEX but a layered hybrid architecture that chooses different trust paradigms at different functional layers.

6.6.3 Expanding the impossible triangle

In Section 5.1.3 of Chapter 5, we examined the *impossible triangle* that constrains the architectural design of an exchange: performance, transparency/verifiability, and

decentralization. The traditional view holds that a system can choose only two of these three dimensions and must sacrifice the third. Technological progress, however, is attempting to *expand the area of the triangle*, so that dimensions that once had to be sacrificed can be achieved simultaneously at a higher level. Four frontier technologies are currently reshaping this boundary.

Zero-knowledge proofs are the most transformative of these technologies. ZK allows one party to prove to another the correctness of a computation without revealing its details. In the exchange context, this means fully verifiable matching and liquidation can be achieved while keeping trading strategies private and on-chain data costs extremely low. ZK essentially creates a new dimension on the *transparency* axis—*verifiable but not transparent*—breaking a combination that was impossible in the traditional triangle. Its scope of application is expanding from proof of reserves to verifiable off-chain computation and cross-chain communication, providing a mathematical-grade guarantee for enhancing privacy and interoperability. The zero-knowledge-proof (ZKP) market is projected to expand from $1.535 billion in 2025 to $7.586 billion in 2033, at a compound annual growth rate of 22.1% [46].

Intent-based trading represents a fundamental shift in the execution paradigm. Under this architecture, users no longer submit specific trading instructions but express high-level execution goals, and a network of professional solvers competitively finds the optimal execution path [47]. This paradigm shifts the complexity of execution from the user side to professional nodes and has already been validated in the automated market maker (AMM) spot-swap scenario through protocols such as UniswapX and CoW Protocol, effectively reducing slippage and the negative impact of MEV. The migration of the intent-based architecture to the perpetual futures scenario, however, faces additional complexity: perpetual futures involve state-dependent operations such as margin management, the position lifecycle, and funding-rate settlement, which are hard to reduce to stateless *intent* expressions. When handling the opening, adjustment, and closing of a leveraged position, a solver must assess margin adequacy and liquidation risk in real time, a complexity far exceeding the single-path optimization of a spot swap. Intent-based trading in the perpetual futures domain is therefore more likely to be applied first to peripheral links such as order routing and cross-platform optimal execution, rather than replacing the core order-book matching logic. In essence, this technology raises system efficiency on the *performance* axis through fine-grained division of labor, but its boundary of applicability in the derivatives scenario still awaits testing in practice.

Modular blockchains, by separating data availability, the consensus mechanism, and the execution layer into different specialized networks (such as Celestia or EigenDA), allow application-chain DEXs to outsource some core functions to specialized underlying infrastructure. This architecture enables a protocol to achieve performance far beyond that of a monolithic blockchain without sacrificing underlying security, raising the system's overall security on the *decentralization* axis through specialized division of labor.

The proliferation of account abstraction narrows the gap between on-chain and CEX at the user-experience level. With the integration of EIP-7702 in Ethereum's Pec-

tra upgrade in May 2025, the adoption of smart-contract wallets accelerated markedly [48]. Account abstraction greatly lowers the threshold for on-chain interaction, allowing users to use features such as gasless transactions, social recovery, and batch operations. Without sacrificing the core principle of self-custody, it brings the on-chain experience remarkably close to that of a CEX, thereby narrowing the gap on the *performance/-convenience* dimension.

Table 6-9 systematically summarizes the four technologies above along the impossible-triangle dimension they expand, their core mechanism, and their representative applications. It shows that the four technologies do not each exert force in isolation on a single dimension; rather, each pushes outward along a different axis of the impossible triangle, and their fusion in real projects is redefining the boundary of what is possible for market structure.

Frontier technology	Dimension expanded	Core mechanism	Representative application
Zero-knowledge proofs	Transparency/verifiability	A new dimension of *verifiable but not transparent*	Lighter ZK-Rollup, proof of reserves
Intent-based trading	Performance	User-solver division of labor, reducing MEV	UniswapX, CoW Protocol
Modular blockchains	Decentralization	Separation and specialization of DA/-consensus/execution	Celestia, EigenDA
Account abstraction	Performance/convenience	Smart-contract wallets, approaching the CEX experience	EIP-7702, Safe

Table 6-9. The mechanisms by which four frontier technologies expand the dimensions of the impossible triangle (Data source: compiled by the author)

As Table 6-9 shows, the four technologies each push outward along a different axis of the impossible triangle: zero-knowledge proofs create the new possibility of *verifiable but without exposing details* on the transparency axis; intent-based trading and account abstraction raise execution efficiency and user experience along the performance axis; and modular blockchains strengthen underlying security along the decentralization axis through specialized division of labor. These technologies do not work in isolation but present a fusion trend in real projects, and Lighter's case is a representative practice of this fusion. Lighter's rise in 2025 is a representative case of these frontier technologies reshaping market structure. As an application-specific ZK-Rollup built on Ethereum, Lighter, with $1.3 trillion in annual volume, joined the ranks of the world's tenth-largest perpetual futures exchange in 2025 and completed a $68 million financing round at a $1.5 billion valuation in November 2025 [40][49]. This figure, however, warrants the same scrutiny applied to Hyperliquid's depth data in Section 6.4.3: as a zero-fee protocol, Lighter faces a major concern about volume inflated by wash trading and incentive-driven trading, and zero fees may attract large amounts of high-frequency noise trading rather than genuine price-discovery flow. The *subsidy-driven versus market-structure-driven* analytical framework advanced in Section 6.4.3 applies equally here: under a zero-fee model, whether volume can be sustained after a business-model transition

(the introduction of fees) is a key test of its market-structure significance. Its core innovation lies in a custom proving engine that can generate execution proofs for hundreds of thousands of transactions in parallel and compress them, through multi-layer aggregation, into a single batch proof submitted to the Ethereum mainnet for verification, achieving an effective combination of high-speed off-chain order-book matching and mathematical-grade on-chain security. User assets are always custodied by an Ethereum smart contract, and an *escape hatch* mechanism guarantees that in extreme situations users can withdraw assets directly on Layer-1. The verification a ZK proof provides is retroactive: it confirms already-executed transactions rather than preventing sequencer misbehavior in real time; during proof generation and L1 confirmation, the system in fact operates under the same trust assumptions as a centralized sequencer. Although the *escape hatch*, through forced L1 withdrawal, provides an ultimate safety guarantee, in practice it may take hours to days to complete. In contrast to application chains that rely on their own small validator networks (such as Hyperliquid), Lighter anchors ultimate security to Ethereum's settlement layer, and its combination of zero fees, non-custody, and verifiable matching demonstrates how ZK technology can redefine the boundaries of a decentralized exchange.

> These four technologies and the Lighter case together show that the impossible triangle is not fixed; its area can be expanded by technological progress, so that dimensions that once had to be sacrificed can be achieved simultaneously at a higher level. The triangle does not disappear, but its area grows—and that is the meaning of technological progress.

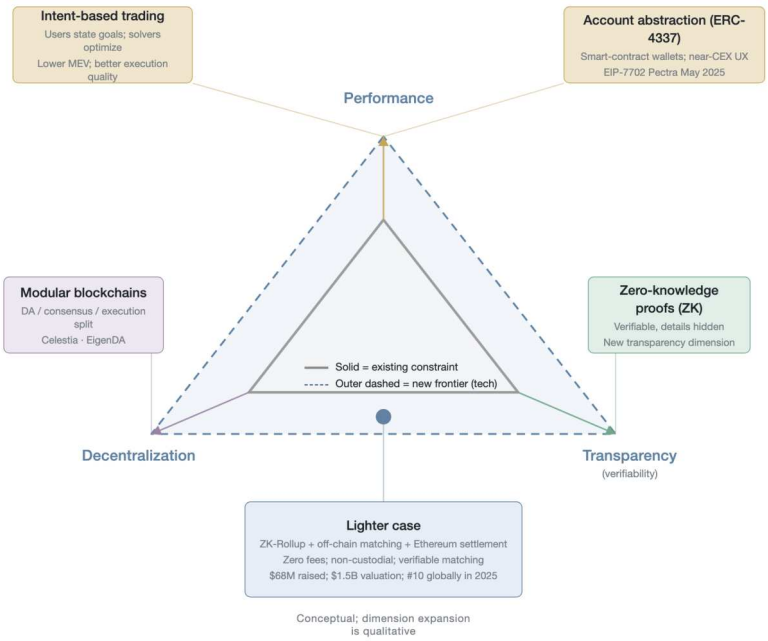

Figure 6-16. The mechanisms by which four frontier technologies expand the impossible triangle, with the Lighter case (a conceptual schematic, with dimension expansion represented qualitatively, not empirical data; Lighter's $68 million financing and $1.5 billion valuation [49] and its position as the world's tenth-largest perpetual futures exchange in 2025 [40][49] are both marked with sources; drawn by the author, based on Grand View Research [46], Paradigm [47], and CoinDesk [49])

Figure 6-16 integrates the analysis above into a unified visual framework: the inner triangle represents the existing constraints under current technical conditions, and the outer dashed triangle represents the new boundary that technological progress can push out; Lighter, as a fusion of ZK-Rollup, high-speed off-chain matching, and Ethereum settlement, is marked as the practical case closest to the outer boundary at present, validating the practical feasibility of technological fusion expanding the impossible triangle.

6.6.4 Open problems

Although technological progress keeps expanding the boundary of the possible, the evolution of the next generation of market structure still faces two fundamental unresolved problems, whose solutions will define the ultimate form of the perpetual futures market.

On the problem of the effectiveness boundary of decentralization, an application chain pursuing high performance inevitably must compromise on the scale of its validator network. Take Hyperliquid: although it achieved rapid growth in 2025 (users grew from 300,000 to 1.4 million, and annual volume reached $2.9 trillion), its number of validators remained at just 16 to 24 for a long time [50][51]. By early 2026, the number of validators had increased to 24; compared with Ethereum's hundreds of thousands of validating nodes, this is still a highly concentrated consensus network [9]. This concentration has raised persistent community concern about censorship resistance and

the potential risk of collusion.

Decentralization is not a black-and-white binary state but a continuous variable. This raises a profound question of governance philosophy: *How much decentralization is enough?* The answer often depends on the specific application scenario and the user's risk preference. There is a fundamental physical tension between the scale of the validator network and system performance: more validators mean higher security and censorship resistance but inevitably lead to increased consensus latency, while fewer validators can provide a CEX-comparable sub-second experience but introduce a stronger trust assumption. How to find that dynamic *effectiveness boundary* between performance and decentralization is a challenge every application chain must confront over the long term. The regulatory dimension of this problem is explored further in Chapter 26.

Parallel to the decentralization-boundary problem, the second problem is the trilemma of tension among transparency, leverage, and security, which is the ultimate extension, at the market-structure level, of the *transparency-fragility paradox* examined in Section 4.4.3 of Chapter 4. In on-chain perpetual futures markets, a fully transparent order book, leverage ratios as high as 50x to 100x, and algorithmic high-frequency execution together constitute an extremely fragile complex system. Application chains have mitigated traditional atomic MEV through protocol design, but the fully transparent liquidation price instead gives rise to strategic MEV, a deeper form of attack, as analyzed in detail in Section 6.3.

The three strategic attacks that occurred consecutively on Hyperliquid from March to November 2025—the whale's self-liquidation after building a roughly $300 million ETH long position at 50x leverage, the JELLY token attack, and the November cross-market price manipulation—provide the most vivid footnote to this tension (the loss magnitudes and mechanisms of the three incidents are detailed in Section 6.3.2).

These events lay bare the trilemma of tension among transparency, high leverage, and system security. Under the combination of *transparency plus high leverage*, the liquidation levels and liquidity depth of all participants are fully visible to attackers, making precise sniping possible and giving rise to strategic liquidation attacks. Under the combination of *high leverage plus security*, the system must possess extremely strong anti-manipulation capability and a deep insurance fund; otherwise, shortfall risk will inevitably be socialized, transferred through auto-deleveraging or vault losses onto innocent liquidity providers. And the more fundamental question is whether 50x to 100x leverage matches the actual loss-absorption capacity of an on-chain protocol. The maximum leverage of traditional futures markets (such as CME and Eurex) is constrained by clearinghouse margin requirements based on decades of volatility data, backed by a mutualized default fund and an explicit central-counterparty guarantee. That on-chain perpetual futures protocols offer equal or even higher leverage in the absence of comparable loss-absorption capacity (both the size of the insurance fund and the depth of the HLP vault being far smaller than a traditional CCP's default fund) makes the reasonableness of their risk pricing questionable. Under the combination of *transparency plus security*, the most counterintuitive insight emerges: in a high-leverage financial game, full transparency may not be net positive. To protect system security, some form of

selective opacity (for example, using ZK technology to achieve *verifiable but without exposing the liquidation threshold*) may be safer than unprotected full transparency. Traditional finance already has mature precedents for such calibrated transparency: when the TRACE (Trade Reporting and Compliance Engine) system in the U.S. corporate bond market introduced post-trade transparency, it imposed delayed reporting on large trades to protect institutional investors (Bessembinder, Maxwell, and Venkataraman, 2006 [52]); the EU's MiFID II framework likewise provides transparency waivers for large trades. These experiences show that *selective opacity* is not a new invention of the crypto market but a well-tested institutional arrangement in financial-market design.

This insight connects the strategic-MEV analysis of Section 6.3, the ZK-technology discussion of Section 6.6.3, and the embedded-compliance design of Chapter 30 into a complete logical chain. Defending against strategic MEV cannot rely solely on increasing matching speed (this is the mental inertia of latency competition) but must involve a fundamental restructuring at the mechanism-design level, which also lays the theoretical foundation for the book's later discussions of the liquidation mechanism (Chapter 11), insurance-fund governance (Chapter 12), and *strategic-MEV-immune* clearing and settlement architecture design (Chapter 29).

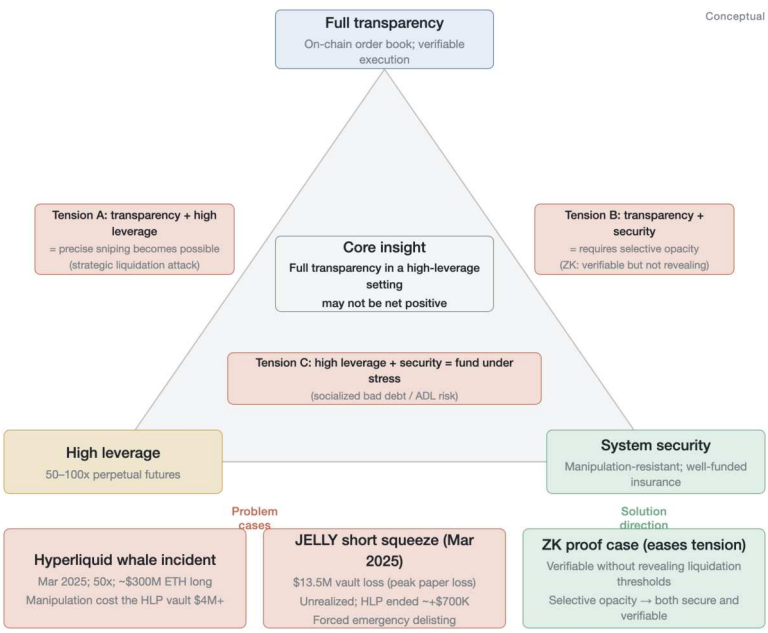

Figure 6-17. The inherent tension among transparency, high leverage, and system security (a conceptual-triangle schematic, with vertex positions representing qualitative tension relationships, not empirical coordinates; the roughly $13.5 million for JELLY is a peak unrealized loss, not a realized loss, with the HLP vault ultimately recording a small profit of about $700,000 [37]; the whale roughly $300 million, HLP roughly $4 million [20], and 50x to 100x leverage are all non-empirical data; Data source: Halborn [25], CoinDesk [37], and Arkham Intelligence [20])

Figure 6-17 visualizes this trilemma of tension as a triangular structure, whose three

edges correspond to three sets of constraint relationships: the combination of transparency and high leverage gives rise to precise liquidation sniping (edge A), the combination of high leverage and security requires a deep insurance-fund reserve (edge C), and the combination of transparency and security points to the counterintuitive conclusion that in a high-leverage environment *selective opacity* may be preferable to full transparency (edge B). The bottom of the figure contrasts the three real 2025 attack cases with the technical logic of ZK proofs as a potential solution path, connecting the problem diagnosis and the engineering solution into a complete logical chain.

6.7 Chapter summary

This chapter concludes Part II, *The Ecosystem: The Trading Ecosystem of Perpetual Futures*. Chapter 4 mapped six classes of participants and advanced the *transparency-fragility paradox*; Chapter 5, through a static dissection of the three architectures, advanced the *risk substitution theorem*; and this chapter pushes the perspective toward dynamic evolution, answering the question of *how different structures compete and converge*. The chapter established four core theoretical contributions. The competition-mode migration thesis argues that the evolution of market structure is not a simple case of *decentralization replacing centralization* but a paradigm shift in the focus of competition—from the latency competition of CEXs, to the information competition of general-purpose public-chain DEXs, to the mechanism competition of application-chain DEXs—with each migration driven by the diminishing economic returns of the previous mode. The definition of strategic MEV elevates MEV from within-block technical arbitrage to a cross-cycle, cross-market economic game, pointing out that its defense can rely only on mechanism redesign, not a speed race. The price-discovery migration hypothesis holds that three structural drivers—the trust premium of verifiable liquidity, the efficiency gains of protocol-level market making, and the on-chain migration of institutions—are shifting pricing power toward application-chain DEXs, and that once the liquidity network effect crosses a critical mass, this migration may become irreversible. The risk visibility-manageability proposition holds that, from CEXs to on-chain venues, risk shifts from *invisible but occasionally catastrophically explosive* to *continuously visible but manageable*, with visibility a necessary precondition for risk management.

After completing this macro analysis of the competition among the three architectures, one key question remains unresolved: How does a macro structural advantage translate into micro trade execution? How do orders express traders' intent, how does the order book aggregate information and form prices, and how do differences in matching rules affect market liquidity? Part III—beginning with the anatomy of the order (Chapter 7), the microdynamics of the order book (Chapter 8), and Hyperliquid's architectural innovations (Chapter 9)—establishes the micro foundations for the subsequent quantitative analysis of price discovery, arbitrage, and liquidity.

Part III
Microstructure

Core question: In a perpetual futures market, how does a trade go from intent to execution, and how is price discovered and formed at the microstructural level?

Orders and the Language of Perpetual Futures Trading

In today's crypto derivatives markets, buying a large position—say, a $10 million Ethereum long—is really a multilayered act of transmitting financial information. How this order is ultimately handled depends on the execution architecture chosen. If the limit order is sent to a centralized exchange such as Binance or OKX, it reaches the exchange's private servers instantaneously over an encrypted API. Within the matching engine's memory, the order is processed in sub-millisecond time. If no matching sell order exists in the current order book, it rests there. Apart from the exchange's internal systems and the handful of high-frequency market makers who can observe partial information through private data feeds, the market as a whole cannot access this $10 million buying intent. The trader can cancel the order at any time at zero cost, leaving no public record.

If the trader instead submits the identical order on an on-chain central limit order book protocol such as Hyperliquid or dYdX, the processing flow differs fundamentally. Once signed by the private key, the order is broadcast to the application chain's validator network. Roughly 200 milliseconds later, it is packed into a block and becomes an immutable on-chain commitment, displayed publicly to the entire world. Every full-node operator, on-chain analytics tool, and arbitrage bot can immediately "see" this $10 million buying intent. If the order does not fill immediately, it hangs publicly on the on-chain order book, becoming a focal point for strategic maneuvering among all parties. To cancel it, the trader must submit another on-chain transaction, which not only incurs a network fee but also endures the latency of block confirmation, and every attempt and withdrawal is permanently recorded as historical data.

These two starkly different processing paths reflect the ongoing evolution of the crypto derivatives market microstructure. In 2025, the crypto derivatives market recorded average daily trading volume of approximately $264.5 billion [1]. Within this vast market, perpetual futures have become the instrument with the largest share of trading volume: they have not only surpassed the trading scale of the spot market but have also become the core mechanism for pricing and liquidity discovery across the entire crypto-asset space. Decentralized derivatives exchanges also grew rapidly over the same period. Driven by high-performance application chains such as Hyperliquid, decentralized exchange (DEX) perpetual futures volume surged 346% in 2025 to reach $6.7 trillion [2]. Hyperliquid in particular reached $2.9 trillion in annual volume, surpassing compliant

giants such as Coinbase International, and in October set a historical record by processing more than $300 billion in volume in a single month [2]. The DEX share of the perpetual futures market jumped from less than 4% at the start of the year to more than 13% by year-end—a structural shift that marks the arrival of on-chain derivatives trading in the mainstream market.

Migrating complex derivatives trading and high-frequency order books from private servers onto public blockchains, however, is not merely a straightforward replacement of infrastructure. It constitutes a reconstruction at the level of market microstructure. In an on-chain environment, an order is no longer merely an expression of trading intent; it becomes a public signal with high information content in its own right. Starting from the theoretical framework of "the order as a signal," this chapter analyzes information leakage and adverse selection in the transparent on-chain environment, the defensive mechanisms market makers deploy within the order book, the "intent-execution gap" faced by ordinary traders, and—progressing from basic to advanced—the toolbox of order types, the three-dimensional strategic extension of perpetual futures, and how the physical constraints of blockchain reshape the economic meaning of orders.

7.1 The signaling function of orders

In the microstructure theory of financial markets, the order is the most fundamental building block [3]. Traditional textbooks tend to treat the order as a purely operational tool ("a market order means immediate execution at the current price; a limit order means resting at a specified price and waiting"). This understanding is necessary but far from sufficient. In the environment of modern high-frequency trading and transparent on-chain ledgers, every order submitted to the market—whether or not it ultimately fills—transmits rich information to the market. This section establishes a conceptual framework: every order simultaneously performs a "trading function" and a "signaling function," and the trader's core strategic challenge is to find the optimal balance between the two. This "order as a signal" framework runs through the entire chapter and provides a unified explanation of the strategic implications of all order types.

7.1.1 The trading function and the signaling function

In crypto derivatives markets, and especially in the on-chain central limit order book (CLOB), every order has an inseparable dual function: an explicit trading function and an implicit signaling function.

The trading function is the surface-level purpose of an order. When a trader submits a buy order, the direct purpose is to acquire a long position in the target asset at a specific price. This function is deterministic and mechanical, executed strictly by the matching engine according to rules such as price priority and time priority. Whether the trading function succeeds is reflected directly in the trader's account balance and position changes. In the context of perpetual futures, the trading function carries additional dimensions: a buy order not only changes the direction and size of a position but also simultaneously changes the effective leverage, the liquidation price, and the proportion

of margin utilized. These derivative effects make order decisions in perpetual futures an order of magnitude more complex than in the spot market.

The signaling function is the deeper attribute of an order. In a market with information asymmetry, a trader's behavior is itself the largest source of information. The type, price, size, and submission time of an order—and even the frequency with which it is canceled—all leak the trader's private information to other market participants, especially market makers and arbitrageurs. Specifically, the signaling function comprises the following dimensions:

Signal dimension	Information leaked	Inference logic
Order direction	The trader's view on price movement	A buy order implies a bullish expectation; a sell order implies a bearish expectation
Order type	The trader's degree of urgency	A market order signals extreme urgency; a limit order signals a willingness to wait
Order size	The trader's capital base and level of conviction	A large order suggests an institutional-grade participant or a strong directional belief
Submission time	The timeliness of the information	Orders submitted around major events are more likely to contain private information
Cancellation frequency	The order's true intent	Frequent cancellation may suggest "probing" orders or market-making adjustments

Table 7-1. The five dimensions of the order's signaling function (Data source: compiled by the author)

Table 7-1 systematically lays out the five dimensions of the order's signaling function: a market maker's algorithms analyze an order's direction, type, size, and timing in combination to infer the identity category and information content of the submitter. Figure 7-1 uses a flowchart to show the transmission path of the trading function and the signaling function from order submission to the trader's optimization objective.

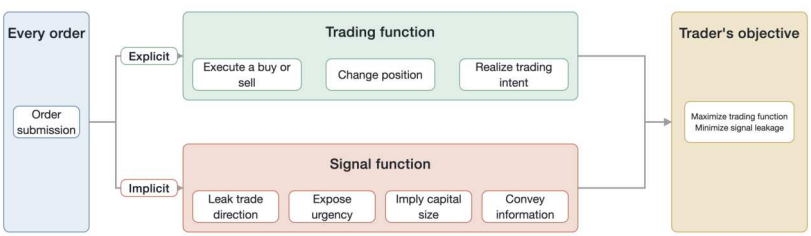

Figure 7-1. The dual function of an order (conceptual/mechanism flow illustration, not empirical data)

This recognition of a dual function can be formalized as a concise optimization framework. For any order, the trader's objective function can be stated as:

> Order optimization objective = maximize (trading-function efficiency) × minimize (degree of signal leakage)

The framework above is a normative benchmark: it describes how a rational trader ought to choose an order type, not how actual traders in fact behave. A large body of empirical research shows that retail traders' order choices are often driven by behavioral factors such as platform UI defaults, urgency bias, and the availability heuristic, and thus systematically deviate from this theoretical optimum. Different order types offer different Pareto-optimal solutions within this objective function. A market order pushes trading-function efficiency to its limit (immediate execution) but also maximizes signal leakage; an iceberg order minimizes signal leakage but sacrifices execution speed and certainty. Understanding this trade-off is the theoretical foundation for understanding all of the order-type analysis that follows.

On a centralized exchange, the signaling function is partly masked by dark pools, iceberg orders, and the exchange's internal data-segregation mechanisms. A trader's limit order is visible only to the exchange and to authorized counterparties, cancellation leaves no public trace, and the signal's range of propagation is strictly confined within the walls of the exchange. In an on-chain CLOB protocol, however, the global visibility of the blockchain ledger dramatically amplifies the order's signaling function. Any participant able to run a full node or access an RPC endpoint can monitor every minute change in the order book in real time. In this fully transparent market, every order transmits information, and it does so to all participants.

7.1.2 The signal-strength spectrum

Not all orders transmit signals of the same strength. Depending on the order type and its parameters, we can construct a "signal-strength spectrum." Along this spectrum, different types of orders exhibit a clear trade-off between execution urgency and the degree of signal leakage.

At one end of the spectrum is the large market order. Orders of this kind transmit strong execution urgency, indicating that the trader is willing to accept any price on the current order book in order to complete the trade immediately. In microstructure theory, market orders are generally regarded as containing the highest proportion of "private information" [4]. Their signal content can be read as: "I need to fill immediately, whatever the slippage, because I may hold time-sensitive material information." When market makers observe a run of one-directional large market orders, they immediately infer that an informed trader is building a position, and they promptly withdraw liquidity or adjust their quotes. Yet the signal from a large market order is not noise-free: panic selling and forced liquidations also generate large market orders, and market makers cannot tell the two apart perfectly in advance—which is precisely the root of the adverse-selection problem.

The middle region of the spectrum holds the various limit orders. Aggressive limit orders (priced very close to, or even better than, the current best bid or offer) transmit a signal strength second only to that of market orders; their implicit message is: "I have a directional view, but I am not especially urgent, and I am willing to wait briefly for a

better price." Such orders seek a balance between urgency and execution price. Passive limit orders placed far from the market price, by contrast, transmit a relatively weak signal; they are seen more as the passive positioning of a liquidity provider—the typical choice of a market maker—or as the "buy-the-dip" strategy of a long-term investor.

At the other end of the spectrum are algorithmic orders (such as TWAP/VWAP) and iceberg orders. These orders are designed from the outset to conceal the trader's true intent and total size. An iceberg order slices a large order into small blocks displayed in sequence, deliberately hiding the true size; time-weighted average price (TWAP) and volume-weighted average price (VWAP) algorithms spread a large order over a longer time window, so that the signal of each small order is so faint as to be nearly indistinguishable from background market noise. Their goal is to split a large order into subordinate orders small enough that each child order's signal strength approaches the level of market noise.

Order type	Signal strength	Signal content	Execution certainty	Typical users
Large market order	Very strong	Urgent need; may hold material information	Highest	Informed traders, panic traders
Ordinary market order	Strong	Has a directional view; needs immediate execution	High	Speculators, trend followers
Aggressive limit order	Moderately strong	Has a directional view; willing to wait briefly	Medium-high	Active traders
Ordinary limit order	Medium	Conviction about value; not in a hurry to fill	Medium	Market makers, value investors
Far-from-market limit order	Weak	Providing liquidity or positioning to buy the dip	Low	Market makers, long-term investors
TWAP/VWAP algorithmic order	Very weak	Spreads size across time	Medium (in tranches)	Institutional traders
Iceberg/hidden order	Very weak	Deliberately conceals true size	Medium-low	Large traders

Table 7-2. The correspondence between order types and signal strength (Data source: compiled by the author)

Table 7-2 reveals a core regularity: the true trade-off axis in order selection is not "signal strength ↔ execution certainty" but rather "execution urgency ↔ price improvement and signal concealment." The large market order sits at the high-urgency end, achieving both the highest execution certainty and the strongest signal leakage (the two move in the same direction at this end); iceberg orders and TWAP sit at the low-urgency end, trading away execution speed in exchange for the weakest signal leakage. Signal strength and execution certainty therefore move together at the passive end and diverge at the active end, rather than forming a simple one-dimensional inverse relationship. (Aggressive limit orders and immediate-or-cancel (IOC) orders, for example, may under

specific conditions combine relatively high signal strength with high execution certainty; moreover, in an on-chain environment, the execution pattern of TWAP/VWAP child orders may be reassembled through pattern recognition by on-chain analytics tools, so that the actual efficiency of signal concealment is lower than the table suggests.) Figure 7-2 arranges the various order types along the two poles of "execution urgency" and "degree of signal leakage."

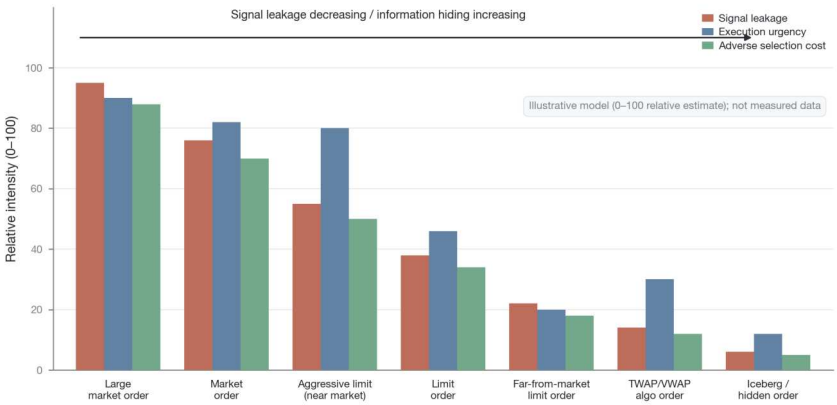

Figure 7-2. The signal-strength spectrum of orders (conceptual model illustration: the 0–100 scale represents relative strength assigned by the author, not empirical data; theoretical basis: Copeland & Galai 1983 [4], Harris 2003 [3], Easley et al. 2012 [29])

> Core strategic implication: traders face a fundamental trade-off between execution urgency (speed) and information concealment (and price improvement), rather than a simple opposition of "execution certainty versus information leakage." A market order has the highest execution certainty but the greatest signal leakage; an iceberg order has the smallest signal leakage but lower execution certainty and greater operational complexity. To choose an order type is to choose one's position within this trade-off.

In an on-chain environment, this trade-off becomes especially acute. Because there is no native privacy-preserving mechanism, a genuine iceberg order is difficult to implement (its transparency tension and formal definition appear in Section 7.3.2, and the mitigation via protocol-level selective opacity appears in Section 7.5.4). On today's mainstream on-chain CLOBs such as Hyperliquid and dYdX, traders rely mainly on off-chain computation and high-frequency order splitting to simulate algorithmic execution; but every child order remains visible on-chain, and a sufficiently sophisticated on-chain analytics tool may still re-correlate these fragments through pattern recognition to infer the trader's true intent. The structural limits the on-chain environment places on signal concealment are the core analytical starting point for understanding the microstructural differences between the on-chain CLOB and the CEX. This section only establishes that conceptual framework; Section 7.5 develops the public-commitment property of on-chain orders in depth from the standpoint of MEV exposure and commitment cost.

7.1.3 The microfoundations of adverse selection

When orders "speak," the most important listener in the market is the market maker. Market makers earn the bid-ask spread by simultaneously providing quotes on both the bid and ask sides; they are the core suppliers of market liquidity. This business model, however, faces one central risk: adverse selection.

The concept of adverse selection was first formalized by Copeland and Galai in their seminal 1983 paper [4]. Glosten and Milgrom (1985) subsequently proved, in a sequential-trade model, that the equilibrium level of the bid-ask spread is determined by the market maker's posterior estimate of the proportion of informed traders [5]; Kyle (1985), starting from the optimal strategy of the informed trader, proved that the price-impact coefficient λ is proportional to the precision of the informed trader's information [6]. Together, these three classic works build the microfoundations of adverse-selection theory. Copeland and Galai's key insight is this: the act of submitting a limit order is, in economic terms, equivalent to giving the market a free option. When a trader posts a buy limit order, they in effect grant anyone in the market the right to sell the asset to them at that price. If the market price remains stable or rises, this "option" is not exercised and the limit order remains unfilled; but if an informed trader learns of information that will cause the price of ETH to crash, they will immediately "exercise" the option, selling their soon-to-depreciate ETH to the limit-order submitter at \$3,000. For the limit-order submitter, being passively filled often means bearing an adverse-selection loss.

As the largest providers of limit orders in the market, market makers face adverse-selection risk continuously. To compensate for this potential loss, market makers must charge an "information premium" to all traders—including uninformed ones—by widening the bid-ask spread. This cost is shared across the entire trading population: the presence of a small number of informed traders systematically raises transaction costs for all participants.

In practice, the way market makers "listen" to orders relies mainly on real-time monitoring of order-flow imbalance. By analyzing the volume difference between aggressive buy orders and aggressive sell orders within a given time window, market makers can infer the direction in which market microstructural momentum is tilting. Research by Bieganowski and Ślepaczuk (2026) confirms that order-flow imbalance is one of the strongest predictive signals of short-term price direction [7]. When a market maker's algorithm detects a sharp rise in buy-side aggression (for example, a succession of large market buy orders), it reacts immediately: widening the ask-side quote and reducing ask-side depth. This is the microstructural mechanism of a "rising price": not some abstract "market force," but rather the market maker "hearing" in the order flow the signal that informed traders are entering, and adjusting risk exposure accordingly. Figure 7-3 formalizes this dynamic process as a closed-loop feedback model: the market-order impact of informed traders triggers the market maker's perception of adverse selection; the market maker defends by widening the spread and withdrawing quotes; and this defensive response in turn further intensifies the market's liquidity contraction, forming a self-reinforcing loop of adverse selection.

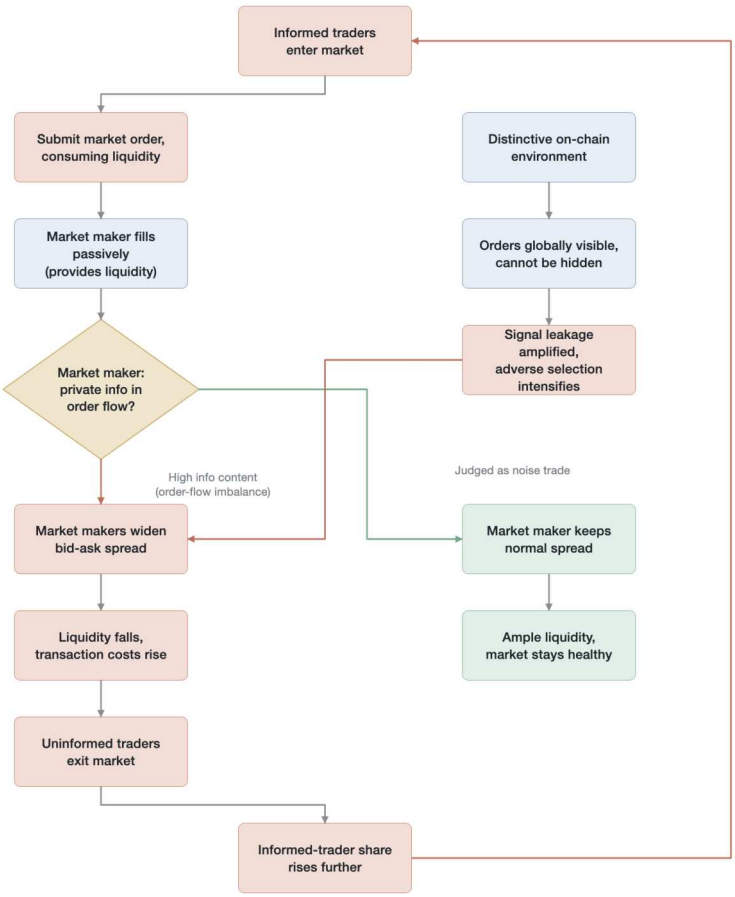

Figure 7-3. The market maker's adverse-selection feedback loop (mechanism feedback-loop illustration, not empirical data; order-flow imbalance is one of the strongest short-term price-prediction signals, per Bieganowski & Ślepaczuk 2026 [7])

Adverse selection in perpetual futures has a distinct amplifying effect. Empirical research by Ruan and Streltsov (2022) finds that a market's transaction costs may actually rise after perpetual futures are introduced [8]. The study's sample period (2020–2022), however, coincided with a period of large-scale retail entry into crypto markets and globally accommodative monetary policy; the rise in transaction costs may partly reflect the dramatic change in the composition of market participants rather than an inherent effect of perpetual futures, and the finding should therefore not be casually generalized as a universal feature of perpetual-futures markets. This seemingly counterintuitive phenomenon is a direct manifestation of an intensified adverse-selection effect. The high-leverage nature of perpetual futures means that an informed trader can command a larger position with less capital, greatly improving the efficiency with which their informational advantage is monetized; at the same time, round-the-clock uninterrupted trading means that market makers must maintain quotes at all times and cannot pause trading after a close as in traditional markets. More fundamentally,

the introduction of perpetual futures creates a new source of adverse selection for spot market makers: informed traders can choose to express their informational advantage in perpetual futures rather than in the spot market, so that the informed component of the order flow facing spot market makers rises and their market-making profit falls. These two factors combined force market makers to widen spreads to compensate for the higher adverse-selection risk.

The extreme market conditions of October 10, 2025, provide a representative observation sample. On that day, amid a macro geopolitical shock, the crypto market suffered a flash crash: open interest in perpetual futures market-wide evaporated by roughly $19 billion in about 36 hours, accompanied by forced liquidations of the same order of magnitude [9]. In this event, market makers on the on-chain CLOB monitored the sudden surge of one-directional market sell orders and enormous liquidation orders (a liquidation order is essentially a form of forced market order) and quickly "understood" the market's panic signal. Within milliseconds, market makers' algorithms responded defensively: withdrawing existing buy limit orders on a large scale and sharply lowering new quotes. This behavior caused order-book depth within the $\pm 2\%$ price band for major pairs (such as BTC-USDT and ETH-USDT) to evaporate by more than 90% in a short time, and bid-ask spreads widened sharply [10]. This is precisely the defensive manifestation of the adverse-selection mechanism under extreme stress. Although it protected market makers' capital, it also caused an instantaneous depletion of market liquidity, so that every trader attempting to execute an order at that moment faced slippage costs far above normal levels.

7.1.4 The intent-execution gap

For the ordinary trader, understanding the signaling function of orders and the defensive mechanisms of market makers ultimately serves the purpose of crossing one central obstacle—the "intent-execution gap." This is the second core theoretical contribution of this chapter.

This gap refers to the difference between the theoretical price a trader has in mind when forming a trading decision ("I want to buy 50 ETH long around $2,050") and the price at which the order actually fills in the market ("actual average fill price $2,053.7, slippage 0.18%, gas fee $1.2, an additional $12 lost to a sandwich attack"). The concept derives from the "implementation shortfall" framework proposed by Perold (1988) [11], but in the context of on-chain perpetual futures the composition and drivers of the gap exhibit a distinctive distribution.

In on-chain perpetual futures trading, the intent-execution gap can be decomposed into the following cost components (Table 7-3):

First, the latency cost arises from the time lag between the trader clicking "buy" and the order being packed into a block and processed by the matching engine. On a CEX this is typically a few milliseconds or even sub-millisecond; on-chain, even on a highly optimized application chain like Hyperliquid (block time of about 200 milliseconds), it takes several hundred milliseconds from order signing to final confirmation, and on a DEX built on a general-purpose public chain it may take several seconds or even tens of seconds. Within this seemingly brief time window, the market price may already have

moved unfavorably, especially during periods of high volatility. At the same time, the size of the trader's own order consumes liquidity on the order book, causing the average fill price to be worse than the initial best quote; this is the source of price impact. The larger the order size, the more pronounced the price impact; on an on-chain CLOB, where liquidity depth is generally lower than on top-tier CEXs, an order of the same size produces a more severe price impact. In addition, the trader must bear the spread cost—the bid-ask spread paid to market makers—which is essentially compensation for the market maker providing immediate liquidity and bearing adverse-selection risk. As noted earlier, the higher adverse-selection risk in an on-chain environment often results in wider spreads.

Beyond these market-microstructure costs, on-chain trading faces two additional, distinctive frictions. The first is network and protocol fees, including the gas fee paid to validators and the trading fee paid to the protocol. Although application chains such as Hyperliquid have internalized the gas fee (users need not pay gas directly), the protocol fee remains an explicit cost component. The second is slippage and MEV cost—the deviation of the actual fill price from the expected price due to network congestion, front-running, or maximal extractable value (MEV) attacks. The full on-chain transparency makes an order vulnerable, before it is packed (while in the mempool), to exploitation by MEV searchers, who can insert their own buy order ahead of the target buy order (raising the price) and then sell after the target buy order to profit—the classic sandwich attack.

Gap component	Magnitude on CEX	Magnitude on on-chain CLOB	Core driver
Latency cost	Very small (sub-millisecond)	Small to medium (200 ms to seconds)	Architectural performance and consensus latency
Price impact	Small (deep liquidity)	Medium (shallower liquidity)	Order size and order-book depth
Spread cost	Small (highly competitive)	Medium (higher adverse selection)	Market maker's adverse-selection compensation
Gas/protocol fee	None	Present (application chains typically internalize gas)	The fee model of the underlying chain
MEV/slippage	Implicit (internal information use)	Explicit (sandwich attacks/front-running)	Transaction visibility and ordering mechanism
Additional liquidation risk	Present	Present, with the liquidation price publicly visible	High leverage layered onto transparency

Table 7-3. A comparison of the cost components of the intent-execution gap (Data source: compiled by the author)

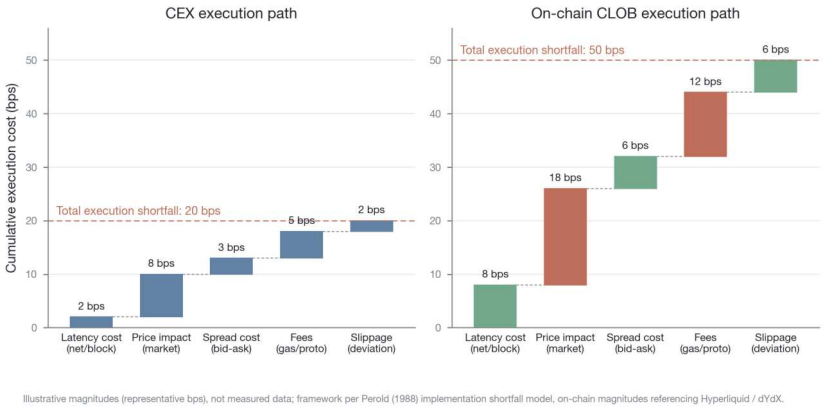

Figure 7-4. A decomposition of the costs of the intent-execution gap (conceptual model illustration: the basis-point components are representative values, not empirical; framework per Perold 1988 [11], with on-chain magnitudes referencing Hyperliquid/dYdX)

> The analytical value of the "intent-execution gap" is that it provides a unified metric dimension for assessing execution quality across different market structures. The point is not to judge simply "which is better," but to understand "how the composition and width of the gap differ." The gap on a CEX is generally narrower, but it contains an unquantifiable "implicit" portion—the risk that the exchange internally exploits order-flow information cannot be audited externally; the gap on an on-chain CLOB may be wider, but every component of it is on-chain observable, quantifiable, and auditable. This is precisely the concrete manifestation, at the level of order execution, of the "transparency paradox" discussed in Chapter 1.

The nonlinear widening of the intent-execution gap during a crisis is a particularly critical phenomenon. Kaiko Research's (2025) analysis of the October 2025 market crisis shows that, under extreme conditions, order-book depth plunged by more than 90% and liquidity contracted sharply [10]. The same $10 million market order incurs slippage that, under normal market conditions, varies by platform type: about 1–5 basis points on a top-tier CEX (such as Binance or OKX), about 10–30 basis points on an application-chain DEX (such as Hyperliquid), and possibly 50–100 basis points or more on a general-purpose public-chain DEX; but in a crisis, slippage may spike to 5% or even 10%, implying an additional cost of $500,000 to $1 million. In other words, the intent-execution gap widens nonlinearly at precisely the moment it most needs to be crossed—when the market is swinging violently and the trader urgently needs to adjust their position. This "liquidity illusion" (liquidity that appears ample in normal times collapsing sharply in a crisis) is an inherent fragility of all order-book-based market structures. The game-theoretic mechanism behind it can be explained by the liquidity-spiral model of Brunnermeier and Pedersen (2009) [12]: when an exogenous shock triggers risk-off sentiment, market makers are forced to withdraw their liquidity supply in unison—each market maker's cancellation is an individually rational defensive act, but the simultaneous withdrawal constitutes a fallacy of composition, causing a collective evaporation of order-book depth. The full transmission chain is: macro or geopolitical shock → the spread of risk-off sentiment → cross-market deleveraging

→ margin calls → forced selling → evaporation of order-book liquidity → amplified price impact → further margin calls. Possible institutional mitigations include imposing minimum-quoting obligations and minimum-quote-time requirements on market makers, but in today's permissionless on-chain DEX environment such constraints are difficult to enforce. Because the on-chain CLOB has a smaller liquidity base, this fragility is even more pronounced.

To bridge this gap, the modern crypto trader must think like an institutional quantitative fund. They no longer focus only on "what to buy" and "when to buy," but devote considerable effort to "how to buy." By allocating orders across multiple liquidity sources through smart order routing, by splitting large orders into smaller ones spread across time through a time-weighted average price algorithm, and by outsourcing order matching to specialized executors through intent-centric solver networks, traders seek to protect their order signals as much as possible in the fully transparent on-chain environment and to secure the optimal execution path. The specific mechanisms of these execution strategies are discussed separately in later sections.

7.2 Basic order types

In the crypto perpetual futures market, the only way for a trader to interact with an exchange's matching engine is to send an order. Orders constitute the basic instruments of trading, and the basic order types—market orders, limit orders, and stop-loss/take-profit orders—are their fundamental types. Understanding these basic order types is not only a prerequisite for mastering a platform's operating interface but also a cornerstone for understanding market microstructure and the price-discovery mechanism.

This section analyzes, from the perspective of microeconomics and market microstructure, the distinctive properties, risk characteristics, and interplay of these three basic order types in the perpetual futures market.

7.2.1 Market orders

A market order is an order that instructs the exchange to execute immediately at the best available price on the current order book. Its core characteristic is to prioritize execution certainty while relinquishing control over the execution price. In microstructure theory, the market order is a "liquidity consumer." When a trader submits a market order, they are in effect "crossing the bid-ask spread," consuming the existing limit-order depth on the order book. The market order is therefore a direct force driving price movement. As Bieganowski and Ślepaczuk (2026) note in their study of crypto microstructure, order-flow imbalance (the net difference between buy market orders and sell market orders) is one of the most critical features for predicting short-term price direction [7].

In the perpetual futures market, market orders have several special properties: high leverage amplifies the impact of slippage. Slippage is the difference between the expected execution price of an order and its actual execution price. In the spot market, 0.1% slippage may be negligible; but in perpetual futures, if a trader uses 50× leverage, 0.1% slippage directly consumes 5% of the initial margin. This means that the implicit

cost of a market order is significantly amplified under leverage. At the same time, in extreme market conditions—precisely when certainty is most needed—the cost is often highest. During a liquidation cascade, order-book depth dries up sharply. A market order submitted at that moment, though guaranteed to fill, will keep "eating" down (or up) the order book for lack of counterparties, producing enormous slippage.

Together these factors point to the fact that a market order transmits a strong information signal. In microstructure models, a large market order is generally seen as a mark of an informed trader entering. When a large market order appears, market makers quickly adjust their quotes to guard against adverse-selection risk, which further raises the execution cost of subsequent market orders.

7.2.2 Limit orders

A limit order is an order that specifies a particular price (or better) and executes only when the market price reaches or improves upon that specified price. In contrast to a market order, a limit order prioritizes price certainty while relinquishing execution certainty. Limit orders are "liquidity providers"; they constitute the depth of the order book. In submitting a limit order, a trader is essentially trading "patience" for a price advantage and lower fees. Limit orders, however, are by no means risk-free. As discussed in Section 7.1.3, submitting a limit order is economically equivalent to giving the market a free option [4]: a buy limit order is equivalent to selling a put, and a sell limit order is equivalent to selling a call.

Building on this theory, limit orders face two main risks. The first is execution risk: when the market moves in the direction favorable to the trader, the limit order may fail to fill, causing the trader to miss potential profit. The second is adverse-selection risk: when a limit order does fill, it is often because the market price has already broken through that limit. Specifically, when a limit order fills, the trader is more likely than not to be in a temporary loss position. In perpetual futures, the empirical research of Ruan and Streltsov (2022) shows that the perpetual-futures funding-rate settlement mechanism further amplifies the adverse-selection risk present in the spot market [8].

In perpetual futures, managing limit orders is more complex because they directly affect effective leverage and the liquidation price. A resting limit order, though not yet filled, occupies available margin (available balance), thereby limiting the trader's ability to withstand the unrealized loss on their current position.

7.2.3 Stop-loss and take-profit orders

Stop-loss and take-profit orders are conditional orders that remain dormant until a specific price condition is triggered. Once the market price reaches the trigger price, they convert into market orders or limit orders. Stop-loss orders play a key role in perpetual futures. A stop-loss is a line of defense the trader proactively sets to cut losses before the liquidation price is reached. Yet the execution mechanics of stop-loss orders conceal many pitfalls that are easily overlooked.

Choice of trigger price source: perpetual futures exchanges generally allow traders to choose the "last traded price," the "mark price," or the "index price" as the trigger

source. Using the mark price as the stop-loss trigger source is strongly recommended. The mark price is typically computed from the spot index price (a weighted median of spot prices across multiple exchanges) plus an exponential moving average (EMA) of the funding-rate basis; it is designed to filter out price anomalies at any single exchange and transient market distortions. The choice of the EMA window parameter directly affects how smooth the mark price is: the longer the window, the more stable the mark price but the more it lags true price movements; the shorter the window, the more responsive but the more susceptible to disturbance from transient volatility. (For a detailed treatment of how the mark price is computed and how the parameters are chosen, see the in-depth discussion in Chapter 14.) The last traded price, by contrast, is easily affected by a single large market order or a transient price distortion, triggering unnecessary stops.

Stop-loss market order vs. stop-loss limit order: whether the order converts into a market order or a limit order when the trigger price is reached determines the type of risk the trader faces (see Table 7-4).

Order type	Advantages	Disadvantages and risks	Applicable scenario
Stop-loss market order	Guarantees a fill (certain position closure); timely loss-cutting under normal liquidity	May face enormous slippage in extreme conditions, with an actual closing price far worse than the trigger price	A hard stop where exiting resolutely is mandatory
Stop-loss limit order	Strictly controls the closing price, with no slippage risk	In a fast one-directional move, the limit order may be "skipped" and fail to fill, resulting in eventual liquidation	Relatively calm conditions, where the closing cost is a sensitive concern

Table 7-4. A trade-off comparison of stop-loss market orders and stop-loss limit orders (Data source: compiled by the author)

The interaction of stop-losses and liquidation: many beginners mistakenly believe that setting a stop-loss makes them absolutely safe. This "illusion of stop-loss safety" is not merely a technical misunderstanding; it has deeper roots in behavioral finance. The illusion-of-control theory proposed by Langer (1975) [13] can explain this phenomenon: through the "active behavior" of setting a stop-loss, traders acquire a false sense of control over risk and thereby underestimate the probability that the stop-loss will fail. In addition, anchoring bias causes large numbers of stops to cluster at round-number thresholds (such as BTC $60,000 or ETH $2,000), and this predictable clustering pattern in turn gives stop-loss hunting economic rationale. As shown in Figure 7-5, there is a "safety buffer" between the stop-loss price and the liquidation price. But in extreme conditions (such as the flash crashes of May 19, 2021, April 2024, or October 2025—this book deliberately cites cases from several different periods to show that this type of risk is not an isolated event but a structural feature of perpetual futures markets), enormous slippage may punch through this buffer in an instant, causing the stop-loss

order to fill at a price worse than the liquidation price, so that the trader still faces liquidation or even a negative account balance (bankruptcy).

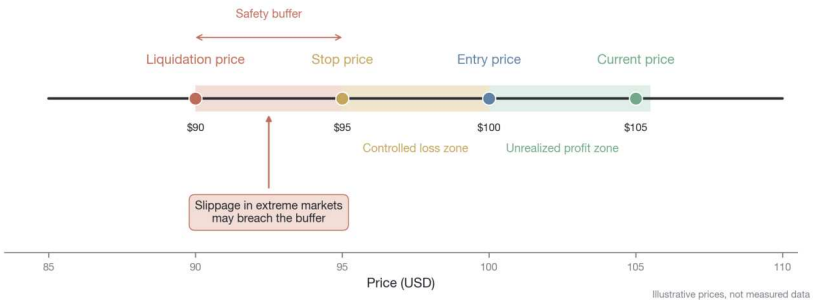

Figure 7-5. The relationship between stop-loss orders and the liquidation price, and the slippage risk under extreme conditions (mechanism illustration: \$90/95/100/105 are illustrative values, not empirical; the long-position safety buffer = stop-loss price − liquidation price, which extreme slippage can punch through)

Trailing stop orders: this is an advanced automated risk-management tool. As shown in Figure 7-6, it has a "ratchet mechanism": the stop line automatically follows as the price moves favorably, but holds unchanged when the price pulls back. This allows the trader to protect gains already secured while leaving room for further profit growth.

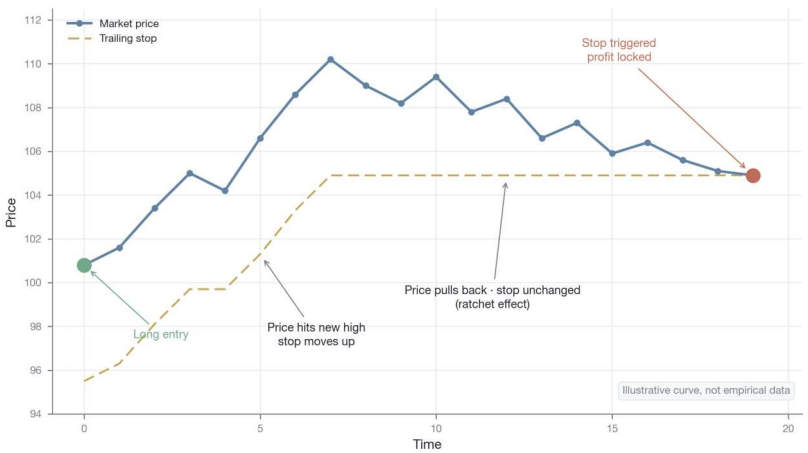

Figure 7-6. The ratchet mechanism of a trailing stop order (long-position example) (ratchet-effect mechanism illustration; the price path uses representative values, not empirical data)

7.2.4 The maker-taker fee model and order selection

Perpetual futures exchanges widely adopt the maker-taker fee model, which is central to understanding the economics of order types. Exchanges incentivize the aggregation of liquidity by charging a higher fee to takers who consume liquidity and a lower fee (or even a rebate) to makers who provide liquidity.

This fee structure strongly shapes a trader's order-selection strategy. As shown in Table 7-5, the difference between maker and taker fees varies enormously across exchanges and VIP tiers. In the fiercely competitive 2025–2026 period, decentralized perpetual futures exchanges such as Hyperliquid have even pushed base fees down to maker 0.015% / taker 0.045% [14].

Order type	Market-microstructure role	Certainty trade-off	Fee attribute	Hidden cost/risk
Market order	Liquidity consumer	Price uncertain, execution certain	Pays the taker fee	Slippage cost; risk amplified under high leverage
Limit order	Liquidity provider	Price certain, execution uncertain	Pays the maker fee (typically lower)	Adverse-selection risk; execution risk
Stop-loss order	Conditional liquidity consumer	Converts to a market/limit order once the condition triggers	Typically pays the taker fee	Liquidation risk from slippage punching through the buffer

Table 7-5. A matrix of the microstructural effects of the basic order types (Data source: constructed by the author)

The core message of Table 7-5 is that the three basic order types display a clear gradient in their certainty trade-offs and hidden costs. The market order offers the highest execution certainty, but its hidden cost (slippage and risk amplification under high leverage) is also the most severe; the limit order provides certainty on the price dimension but exposes the trader to execution risk and adverse-selection risk; the stop-loss order layers the uncertainty of a conditional trigger onto the slippage risk of a market order and may produce unexpected adverse outcomes in extreme conditions.

Within this microstructural ecosystem, limit orders, market orders, and stop-loss orders form a dynamic feedback loop (Figure 7-7). Limit orders constitute the depth structure of the order book, market orders drive price movement by consuming that depth, and stop-loss orders convert into market orders once triggered at a specific price level. When market orders push the price to trigger a large number of stop-loss orders, those stops convert into new market orders that further consume limit-order depth—and this positive-feedback mechanism is precisely the microfoundation of the violent volatility of perpetual futures markets.

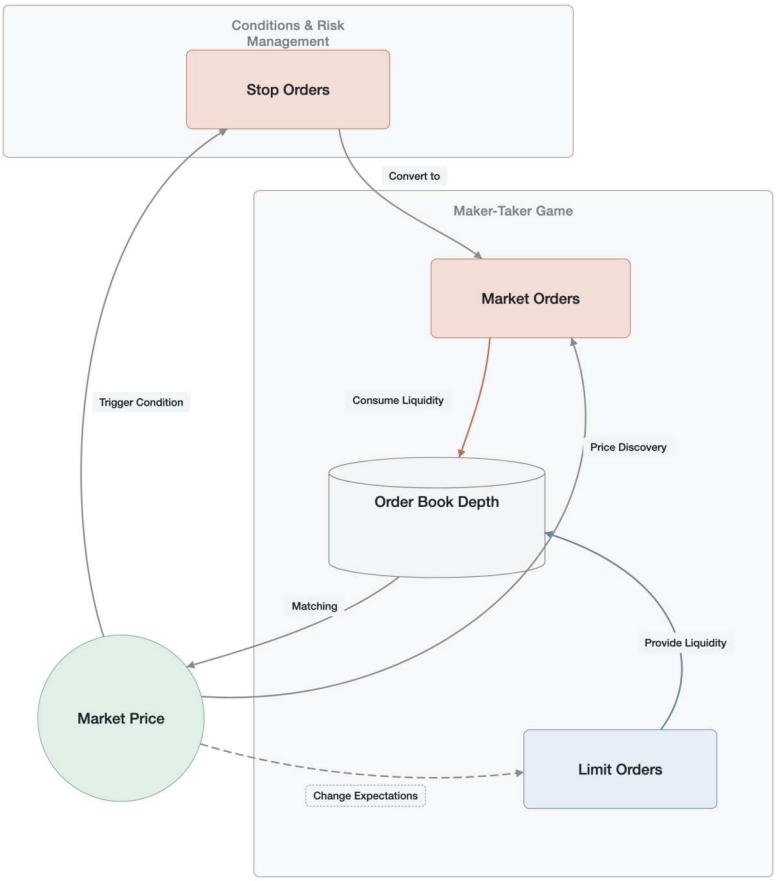

Figure 7-7. The dynamic feedback loop of order flow and price discovery (mechanism feedback-loop illustration, not empirical data)

Having grasped this game mechanism, a trader understands that providing liquidity requires bearing adverse-selection risk and earning corresponding compensation, while execution certainty comes at the cost of higher fees and slippage. In perpetual futures trading, advanced traders rarely enter and exit using market orders alone; instead, they seek the optimal solution between certainty and cost through advanced order types and algorithmic execution. The next section analyzes these in detail.

7.3 Advanced order types

On top of the basic order types, advanced order types allow traders to refine the expression of their strategy along dimensions such as time, size, and execution conditions. As the crypto derivatives market becomes more institutionalized, simple buy and sell instructions can no longer meet complex execution needs. Advanced order types allow traders to express their trading strategies with precision along four dimensions—time, size, execution constraints, and conditional triggers—thereby gaining an edge or lower-

ing costs within a complex microstructure.

7.3.1 Time-control orders

Time-control orders determine the lifespan of an order within the matching engine. They are essential tools for high-frequency trading and arbitrage strategies.

Fill-or-kill (FOK) is an extremely strict order type. It requires the order to fill immediately and in full, or else the entire order is canceled; partial fills are never permitted. FOK has an important role in calendar-spread arbitrage or funding-rate arbitrage. When an arbitrageur spots a price gap between two markets, they need to establish equal positions on both sides simultaneously. Using an ordinary market order might fill one side while the other fills only partially (leg-execution risk), leaving exposure to a one-sided position. FOK ensures the certainty of "all or nothing." Immediate-or-cancel (IOC) requires the order to execute any fillable portion immediately and then cancel the entire unfilled remainder. Unlike FOK, IOC permits partial fills. It is commonly used for "sweeping" operations, in which the trader is willing to consume all favorably priced liquidity on the current order book but unwilling to leave the unfilled portion resting as a limit order, so as not to expose their trading intent. In addition, good-til-time/good-til-block (GTT/GTB): on on-chain order-book decentralized exchanges, GTT often evolves into GTB (good-til-a-specified-block-height). Because blockchain networks are subject to latency and reorganization risk, a trader who does not want their limit order to be unexpectedly executed after market conditions have changed drastically (say, several blocks later) attaches a GTB constraint.

7.3.2 Size-hiding orders

When an institutional investor needs to execute a large order that far exceeds the current order-book depth, they face significant information-leakage risk. Posting a huge limit order directly would immediately alert other market participants (especially high-frequency market makers) to this enormous selling or buying pressure, prompting them to front-run or withdraw quotes, so that the large order becomes difficult to fill or fills at a badly unfavorable price.

The iceberg order was created precisely to solve this pain point. As the name suggests, an iceberg order exposes only a small fraction of its total size to the public order book while hiding the vast majority. Once the visible portion fills completely, the matching engine automatically slices a new visible quantity from the hidden portion and replenishes it onto the order book, until the total order is fully executed.

On a centralized exchange, the logic of the iceberg order is maintained by the centralized matching engine in the background. On an on-chain perpetual futures DEX, however, implementing a genuine iceberg order faces an important technical challenge: there is an inherent tension between the transparency of the blockchain and the need to hide size. All on-chain state is public by default. At present, some cutting-edge DEXs are beginning to explore using zero-knowledge proofs or trusted execution environments to build on-chain dark pools, allowing traders to match large liquidity without broadcasting their true intent to the entire network.

7.3.3 Execution-constraint orders

These two constraint-type orders appear extremely frequently in the daily operations of perpetual futures traders; they target fee optimization and position safety, respectively.

Post-Only (maker-only): for a limit order with the Post-Only attribute attached, the system guarantees that it will never match and fill immediately against an existing order on the book. If the order would immediately match an existing order upon submission (for example, a buy limit priced above the current best ask), the system cancels the order outright rather than converting it into a market order for execution. The core value of Post-Only is to strictly lock in the maker fee. As discussed in Section 7.2, the maker fee is typically far lower than the taker fee (or even negative). Market makers and algorithmic traders use Post-Only to ensure that they only ever provide liquidity and never accidentally consume it, thereby precisely controlling trading costs.

Reduce-Only: this is an order attribute unique to the derivatives market. A Reduce-Only order can only be used to reduce the current position; it never increases a position or establishes a new position in the opposite direction. This feature has an important role when setting take-profit and stop-loss orders. Suppose a trader holds a long position and has set an ordinary sell limit order as a take-profit; if they subsequently close the long manually but fail to cancel the take-profit order, then when the price reaches the take-profit level the sell order will be triggered, unexpectedly establishing a naked short position. If the order has the Reduce-Only attribute attached, then when the long position is zero the system will automatically cancel or refuse to execute the order, entirely eliminating this risk of unintended position-building.

7.3.4 Algorithmic orders: TWAP and VWAP

For truly enormous orders, even an iceberg order may be identified by a clever algorithm because of its frequent replenishment actions (known as “iceberg detection”). At that point, an institution must turn to algorithmic execution strategies, of which the most classic are TWAP and VWAP. Figure 7-8 contrasts the core logical differences among three large-order execution strategies—TWAP, VWAP, and the iceberg order—in terms of execution cadence and information concealment; each is discussed in turn below.

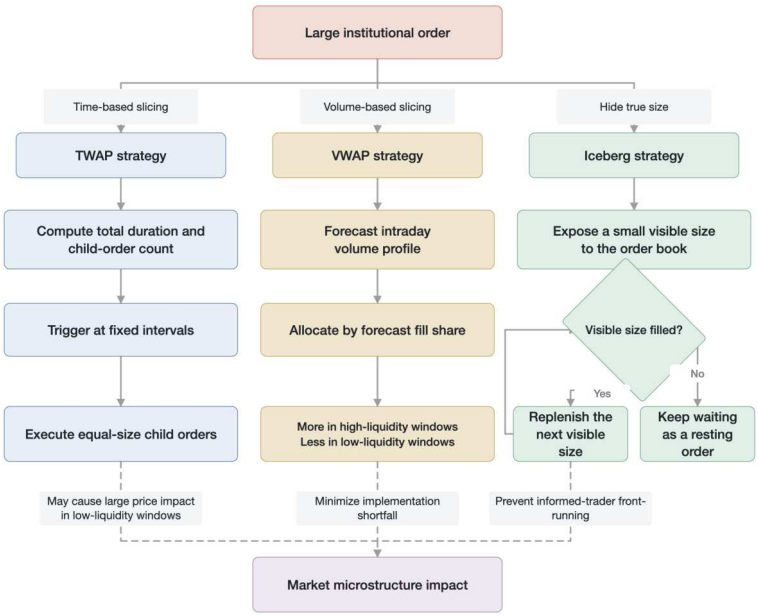

Figure 7-8. A logical comparison of the mainstream large-order algorithmic execution strategies (TWAP, VWAP, and the iceberg order) (conceptual logical-comparison illustration, not empirical data)

The TWAP algorithm divides a large order evenly into many equal-sized child orders over a specified total time and sends them to the market at fixed time intervals. TWAP's advantage lies in its simplicity and robustness; it requires no prediction of market behavior at all. However, liquidity in the crypto market is highly uneven across the intraday cycle. Blindly executing a fixed-quantity TWAP during a low-liquidity window—such as the middle of the night in Asia—will cause considerable price impact.

The VWAP algorithm is more intelligent: it aims to keep its execution cadence aligned with the market's actual volume distribution. In practice, institutional traders typically use adaptive VWAP—re-estimating the volume curve of the remaining window in real time during execution rather than relying entirely on historical data. This distinction is especially important on event-driven days (such as major regulatory announcements or black-swan events), when the historical "twin-peak" volume pattern may fail entirely and the execution performance of a static VWAP deteriorates markedly. As shown in Figure 7-9, according to research by Talos (2025) and Jasiak and Zhong (2024) on the intraday trading characteristics of Bitcoin, crypto-market liquidity exhibits a pronounced "twin-peak" feature: it reaches its highest peak at 14:00–15:00 UTC (the U.S. stock market open), a secondary peak at 08:00–10:00 (the European open), and its trough at 00:00–04:00 (the middle of the night in Asia) [15][16].

The VWAP algorithm predicts this intraday volume curve, allocating more execution quantity during windows predicted to have high liquidity (such as the U.S. open) and less during low-liquidity windows. Research by Genet (2025) further shows that using a deep-learning framework to optimize the VWAP execution objective directly can signif-

icantly outperform the traditional benchmark VWAP strategy, effectively minimizing implementation shortfall—the difference between the ideal decision price and the actual execution price [17].

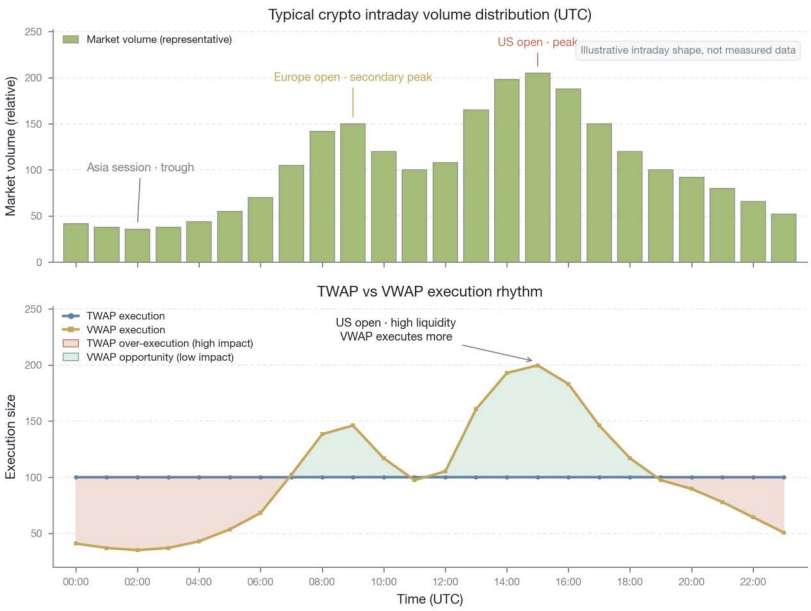

Figure 7-9. A comparison of the typical intraday volume distribution in crypto with the execution cadences of TWAP/VWAP (representative intraday volume-profile illustration: the curves are stylized values, not empirical; the twin peaks are per Talos 2025 [15] and Jasiak & Zhong 2024 [16], and DL-VWAP is per Genet 2025 [17])

Table 7-6 systematically compares TWAP and VWAP along four dimensions: core logic, advantages, disadvantages, and applicable scenario. The core trade-off between the two algorithms is that TWAP trades execution simplicity for a disregard of changes in market structure, whereas VWAP trades reliance on the historical volume pattern for a better execution price.

Algorithm type	Core logic	Advantages	Disadvantages and risks	Applicable scenario
TWAP	Splits the order linearly and evenly over time	Simple logic, no reliance on historical-data prediction; provides some smoothing against extreme "wicks"	Ignores intraday liquidity variation; forced execution during low-liquidity windows leads to costly slippage	Assets lacking a reliable volume-prediction model; tasks with extremely high time-certainty requirements
VWAP	Splits the order in proportion to predicted market volume	Execution trajectory tracks market depth, minimizing impact on market microstructure and implementation shortfall	Highly dependent on the accuracy of the volume-curve prediction; prediction fails when the market undergoes a structural break	Mainstream assets with clear cyclical liquidity patterns (such as BTC/ETH); large position-building highly sensitive to slippage

Table 7-6. A matrix of algorithmic execution strategies for advanced order types (Data source: constructed by the author)

As Table 7-6 shows, TWAP is suited to long-tail assets that lack a reliable volume-prediction model, whereas VWAP performs better in large position-building scenarios for mainstream assets (such as BTC/ETH). In actual execution, institutional traders typically switch between the two algorithms according to the liquidity characteristics of the underlying asset and the execution time window.

7.3.5 Conditional orders

Beyond conventional price triggers (such as stop-loss/take-profit), modern perpetual futures platforms have also spawned conditional orders based on more complex microstructure data. These orders allow traders to push strategy logic directly down to the matching-engine level.

A funding-rate-based conditional order triggers when the funding rate deviates beyond a certain threshold. For example, an algorithmic trader can set: "when the BTC funding rate exceeds 0.05% (longs extremely crowded), automatically trigger a market sell to go short." This allows the trader to capture fleeting rate-arbitrage opportunities. Trading strategies executed automatically on algorithmic conditions may, in several jurisdictions, be classified as algorithmic trading, thereby triggering compliance obligations such as registration, risk-control systems, and trade reporting (for example, the definition of algorithmic trading under the EU's MiFID II and the related rules of the U.S. SEC). A conditional order based on open interest is another option, as OI is a key indicator of market momentum. When open interest (OI) surges in a short period, it often foreshadows imminent violent volatility. A conditional order based on changes in OI can help a trader intervene automatically at the early stage of a trend breakout. There is also the conditional order based on the liquidation heatmap, a highly advanced form of strategy expression. A trader who anticipates that a dense cluster of highly

leveraged long liquidation lines exists at a certain price level can set a conditional order to automatically provide liquidity (buy) when that region is triggered, thereby acquiring a position at a lower price amid a large-scale liquidation cascade.

The evolution of advanced order types is, in essence, an escalation of the game between traders and market microstructure. From the market order's direct impact on the order book, to the limit order's passive waiting to fill, to VWAP's adaptation to the market's liquidity cadence, the richer the available order toolkit, the finer the granularity of strategy expression—and the greater the probability of surviving in the zero-sum game of the derivatives market.

7.4 The strategic dimensions of perpetual futures

In traditional spot trading, the order decision is generally a relatively simple two-dimensional optimization problem: the trader mainly weighs price (at what price to execute) against signal leakage (which order type to choose to control information exposure). In perpetual futures, however—the most dominant derivative instrument in the crypto market—the order decision gains three additional strategic dimensions: leverage, liquidation, and time. These three dimensions make the order decision in perpetual futures an order of magnitude more complex than in the spot market, and they also give "a good order strategy" an influence on a perpetual futures trader's profit and loss far exceeding that in the spot market. For ineffective traders who suffer systematic losses in the market over the long run, the losses often stem not from errors in directional judgment but from their unconscious exposure along these three key dimensions. Behavioral-finance research further shows that even when traders understand the three dimensions of leverage, liquidation, and time at a cognitive level, they still make erroneous decisions because of systematic cognitive biases: overconfidence bias causes traders to systematically underestimate liquidation risk ("I won't get liquidated"), the disposition effect causes them to hold losing positions too long and close winning positions too early, and mental accounting causes them to treat each position under cross-margin mode as an independent bet while ignoring portfolio-level risk contagion. Figure 7-10 uses a three-dimensional coordinate system to show how these three dimensions layer onto the traditional price-signal two-dimensional framework: the horizontal axis represents leverage (from 1× to maximum leverage), the vertical axis represents liquidation distance (from safe to dangerous), and the time axis represents the funding-rate settlement cycle. Every order has a definite coordinate in this three-dimensional space, and that coordinate determines the order's overall degree of risk exposure.

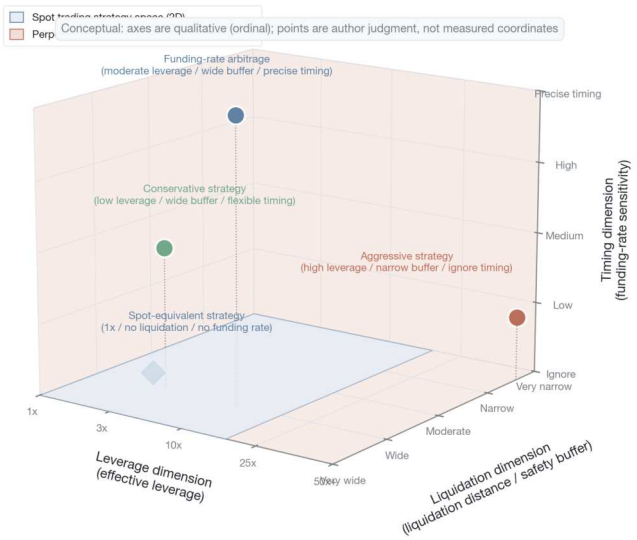

Figure 7-10. The three additional dimensions of perpetual futures order strategy (conceptual three-dimensional strategy-space illustration; the positioning points reflect the author's judgment, not measured coordinates)

7.4.1 The leverage dimension

In the spot market, executing a buy order merely converts cash into an asset, and the risk exposure is linear and bounded. In perpetual futures, however, each order execution not only changes the direction and size of a position but also directly changes the account's effective leverage. Effective leverage is defined as the ratio of notional position value to total account margin (including unrealized profit and loss), computed as:

> Effective leverage = total notional position value / total account equity (margin + unrealized P&L)

When a trader submits a new add-on order on top of an existing position, that order in effect "compresses their risk tolerance." Consider a concrete numerical case to illustrate this dynamic. Take an account with $10,000 of margin, initially holding no position. Executing a $50,000 notional Ethereum perpetual long order takes the account's effective leverage from 0× to 5×. At this leverage level, assuming a maintenance margin rate of 0.5% (charged on notional position value; in practice exchanges generally use a tiered, dynamic maintenance margin rate—Binance's, for example, ranges from 0.4% for small positions to 5% for large ones—so the 0.5% here is merely a pedagogical simplification), the liquidation price sits roughly 19.5% below the entry price. If the trader then executes another $50,000 buy order, the total notional value reaches $100,000 and effective leverage jumps to 10×. At this point the liquidation price rises sharply, narrowing to only about 9.5% below the average entry price. A single add-on order has compressed the "risk tolerance" by half.

> Core insight: in perpetual futures, every add-on order "compresses your risk tolerance," and every reduce order "expands your risk tolerance." The "next order," therefore, is not merely a trading decision but a profound risk-management decision.

This dynamic variation in the leverage dimension requires traders to implement strict margin-allocation strategies at the order level. Two common strategic patterns embody different risk-management philosophies:

Incremental position-building (the leveraged version of dollar-cost averaging) requires the trader to execute the target total position in tranches. After each add-on order fills, the new effective-leverage level is systematically assessed. Once effective leverage approaches the trader's preset upper limit of risk tolerance, further adding stops. The core advantage of this strategy is that the trader retains, at every step, the option "not to keep adding," rather than exposing all margin to a single entry price at once.

Pyramiding, by contrast, requires the trader to add to the position using a sequence of orders of decreasing size after the market trend is confirmed. For example, the first order is 40% of the target position, the second 30%, the third 20%, and the last 10%. This order strategy can increase profit exposure while preventing the average entry price from converging too quickly toward the current market price, thereby keeping effective leverage within a relatively safe range. Its essence is to trade "decreasing marginal commitment" for "increasing trend confirmation."

7.4.2 The liquidation dimension

The liquidation dimension is the most distinctive part of the perpetual futures order decision. In the traditional spot market, the "worst outcome" an investor faces is that the asset value goes to zero, but never a liability. In the high-leverage environment of perpetual futures, the "worst outcome" is not only complete forfeiture of margin but, under extreme market volatility and liquidity depletion, may even produce a bankruptcy liability (though most platforms absorb this portion of the risk through an insurance-fund mechanism). The liquidation price is precisely the rigid mathematical threshold that triggers this "worst outcome." Taking a long position as an example, the approximate formula for its liquidation price is:

> Liquidation price (long) $\approx$ average entry price $\times$ (1 $-$ 1/effective leverage + maintenance margin rate)
> Liquidation price (short) $\approx$ average entry price $\times$ (1 + 1/effective leverage $-$ maintenance margin rate)

The approximate formulas above apply to a single position under isolated-margin mode. Under cross-margin mode, the liquidation price is determined by total account equity rather than the margin of a single position, and the formulas above no longer apply. The approximate formulas can also produce large errors under high leverage (50$\times$ to 100$\times$), because they ignore the effects of cumulative funding, trading fees, and fluctuations in unrealized P&L. In actual trading, a trader should rely on the exchange's real-time computed liquidation price rather than estimate it from a simplified formula.

Within this dimension, the most critical order decision is the setting of the stop-loss order and its interaction with the liquidation price. When submitting any opening order, a trader must simultaneously compute and plan the spatial relationship between the liquidation price and the stop-loss price. This relationship has three basic states:

If the stop-loss trigger price is set beyond the liquidation price (that is, for a long, the stop-loss price is below the liquidation price), the stop-loss order is logically entirely ineffective. This is because, before the market price reaches the stop-loss price, the exchange's risk engine has already forcibly taken over the position and executed the liquidation procedure. Surprisingly, in actual trading, such "ineffective stop-loss" settings—arising from an insufficient understanding of the liquidation mechanism—are not rare. Viewed from another dimension, if the stop-loss order is set before the liquidation price with an ample buffer, it can provide effective protection under normal market conditions. However, as discussed earlier (Section 7.2.3), in extreme conditions a stop-loss market order may encounter enormous execution slippage due to oracle latency or an instantaneous drain of order-book liquidity, causing the final fill price to be even worse than the theoretical liquidation price. The third state is a stop-loss price set flush against the liquidation price, with an extremely narrow buffer. This configuration pursues extreme capital efficiency, but it essentially outsources the trader's own risk management to the exchange's liquidation engine. In a transparent on-chain environment, such an extremely narrow buffer is prone to becoming the target of deliberate price pushing—a risk Section 7.5 analyzes in detail.

The distance between the "liquidation price and the stop-loss price" constitutes the "safety buffer" that the trader actively chooses. The wider the buffer, the higher the trader's probability of surviving violent volatility; but this also means the trader must accept lower effective leverage or a larger single stop-loss, thereby compressing the potential return on capital. This trade-off has no "correct answer," only "an answer matched to the trader's risk preference."

7.4.3 The time dimension

Perpetual futures can track the spot price closely without expiry delivery because of the funding-rate mechanism. This mechanism typically settles once every 8 hours (on some application chains the frequency is higher: Hyperliquid settles once every hour, while dYdX v4 adopts a continuous-accrual model in which the funding rate accrues proportionally within each block without waiting for a fixed settlement point). (For a detailed analysis of the funding-rate formula, the clamp mechanism, and the game-theoretic structure, see Chapter 10.) At the moment of settlement, funds transfer directly between traders holding positions: when the perpetual futures price is above the spot price, longs pay funding to shorts, and vice versa. This periodic flow of funds creates a strategic dimension entirely absent from the spot market—the choice of order timing around the settlement moment.

In the traditional spot market, the "timing" of order execution mainly affects slippage and market-impact cost, a matter of execution-level optimization. In perpetual futures, however, execution timing directly determines whether the trader pays or receives funding—a source of profit and loss independent of price direction. This gives

rise to a series of specific order strategies:

The rate-sniping strategy is the most direct application of the time dimension. When market sentiment is extremely one-sided, causing the expected funding rate to be abnormally high (for example, extremely crowded longs producing an extremely high positive rate), a trader may submit a short market order or an aggressive limit order minutes or even seconds before settlement. After crossing the settlement moment and collecting the high funding rate, they close the position quickly. The core of this strategy is to weigh the net benefit between "the funding collected" and "the slippage and fees generated by the two orders." On platforms that settle hourly, such as Hyperliquid, the frequency and precision with which this strategy can be executed far exceed those of the traditional 8-hour settlement cycle. In practice, however, the strategy faces severe execution constraints. First, the order book during a high-rate settlement window is often extremely thin (other participants are also competing for the same direction), so the adverse-selection cost rises significantly. Second, even within a 1-hour settlement cycle, a 1% adverse move in the underlying asset means a 10% margin loss at 10× leverage, whereas the corresponding rate gain is typically only 0.01%–0.05%—directional risk can be dozens of times the rate gain. Third, some exchanges have adopted time-weighted rate calculations (prorating by the ratio of holding time to the settlement cycle), greatly reducing the effectiveness of last-moment sniping. Consider a simplified numerical case to illustrate the break-even condition: assume the expected funding rate is 0.05% and the trader uses 10× leverage to establish a $1 million notional short position ($100,000 of margin); the single-period rate gain is $500 ($1 million × 0.05%). If the round-trip trade (the two legs of opening and closing) incurs fees of 0.05% × 2 legs = $1,000, plus estimated slippage of 0.02% × 2 legs = $400, then the trading cost alone reaches $1,400 and the strategy makes a net loss of $900. This strategy has positive expected value only when the rate is extremely high (typically above 0.1%) and trading costs are extremely low, and its profitability has a strong dependence on the macro cycle: in a sustained one-directional trend, the funding rate may remain in the same direction for a long time, invalidating the mean-reversion assumption.

The avoidance-reduce strategy exploits the time dimension from a defensive angle. If a trader holds a large trending long position and currently faces an extremely high positive funding rate, they may choose to submit a reduce order before settlement to avoid paying the expensive funding, and re-establish the position after settlement. However, this operation of moving in and out of the order book frequently not only increases trading costs (two sets of fees plus potential slippage) but may also expose the trader's intent, making them a source of signal leakage.

> Core insight of the time dimension: the funding-rate mechanism of perpetual futures makes "order timing" an independent strategic variable. An originally perfect trend-following order, if it merely chooses the wrong execution timing and pays a high funding rate for several consecutive days, may have its final profit-and-loss outcome completely reversed. Chapter 10 analyzes the game-theoretic structure of the funding rate in depth.

7.4.4 The choice of margin mode

Beyond the three dynamic dimensions above, perpetual futures order strategy is also profoundly constrained by the underlying account-level institutional framework. Before submitting an order, a trader must choose the margin mode in which the order sits, and this choice determines the boundary of risk contagion and constitutes the institutional framework for all subsequent order behavior (a comparison of the two modes appears in Table 7-7).

Under isolated-margin mode, each position has its own isolated margin. The loss and eventual liquidation of one position will absolutely not affect the other positions in the account or the available balance. The philosophy of this mode is to "isolate the risk exposure of each position," achieving strict risk isolation. For high-risk, high-leverage one-directional speculative orders, isolated mode is the preferred choice, because it strictly confines the "worst outcome" to the margin allocated to that position. Its cost, however, is low capital efficiency: funds cannot be shared across different positions, and even if one position has a large amount of unused margin, it cannot be used to support another position that is taking a loss.

Under cross-margin mode, all positions in the account share a single margin pool. The unrealized profit of a winning position can serve as collateral to "support" a losing position, greatly improving capital efficiency. The philosophy of this mode is to "bring all positions into a unified risk pool to improve capital efficiency." However, cross-margin has strong procyclicality. Ali (2025), in a study of the crypto-market liquidation cascade of October 2025, notes that the event cleared $19 billion of open interest in 36 hours, and that the procyclicality of cross-margin was a key systemic-risk amplifier [9]. Its mechanism is as follows: when a macro shock causes all assets to fall together, the collateral value of all positions in a cross-margin account shrinks simultaneously, systematically lowering the margin health of the entire account and ultimately causing even originally safe positions to be liquidated by association. This chain of intra-account liquidation contagion does not occur under isolated mode (though market-level and liquidity-level contagion still exist).

The risk profile of cross-margin, however, has a pronounced "two-sidedness," and one must avoid simplistically labeling it a "risk amplifier." Under normal market volatility and with asset correlations near their historical means, cross-margin actually acts as a stabilizer: the unrealized profit of winning positions provides a buffer for losing positions, lowering the probability that a single position is liquidated by temporary volatility. Only when the market undergoes a regime switch—when asset correlations suddenly jump from normal levels to near 1 (that is, "all assets fall at once")—does cross-margin flip into an amplifier: the collateral value of all positions shrinks in unison, the profit buffer vanishes, and the liquidation probability jumps nonlinearly. This critical feature of the regime switch is key to understanding the systemic risk of cross-margin.

Looking further, the systemic shock produced by liquidation propagates in turn through three levels: intra-account contagion (under cross-margin mode, the liquidation of a single position consumes shared margin and drags down other positions) → market contagion (the forced market orders produced by liquidation strike the order book, pushing the price further away and triggering the liquidation of more accounts) →

liquidity contagion (after observing the signal of a liquidation cascade, market makers withdraw liquidity on a large scale, order-book depth plunges, and the price impact of subsequent liquidations intensifies). This contagion path is not unique to crypto markets. Adrian and Shin (2010), in a study of the traditional financial system, had already revealed the systemic-risk mechanism of procyclical leverage and margin spirals [18]. The cross-margin problem in crypto markets is, in essence, an accelerated version of this known systemic-risk mechanism in a 24/7, high-leverage, digital-native environment.

Dimension	Isolated margin	Cross margin
Risk isolation	Strict isolation; liquidating one position does not affect others	No isolation; losses contaminate the entire account
Capital efficiency	Low; funds locked in a fragmented way	High; funds shared and utilized
Liquidation trigger	Triggered when a single position's margin is insufficient	Triggered when total account equity is insufficient
Procyclical risk	Low; risk is isolated	High; risk amplified in a market-wide sell-off
Applicable scenario	High-leverage speculation, standalone strategies	Hedged portfolios, low-leverage multi-asset allocation
Mental model	"Each trade is an independent bet"	"All trades are one portfolio"

Table 7-7. A comparison of isolated margin and cross margin (Data source: compiled by the author)

The choice of margin mode, therefore, is by no means a simple technical setting; it is a fundamental risk-management decision that affects all subsequent order behavior. It determines "whether, and how, the loss from one bad order contaminates the entire portfolio."

7.4.5 A unified decision framework

By combining the traditional order-selection dimensions (price, signal) with the three extended dimensions unique to perpetual futures (leverage, liquidation, time) and the margin-mode institutional framework, we can construct a unified order-decision framework. Under this framework, the formation of every perpetual futures order must pass through a multi-objective optimization process comprising seven decision nodes.

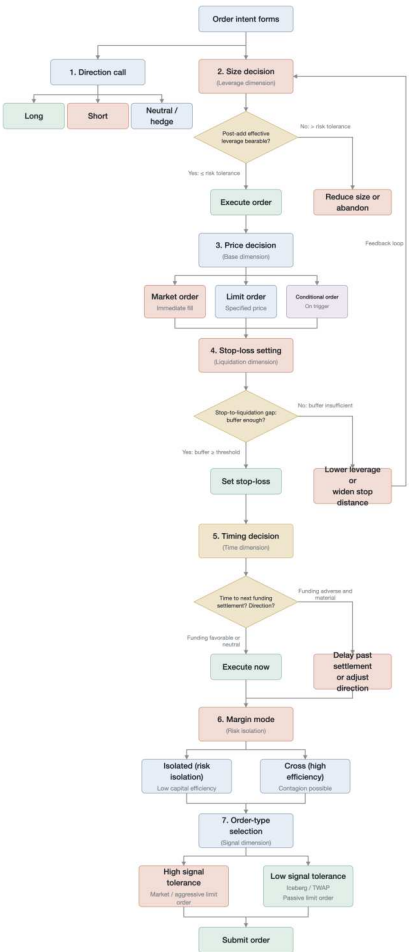

Figure 7-11. A unified decision tree for perpetual futures order strategy (conceptual decision-tree illustration, not empirical data)

As shown in Figure 7-11, after forming a preliminary trading intent, a mature trader must pass in turn through the following seven nodes:

The trader's starting point is directional judgment—deciding, based on fundamental analysis or technical signals, whether to go long, go short, or construct a neutral hedge. This is the step every trader performs, and the only step most ineffective traders perform. Building on this, the trader must convert the directional judgment into a sizing decision, calculating whether effective leverage after adding remains within their risk tolerance. If it exceeds the tolerance, they must reduce the order size or forgo the trade, thereby converting the subjective judgment of "I favor this direction" into the quantified decision of "how much risk I am willing to bear." Next comes the price decision: choosing immediate execution (a market order), waiting at a specified price (a limit order), or a conditional trigger (a stop-loss/take-profit order). This dimension exists in the traditional spot market as well, but in perpetual futures the price decision is tightly coupled with leverage, and different entry prices imply different effective leverage and

liquidation distances.

At the same time, the stop-loss setting constitutes a key feedback loop in the decision tree: the trader must assess whether the safety buffer between the stop-loss price and the liquidation price is sufficient to withstand slippage in extreme volatility, and if the buffer is insufficient, they must fall back to lower the leverage or widen the stop-loss distance. Then the timing decision requires the trader to examine the time remaining until the next funding-rate settlement and the expected direction of the rate, and decide whether to execute immediately or defer until after settlement. For a large position, the funding cost may be a non-negligible factor in profit and loss.

Having established the risk framework, the trader must still make two structural choices. The margin mode determines whether this order is placed in the capital-efficiency-seeking cross-margin pool or under the risk-isolation-seeking isolated mode, thereby defining the order's risk-contagion boundary. The choice of order type then requires the trader, based on their own tolerance for information leakage, to make the final trade-off between execution certainty and signal concealment: for a trader with high signal tolerance, a market order or an aggressive limit order is a reasonable choice; for a large trader who needs to hide intent, an iceberg order, TWAP, or a passive limit order is the better strategy.

> Every perpetual futures order is a multi-objective optimization across these seven decision nodes. This is precisely the microfoundation of why perpetual futures trading is "simple to operate but complex to decide." Ineffective traders who suffer systematic losses in the market over the long run typically stop at only the first node of the decision tree—"directional judgment"—while entirely neglecting the six critical decision nodes that follow. This insufficient analysis is precisely the microstructural operationalization of the systematic losses of the "ineffective traders" analyzed in Chapter 4.

7.5 The commitment property of on-chain orders

Having understood the essence of the order as a signal and the three-dimensional extension that perpetual futures confer on orders, we must now turn our attention to the execution architecture itself. Traditional financial theory generally treats the execution architecture as a neutral background variable: whether at the New York Stock Exchange or on Nasdaq, the economic meaning of a limit order is assumed to be the same. In decentralized finance, however, the physical constraints of the underlying blockchain reshape the economic semantics of an order.

In the two starkly different environments of the centralized exchange and the on-chain central limit order book, the same order faces different processing flows. The core difference is this: on an on-chain CLOB, an order changes from a "private expression of intent" on a CEX into a public, costly, on-chain commitment observable by everyone. This commitment property is the ultimate concretization, at the order level, of the "transparency paradox" of Chapter 1 and the "transparency-fragility paradox" of Chapter 4, and it changes the trader's strategic choices. Taking a single limit order as an example, Figure 7-12 contrasts the "private expression of intent" on a CEX with the "public commitment" on an on-chain CLOB along three dimensions: visibility, cancella-

tion cost, and confirmation latency (the mechanism of each path is detailed in Sections 7.5.1 and 7.5.2).

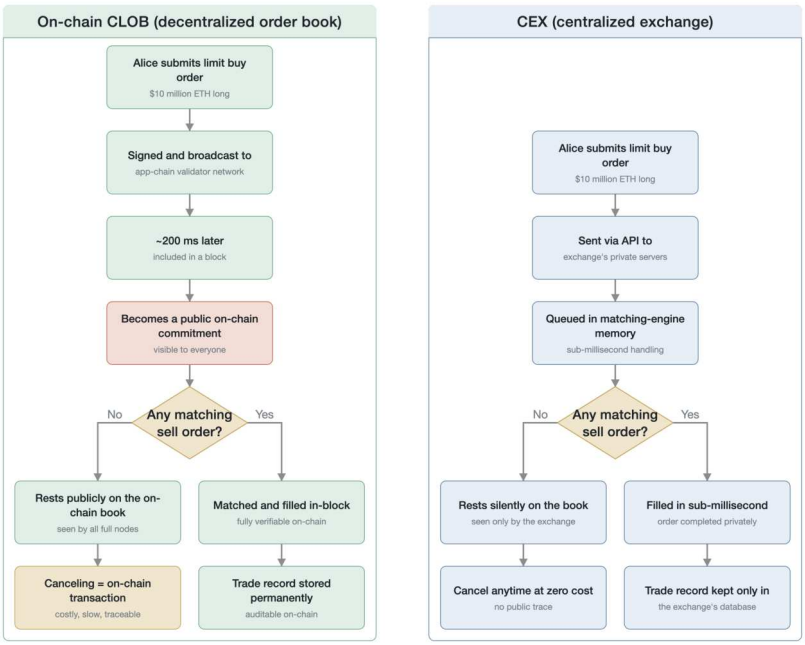

Figure 7-12. The different processing paths of an order on a CEX versus an on-chain CLOB (mechanism-path comparison illustration, not empirical data)

7.5.1 The privacy of CEX orders

In a traditional CEX architecture, when a trader submits a limit order, the order is sent through an API or web front end directly to the exchange's internal private matching engine. Within the matching engine's memory, this order is visible only to the exchange itself and to specific authorized counterparties (such as certain market makers who enjoy a special data feed). If the order is not executed immediately, it rests at a price level on the order book, entirely invisible to the outside world.

For the trader, the CEX environment offers a high degree of strategic flexibility. If market conditions change slightly, the trader can cancel this order at any time, at sub-millisecond speed and zero cost. After the order is canceled, no external observer can prove that the order ever existed; it leaves no public record and no on-chain trace.

Advantage: strategic-privacy protection relative to the public on-chain ledger (though this privacy does not extend to the exchange itself). The trader's intent, capital base, and degree of patience cannot be obtained and exploited in advance by external market participants. This privacy allows large traders to use advanced strategies such as iceberg orders relatively safely to hide their true intent, and allows market makers to instantly withdraw all quotes when unfavorable information appears in order to avoid adverse selection.

Disadvantage: unverifiability and trust cost. The opaque nature of a CEX means that an ordinary trader cannot verify "whether the order book you see is real." The exchange is fully capable of displaying fake market depth, or of using its exclusive visibility into the global order flow to grant itself preferential treatment (such as front-running customer orders). Under this architecture, "the trader's strategic privacy is protected, but at the same time the integrity of the market data cannot be independently verified." This is the structural paradox of the CEX order model.

7.5.2 The public-commitment property of on-chain orders

When the same limit order is submitted to a CLOB protocol built on a general-purpose public chain or an application chain, its nature undergoes an important transformation. The order must be cryptographically signed and broadcast as a transaction to the validator network. From the moment it enters the mempool or is packed into a block, this limit order becomes an on-chain observable public commitment.

Everyone in the world running a full node can clearly see that "someone has committed to buying quantity Q of an asset at price P." More importantly, this commitment cannot be canceled "quietly." Canceling the order likewise requires sending an on-chain transaction, which not only incurs a gas fee (or is constrained by network bandwidth) but also requires waiting at least one block of consensus confirmation. During the time spent waiting for the cancellation to confirm, the original order is still "alive" and can still be filled by anyone.

This "public commitment" property brings mechanism effects that are both positive and negative. The positive meaning: verifiable, genuine liquidity. The on-chain order book achieves verifiability at levels L3 to L4 of the verifiability ladder of Chapter 5. External observers can independently audit every drop of liquidity in the order book, ensuring that no fake depth fabricated by the exchange exists. Everyone sees the same real, fair market state; with respect to the single dimension of fake depth, information asymmetry is significantly reduced at the infrastructure level. This transparency is a structural advantage that current CEX architectures generally cannot provide (without introducing additional cryptographic proofs). The negative meaning: strategy exposure and cancellation cost. Your limit order tells the whole world "I have definite demand at this price." MEV searchers, competing market makers, and other strategic traders can all exploit this public information at no cost to adjust their own strategies. At the same time, because cancellation carries latency and cost, a market maker facing sudden unfavorable information cannot instantly withdraw all quotes as on a CEX, and this significantly increases the adverse-selection risk they face (the transmission by which they widen spreads and pass the cost on to liquidity consumers is detailed in Section 7.6.3).

7.5.3 The MEV exposure surface of orders

In a transparent on-chain environment, an order is no longer merely a number in a matching engine but an object that various algorithms may exploit. Different types of orders, because of the differences in the information they leak to the market and in their execution mechanisms, face starkly different MEV exposure surfaces.

According to data analysis by EigenPhi (2025), the monthly amount extracted by sandwich attacks on the Ethereum mainnet has fallen from nearly $10 million in late 2024 to about $2.5 million by October 2025 [19]. This decline may be partly attributable to the spread of private RPCs and MEV-resistant routing (such as Flashbots Protect and MEV Blocker), as well as to competition among searchers compressing profit margins [20]. For large orders on an on-chain CLOB, however, MEV remains one of the largest implicit execution costs.

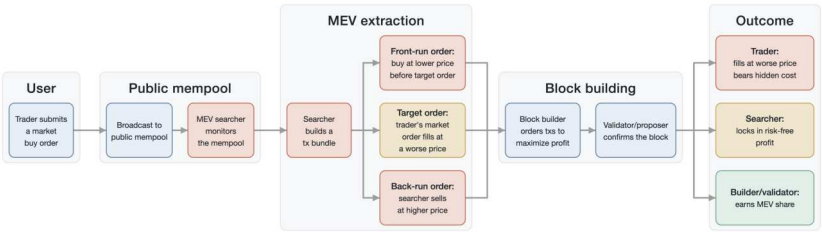

Figure 7-13. The on-chain path of a speculator's market order and MEV intervention (on-chain MEV-intervention mechanism-path illustration, not empirical data; the monthly sandwich extraction of about $10M → about $2.5M is discussed in the text, per EigenPhi [19] and Flashbots [20])

In a perpetual futures environment, the MEV exposure surface of an order is not limited to the traditional sandwich attack; it also includes the deliberate triggering of stop-losses. When a stop-loss order's trigger price is publicly visible on-chain, an attacker can precisely calculate the expected-value relationship between "the capital needed to push the price to the trigger" and "the profit obtainable after triggering." Only when this expected value is positive—as noted at the end of this paragraph, this generally holds only under the narrow conditions of shallow order-book depth at the target level and a high concentration of stop-loss/liquidation positions—does deliberately triggering a stop-loss become a rational attack strategy. Deliberately pushing the price to trigger others' stop-losses, however, is explicitly characterized as market manipulation under the major regulatory frameworks. U.S. SEC Rule 10b-5 renders illegal any fraudulent conduct intended to artificially affect market prices; Article 12 of the EU's Market Abuse Regulation (MAR) defines "manipulative trading" to include trading conduct aimed at creating artificial price levels; and the CFTC's anti-manipulation authority derives mainly from Section 6(c)(1) of the Commodity Exchange Act and Rule 180.1, which is modeled on SEC Rule 10b-5. The CFTC's 2023 enforcement action against Ooki DAO, by contrast, was not based on anti-manipulation grounds but rather established the precedent that a DAO can bear legal liability as an "unincorporated association," as well as the precedent of violations such as operating unregistered illegal leveraged trading; the significance of that case for the legal-personhood status of decentralized protocols is independent of the anti-manipulation rules themselves. As crypto-asset-specific regulations such as the EU's MiCA framework are implemented, the legal risk faced by participants who carry out such strategies—even on decentralized platforms—is steadily increasing. This book's analysis of the stop-loss-hunting strategy here is therefore purely for the academic purpose of understanding market microstructure, and readers should fully recognize the substantial legal risks involved

in engaging in such conduct. From the standpoint of economic analysis, the feasibility of deliberately triggering a stop-loss depends on the relationship between the attack cost and the expected return: the attacker must deploy enough capital to push the price into the stop-loss trigger region (the cost depends on the order-book depth at the target level), while the expected return depends on the total volume of stop-loss orders clustered in the trigger region and the size of the reverse position the attacker has established in advance. Only under specific conditions (namely, shallow order-book depth near the target level but a high concentration of stop-loss/liquidation positions) does such an attack have positive expected value.

Order type	Degree of MEV exposure	Exposure mechanism and attack vector	Mitigation
Large market order (public mempool)	Very high	The trading intent is fully public before filling, making it vulnerable to sandwich attacks and front-running. Searchers can precisely calculate the slippage tolerance and maximize the value extracted.	Use a private transaction pool (such as MEV Blocker); set strict slippage protection.
Stop-loss market order (on-chain trigger)	High	The stop-loss trigger price is publicly visible. In a transparent environment, this amounts to telling the attacker, "push the price here and you trigger my forced sell."	Use a "stop-loss + limit order" combination, or split a large stop into multiple small trigger orders.
Limit order (on-chain order book)	Medium	A long-resting limit order exposes the trader's strategic intent and may be used by counterparties to infer their liquidation price or overall capital strength.	Shorten the resting time (use GTT orders), or use conditional triggers where the protocol supports them.
Iceberg order (on-chain implementation)	Depends on implementation	A simple smart-contract implementation may expose the iceberg order's total size through its state-change pattern, causing the concealment to fail.	Rely on native protocol-level support from the application chain or on zero-knowledge-proof technology.

Table 7-8. The MEV exposure matrix of different order types (Data source: constructed by the author)

After Table 7-8 summarizes the qualitative risk level of each order type, Figure 7-14

goes further, using a heatmap to quantify the degree of exposure of eight common order types under five MEV attack vectors:

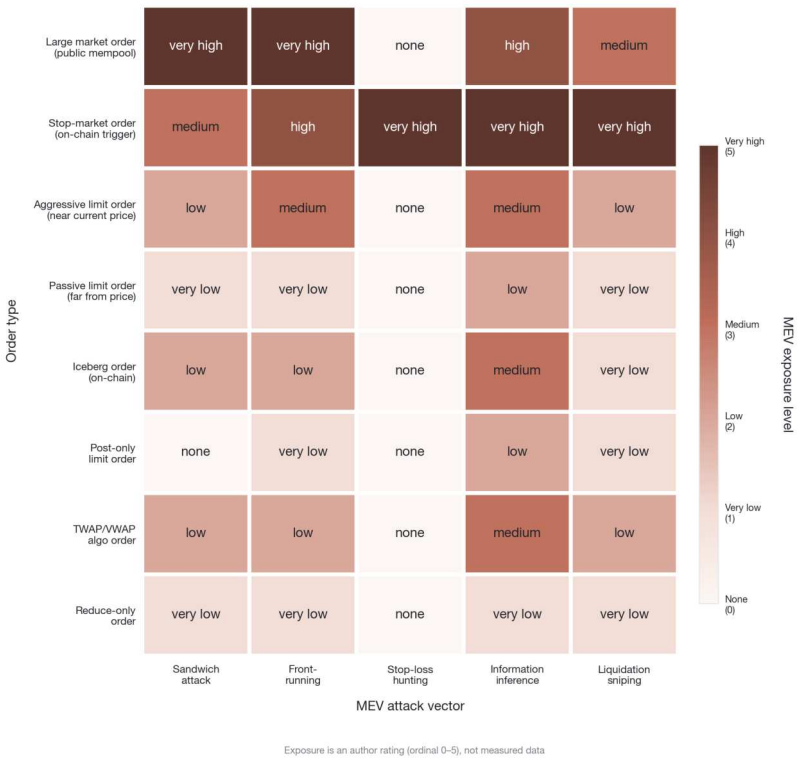

Figure 7-14. The degree of exposure of different order types under five MEV attack vectors (author's qualitative rating matrix; the 0–5 scale reflects the author's judgment, not empirical data; the MEV taxonomy is per Flashbots 2024 [20] and EigenPhi 2025 [19])

Figure 7-14 reveals a key pattern unique to the perpetual environment: although the stop-loss market order has only "medium" exposure on the sandwich-attack dimension, it reaches "very high" on both the deliberate-stop-triggering and information-inference dimensions—a risk-amplification effect unique to the perpetual futures environment. The "very high" exposure of large market orders on the sandwich and front-running dimensions, and the low exposure of Post-Only limit orders and Reduce-Only reduce orders across attack vectors owing to their passive nature, can all be read directly from the heatmap.

> Core insight: on an on-chain CLOB, the public visibility of the stop-loss order is directly related to the "transparency-fragility paradox" of Chapter 4. When your stop-loss price is seen by everyone and you use high leverage, "pushing the price to trigger your stop-loss" can become a positive-expected-value attack strategy for a market maker or an MEV bot. This is a systemic risk unique to perpetual futures in the transparent on-chain environment. At the same time, because deliberately triggering a stop-loss constitutes market manipulation under most regulatory frameworks, participants in such conduct

> also face steadily increasing legal risk.

7.5.4 The order-protection mechanisms of application chains

To address the negative effects of the on-chain order commitment property, a new generation of derivatives application chains (such as Hyperliquid and dYdX v4) has undertaken extensive innovation at the protocol layer, seeking a new balance point between "verifiability" and "strategic privacy." These application chains abandon the global-state model of general-purpose public chains such as Ethereum, opting instead for a highly customized architecture designed for order-book trading, thereby providing three core classes of order-protection mechanism.

The private mempool is the first class of protective measure these application chains adopt. On a general-purpose public chain, a transaction must be broadcast in a public P2P network before it is packed, giving MEV searchers a "submit-to-confirm" time window to observe and exploit pending orders. Many application chains, by contrast, adopt a private mempool or validator-level direct routing, encrypting the user's order or sending it directly to the current block proposer, so that it is not disclosed publicly before it is formally packed into a block and executed. This eliminates the MEV exposure in the "submit-to-confirm" time window and deprives the traditional sandwich attack of its target. The cost of this design, however, is that trust is transferred from the "trustless public network" to the validator nodes, and this transfer of trust introduces a non-negligible centralization risk. Under a private-mempool architecture, validators have complete visibility into and ordering power over the user's order flow, functionally no different from the operator of a CEX matching engine. A malicious or compromised validator can carry out a variety of concrete attacks: selectively delaying a particular user's orders to create an execution environment favorable to itself, front-running high-value orders, censoring (refusing to pack) transactions from particular addresses, and colluding with external parties to leak order-flow information. Take Hyperliquid as an example: its validator set is relatively small (about 4–16 nodes) and its admission mechanism is restricted, so compromising or bribing a single validator suffices to gain an informational advantage over all the order flow that validator processes. Mitigations currently under exploration include: threshold encryption (encrypting an order and distributing it to multiple validators, decryptable only when more than a threshold number of validators cooperate), commit-reveal schemes (the trader first submits a hash commitment of the order and reveals the order contents only after the block is confirmed), and periodic ordering-fairness audits. To assess the current state candidly: mainstream application-chain DEXs are far less decentralized than general-purpose public chains such as Ethereum, and their security model still relies largely on trust in a small number of validators rather than on cryptographic guarantees. From the standpoint of regulatory classification, a private mempool is functionally equivalent to a dark pool or a systematic internalizer in traditional finance, which are subject to extensive transparency and fairness regulation under the SEC and MiFID II frameworks—a regulatory equivalence that has not yet received sufficient attention in the current discussion of DeFi regulation.

Building on this, protocol-level deterministic ordering provides a complementary safe-

guard. General-purpose public chains typically use a priority-fee auction mechanism: whoever pays more gas has their transaction ordered first, which creates the economic basis for front-running, as an attacker need only pay slightly more gas than the target transaction to ensure their own transaction is executed first. Application chains, by contrast, typically enforce first-in-first-out or other deterministic ordering rules at the consensus level: as long as the order in which orders arrive at the validators is determined, their execution order is locked, thereby eliminating the possibility of prioritizing an order by paying a higher fee. Deterministic ordering, however, cannot fully eliminate the validator's internal ordering advantage; validators can still selectively delay or reorder the transactions they receive.

Going further, an application chain, by virtue of its full-stack control (from the consensus layer to the application layer), can also provide native support at the protocol layer for advanced orders such as iceberg orders and implement selective opacity. For example, it can record on-chain only the currently visible portion of an order while hiding the total size in encrypted state. This "selective opacity" design is precisely a response to the profound recognition that "full transparency is not net-positive in a high-leverage environment." It responds to the "transparency-leverage-safety trilemma" analyzed in Chapter 6: in some scenarios, moderate opacity can actually improve the overall safety and efficiency of the market. Zero-knowledge-proof technology offers a more elegant solution in this direction: "prove compliance without exposing the details" (see the analysis of the prospects for zero-knowledge proofs in order protection in Chapter 30).

The evolution of on-chain orders from "private intent" to "public commitment" is not merely a technological shift but an architectural transformation of market microstructure. It requires traders to relearn the "on-chain dialect" of this language—to enjoy the transparency and fairness that decentralization brings while learning to use the new infrastructure to protect their own strategies from strategy-exposure risk. And the application chains' ongoing exploration between "verifiability" and "strategic privacy" is defining the boundaries of this new architecture.

7.6 The execution-architecture spectrum and the reshaping of order semantics

In traditional financial markets, the lifecycle and execution logic of an order are built on highly centralized, low-latency physical infrastructure. The matching engine runs on dedicated hardware, order submission, matching, and cancellation complete at the sub-millisecond level, and the trader hardly needs to care about the physical characteristics of the underlying infrastructure. When perpetual futures trading migrates to an on-chain environment, however, the physical constraints of the underlying blockchain—the discreteness of block time, the latency of the consensus mechanism, the volatility of gas fees, and the costliness of state storage—reshape the semantics of an order. An order whose semantics are clear and whose behavior is predictable on a centralized exchange may exhibit a starkly different lifecycle, cost structure, and risk profile in an on-chain environment.

This section systematically examines the differences in the core properties of the three

main execution architectures (the centralized exchange, the fully on-chain DEX, and the application-chain DEX), and analyzes one by one how the physical constraints of blockchain reshape the economic meaning of an order along five key dimensions: order lifecycle, cancellation mechanism, conditional triggering, matching logic, and state management.

7.6.1 A comparison of the three execution architectures

Three execution architectures currently exist in the crypto derivatives market: the centralized exchange, the fully on-chain decentralized exchange, and the application-chain-based decentralized exchange. These three architectures exhibit a starkly different feature spectrum in latency, throughput, order cost, transparency, and censorship resistance, forming a continuum from "extreme performance but complete opacity" to "complete transparency but limited performance."

On a centralized exchange, the matching engine runs on a single high-performance server or a tightly coupled cluster, and order submission, matching, and cancellation typically complete at the sub-millisecond level. The matching engines of top-tier CEXs such as Binance and Bybit can reach an order-processing throughput on the order of a million orders per second, and order submission and cancellation incur no direct fees. This architecture offers extreme execution efficiency, but at the cost of entirely opaque operation: the trader cannot verify whether the matching engine has fairly executed the price-time priority principle, nor audit whether the exchange engages in improper conduct such as internal front-running or selective execution.

The fully on-chain DEX (such as protocols based on the Ethereum mainnet or a general-purpose Layer 2) goes to the other extreme. The submission, matching, and settlement of every order must, as an on-chain transaction, pass through the consensus confirmation of the entire network. The Ethereum mainnet's block time is about 12 seconds, and even an Optimistic Rollup such as Arbitrum requires a soft-confirmation time of about 250 milliseconds. This brings extremely high transparency and censorship resistance (anyone can independently verify the execution process of every transaction), but it also introduces significant latency and high, volatile gas costs. During periods of network congestion, a simple order submission may require paying tens of dollars in gas fees.

The application-chain DEX (such as dYdX v4 and Hyperliquid) seeks a new balance point between the two. By building a sovereign blockchain purpose-optimized for trading, with a customized consensus mechanism and in-memory order-book state management, this class of architecture can achieve sub-second latency and extremely high throughput. Hyperliquid's block time is about 200 milliseconds, and its official documentation claims it can process about 200,000 order operations per second (about 200,000 OPS) [14] (this figure is self-reported from Hyperliquid's official documentation and represents theoretical peak processing capacity rather than sustained throughput under stress; the JELLY incident of March 2025 exposed the platform's operational constraints under extreme market conditions, indicating that sustained processing capacity under actual stress may be significantly lower than the theoretical peak). dYdX v4, built on the Cosmos SDK, has constructed an independent application chain that

maintains the order book in the validators' memory rather than in on-chain state, thereby greatly improving performance while preserving non-custodial and verifiable properties [21]. Figure 7-15 uses a radar chart to compare these three architectures along six dimensions—latency, throughput, order cost, transparency, censorship resistance, and degree of decentralization: the CEX excels on the performance dimensions while its transparency/censorship resistance is nearly zero, the fully on-chain DEX is the reverse, and the application-chain DEX has the most balanced profile.

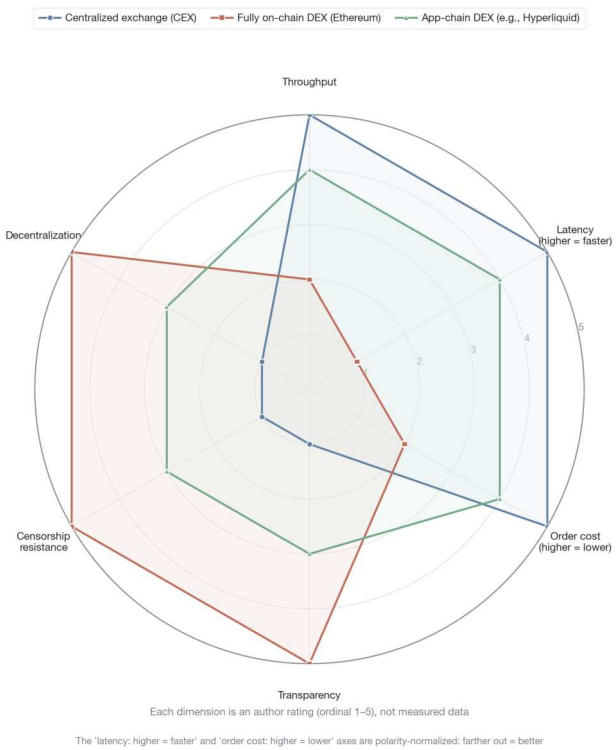

Figure 7-15. A comparison of the core properties of the three execution architectures (author's relative-rating radar; the 1–5 scale reflects the author's judgment, not empirical data; six dimensions, including degree of decentralization, consistent with the text; the latency/order-cost axes have been polarity-normalized so that farther out = better; platforms as of 2025, per Hyperliquid [14] and dYdX [21])

Property	Centralized exchange	Fully on-chain DEX	Application-chain DEX
Latency	< 1 ms	100 ms – 12 s	~200–1,000 ms
Throughput	> 1,000,000 TPS	~15–2,000 TPS	About 200,000 OPS (200,000 operations/second)
Order cost	Zero	High and unstable (gas fee)	Zero or extremely low
Order visibility	Private (visible only to the exchange)	Public (visible network-wide)	Configurable (short-term private/long-term public)
Matching mechanism	Continuous matching	Batch matching	High-frequency batch matching
Censorship resistance	Low	High	Medium
State-storage location	Centralized database	On-chain global state	Memory (short-term) + on-chain (long-term)

Table 7-9. A comparison of the key physical metrics of the three execution architectures (Note: "TPS" in the table refers to order-operation processing capacity, including operations such as order submission, cancellation, and matching, which differs from the transaction-level TPS of the underlying blockchain. The data for the application-chain DEX are the theoretical peak self-reported in official documentation, and sustained throughput under stress may be significantly lower than this value. The "censorship resistance: medium" rating is based on the following dimensions: the size of the validator set, the openness of the validator-admission mechanism, and whether users have a feasible alternative submission path when censored.) (Data source: compiled by the author)

Table 7-9 converts the qualitative comparison of the radar chart into concrete quantitative metrics. Most noteworthy is the order-of-magnitude difference: the CEX's latency is under 1 millisecond, whereas the fully on-chain DEX's latency may exceed 12 seconds—a gap spanning four orders of magnitude. This order-of-magnitude difference is not merely a matter of "fast versus slow"; it fundamentally determines the space of feasible order strategies under each architecture: the speed-sensitive high-frequency market-making and latency-arbitrage strategies that can be implemented at sub-millisecond latency lose essentially all economic viability at second-scale latency.

7.6.2 The order lifecycle

In traditional markets and on centralized exchanges, "good-til-canceled" is the most common order-lifecycle type. A trader can submit a GTC order, which will rest on the order book until it fills completely or the trader actively cancels it. The marginal cost of maintaining an order record in a centralized database is nearly zero, so there is no technical obstacle to implementing GTC.

In a blockchain environment, however, maintaining long-term on-chain state consumes costly storage resources. Every unfilled limit order occupies the disk space of full nodes, and if orders were allowed to exist permanently, the blockchain state would expand without limit, ultimately making node operating costs unbearable. Almost all on-chain order-book protocols have therefore abandoned GTC in its true sense, replacing it with order types that have a well-defined lifecycle.

The design of dYdX v4 provides a highly representative example. Its architecture explicitly distinguishes "short-term orders" from "stateful orders," which use starkly different mechanisms for lifecycle management [22]:

Short-term orders are aimed mainly at high-frequency market makers; their lifecycle is measured in block height, with a maximum survival time of only the current block height plus 20 blocks (about 20–30 seconds). Orders of this kind reside only in the validators' memory and are not written to on-chain state. If the network restarts or halts, these ephemeral orders are simply discarded. This feature introduces a noteworthy asymmetric risk in the chain-halt-and-restart scenario: short-term maker orders (a market maker's bid and ask quotes) are cleared on restart, while long-term stateful taker orders (such as stop-loss and take-profit orders) survive. If the external market price moved violently during the halt, the order book after restart will face a situation of severely insufficient depth while conditional orders can still be triggered—which may lead to a "restart flash crash" in which stop-loss orders fill at enormous slippage on an order book with almost no counterparty liquidity. Whether protocol designers should implement a cooling-off period or an auction-style reopening mechanism to mitigate this risk is a design question worth exploring in depth. This design appears "unreliable," but it is in fact a protective mechanism for market makers: after violent market volatility, stale market-making quotes that remain valid would expose the market maker to high adverse-selection risk. By letting orders expire automatically within an extremely short time, market makers can ensure that their quotes always reflect the latest market state.

Stateful orders are aimed at ordinary retail traders and institutional investors; their lifecycle is measured by timestamp (Good-Til-Time), with a maximum validity of up to 95 days. Orders of this kind are formally written to on-chain state and can be restored after a validator restart, ensuring the durability of long-term trading intent. Conditional orders (such as stop-loss and take-profit orders) also fall within the category of stateful orders.

> Core insight: the shift from GTC to GTT/GTB means that market makers can no longer "submit an order and then ignore its state" as on a CEX. They must develop dedicated infrastructure to continuously monitor the remaining lifecycle of on-chain orders and refresh them in time before expiry, which significantly increases strategic complexity and infrastructure cost.

Hyperliquid takes a more aggressive route. By virtue of the application chain's high throughput and lower state-management cost, Hyperliquid has once again made GTC viable in an on-chain environment, its design philosophy contrasting sharply with that of dYdX [14]. This difference itself reflects the different trade-offs that application-chain designers make between state-management cost and user experience.

Time-in-force type	Meaning	CEX support	Fully on-chain DEX	Application-chain DEX	Typical users
GTC	Valid permanently until filled or canceled	Standard	Generally unsupported	Partially supported	Retail traders, hedgers
GTB	Expires after a specified block height	Not applicable	Partially supported	Standard (short-term orders)	Market makers, high-frequency traders
GTBT	Expires after a specified timestamp	Not applicable	Partially supported	Standard (stateful orders)	Speculators, hedgers
IOC	Immediate-or-cancel	Standard	Complex to implement	Standard	Arbitrageurs
FOK	Fill-or-kill	Standard	Complex to implement	Standard	Arbitrageurs

Table 7-10. A comparison of how the time-in-force types are implemented across the different execution architectures (Data source: compiled by the author)

Table 7-10 reveals a key trend: the application-chain DEX has approached the completeness of the CEX in its support for time-in-force types, and the introduction of GTB and GTBT provides differentiated lifecycle-management tools for market makers and ordinary traders, respectively. The "complex to implement" label on IOC and FOK for the fully on-chain DEX, however, reveals a fundamental constraint: these two order types require immediate feedback (filled or canceled), and the consensus mechanism of a blockchain inherently cannot provide sub-second confirmation feedback—which constitutes a structural bottleneck in the functional completeness of the fully on-chain CLOB.

7.6.3 The order-cancellation mechanism

The semantics of the cancellation operation undergo a significant change in an on-chain environment. On a centralized exchange, cancellation is a free and instantaneous operation. High-frequency market makers frequently use the strategy of "placing large numbers of orders and quickly canceling them before they fill" to probe market liquidity and manage inventory risk. By some estimates, the cancel-to-fill ratio of market makers on top-tier CEXs typically exceeds 95% (this figure is a widely cited industry rule of thumb; the specific ratio varies significantly by trading pair, exchange, and time period—see the SEC's statistics on cancellation rates in the U.S. equity market and the publicly disclosed market-maker-activity reports of various exchanges), meaning that of every 100 orders submitted, more than 95 are ultimately canceled rather than filled.

In a fully on-chain architecture, however, cancellation is no longer free. Every cancellation instruction is an on-chain transaction that must be broadcast, queued, packed, and charged gas. During periods of Ethereum network congestion, the gas cost of canceling an order may be as high as tens or even hundreds of dollars. More seriously, because of the confirmation latency of on-chain transactions, there is a non-negligible time window

between the broadcast of a cancellation instruction and its ultimate effect. Within this window, the order the trader intended to cancel is still "active" and may be targeted for a fill by other traders (especially MEV searchers and arbitrage bots).

> The asymmetry of latency and cost in cancellation significantly weakens a market maker's ability to respond to adverse selection. This portion of extra risk is ultimately passed on to all liquidity consumers in the form of wider bid-ask spreads, becoming an implicit cost of on-chain trading.

To mitigate this problem, application-chain architectures adopt differentiated approaches. For short-term orders, dYdX v4 propagates cancellation instructions rapidly among validators via a gossip protocol, handling them on a "best-effort" basis [22]. This mechanism does not guarantee the absolute success of a cancellation (under network congestion or in the presence of a malicious validator, the cancellation instruction may fail to take effect in time), but it greatly reduces latency and cost, allowing market makers to adjust their quotes at a frequency close to that of a CEX. For stateful orders, cancellation still requires a formal on-chain transaction, but thanks to the application chain's high-frequency block production (such as Hyperliquid's 200-millisecond block time), the latency is compressed to within 1–2 blocks. Figure 7-16 uses a sequence diagram to compare the complete cancellation flow under the three architectures and the processing steps and time overhead of each stage.

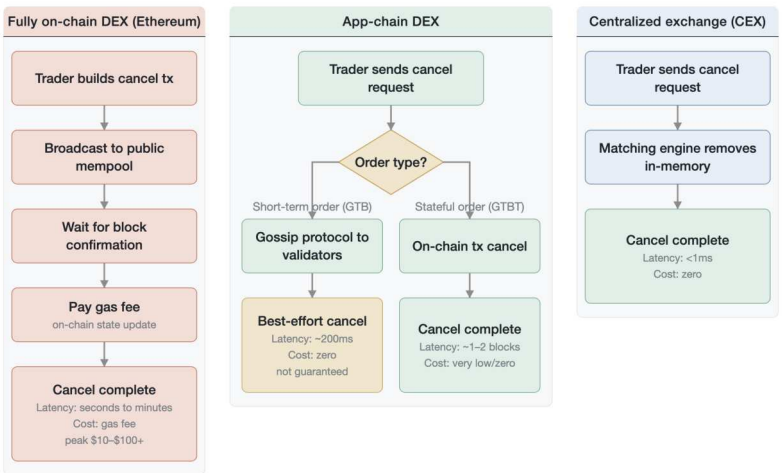

Figure 7-16. The evolution of the order-cancellation flow under the three execution architectures (cancellation-flow mechanism illustration, not empirical; the short-term-order gossip "best-effort" is per dYdX [22], and the fully on-chain gas of $10–$100+ is a peak-period magnitude)

Figure 7-16 shows the qualitative differences in the cancellation flow, and Figure 7-17 quantifies this difference along the two dimensions of latency and cost on a logarithmic scale (see the figure caption for specific magnitudes).

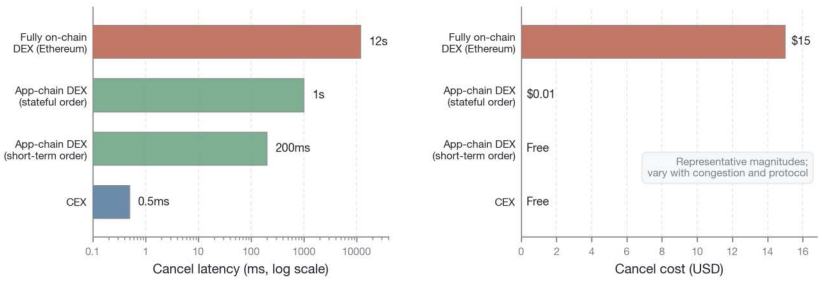

Figure 7-17. A quantitative comparison of cancellation latency and cancellation cost (representative-magnitude comparison illustration: 12s/$15, 1s/$0.01, 200ms/free, 0.5ms/free are order-of-magnitude representative values, not empirical; mapping to the text and to [22][14])

The quantitative comparison in Figure 7-17 reveals a conclusion with profound implications for market makers: on a fully on-chain DEX, the dual pressure of cancellation latency and cancellation cost makes the "place many orders, cancel quickly" style of market making common on a CEX all but infeasible. Although the application-chain DEX achieves a significant improvement on the latency dimension (compressing it from seconds to hundreds of milliseconds), it still lags the CEX's sub-millisecond level by two to three orders of magnitude. This gap directly dictates that on-chain market makers must use wider quote spreads and fewer quote layers to compensate for the structural disadvantage of being unable to cancel quickly.

7.6.4 Conditional-order triggering

The execution logic of conditional orders (such as stop-loss and take-profit orders) undergoes an important change in an on-chain environment. On a CEX, a conditional order is triggered directly by the internal matching engine according to the last traded price generated in real time, and the entire process from the price touching the trigger threshold to the order entering the matching queue completes at the microsecond level. In on-chain derivatives protocols, however, a smart contract cannot directly obtain external market prices, and the triggering of a conditional order generally relies on a price feed provided by an external oracle.

This reliance on the oracle introduces two key physical constraints: discontinuity and inherent latency.

Oracle price updates are discrete rather than continuous, and oracles differ fundamentally across execution architectures in their update frequency and mechanism. In DeFi protocols on general-purpose public chains, conditional orders typically rely on third-party oracle networks such as Chainlink. Chainlink, for example, generally pushes a new price only after the price deviation reaches a certain threshold (such as 0.5%) or a specific time interval elapses (such as the heartbeat period, which varies by feed and chain—for mainstream pairs on the Ethereum mainnet it is often about 1 hour, and for some it can reach 24 hours) [23]. This means that in a general-purpose-public-chain environment, the price changes the on-chain system perceives exhibit a pronounced stair-step character. Mainstream application-chain DEXs, however, adopt a starkly

different oracle architecture. dYdX v4 uses a custom oracle module: validator nodes aggregate price data from the APIs of multiple centralized exchanges and reach price consensus during the consensus process of each block, achieving one update per block (about 1–2 seconds). Hyperliquid runs an internal oracle network in which validators publish a price about once every 3 seconds (first taking a cross-exchange weighted median, then aggregating among validators by stake weight); although its update frequency is faster than that of third-party oracles on general-purpose public chains, it is still significantly slower than its roughly 200-millisecond block production. The update frequency of these custom high-frequency oracles is far higher than Chainlink's, so the conditional-order trigger latency of an application-chain DEX is far lower than that of a general-purpose-public-chain DeFi protocol. Chainlink's parameters (a 0.5% deviation threshold and a 1-minute heartbeat) apply only to describing DeFi protocols on general-purpose public chains and should not be generalized as the oracle characteristics of all on-chain derivatives platforms.

Despite the order-of-magnitude difference in oracle update frequency, all on-chain oracles face a more serious security threat: the oracle-manipulation attack. An attacker can use a flash loan to temporarily manipulate the price source on which the oracle relies within a single transaction, artificially creating an extreme price deviation and thereby triggering stop-losses and liquidations en masse. The Mango Markets incident of October 2022 is a representative case of this attack vector: the attacker manipulated the oracle price of Mango Markets, artificially inflating the price of the MNGO token and then using the fake collateral value to borrow protocol assets, causing a loss exceeding $110 million (over $110 million per the CFTC/DOJ figure; about $116 million per the SEC) [24]. In a perpetual futures system that relies on an oracle to trigger stop-losses and liquidations, a manipulated oracle price can trigger thousands of stop-losses and liquidations simultaneously, causing a catastrophic market impact. The main mitigations include: adopting a TWAP (time-weighted average price) oracle to smooth out instantaneous manipulation; aggregating multiple independent price sources and discarding outliers; and activating a circuit breaker when the price deviation exceeds a threshold, suspending liquidation and stop-loss triggering.

When the market swings violently, the compounding effect of discontinuity and latency may produce adverse consequences, but the severity varies by oracle architecture. In general-purpose-public-chain DeFi protocols, oracle update latency can reach seconds or even tens of seconds, and the lag in stop-loss triggering is especially pronounced. On application-chain DEXs, thanks to custom high-frequency oracles, the trigger latency is compressed to about 200 milliseconds to 1 second, but it still cannot be entirely eliminated. Consider a concrete scenario: with ETH at $2,000, a stop-loss order is set with a trigger price of $1,900. If the market plunges to $1,800 in an extremely short time, then on a general-purpose public chain the oracle may update only once, to $1,850, so the stop-loss triggers at $1,850, by which point the actual market price may already be far below $1,850; on an application chain such as Hyperliquid, the oracle updates at a second scale (about 3 seconds), still faster than the tens-of-seconds third-party oracles on general-purpose public chains, so the trigger lag is relatively small but not eliminated. Furthermore, after a conditional order is triggered, it generally must wait for the next block before it can enter the matching engine as a market order or

a limit order. On dYdX v4, conditional orders are checked and triggered during the EndBlocker stage of block processing (the final processing step of the current block), and the resulting market/limit order does not participate in matching until the next block—an inherent latency of at least one block from trigger to execution [22].

> In extreme conditions, the price may swing more than 5% within 1 second. A 1-second latency is enough to let a stop-loss order intended to cap a loss at 10% ultimately fill at a loss of 20% or more. This is an implicit risk that on-chain traders must understand and manage.

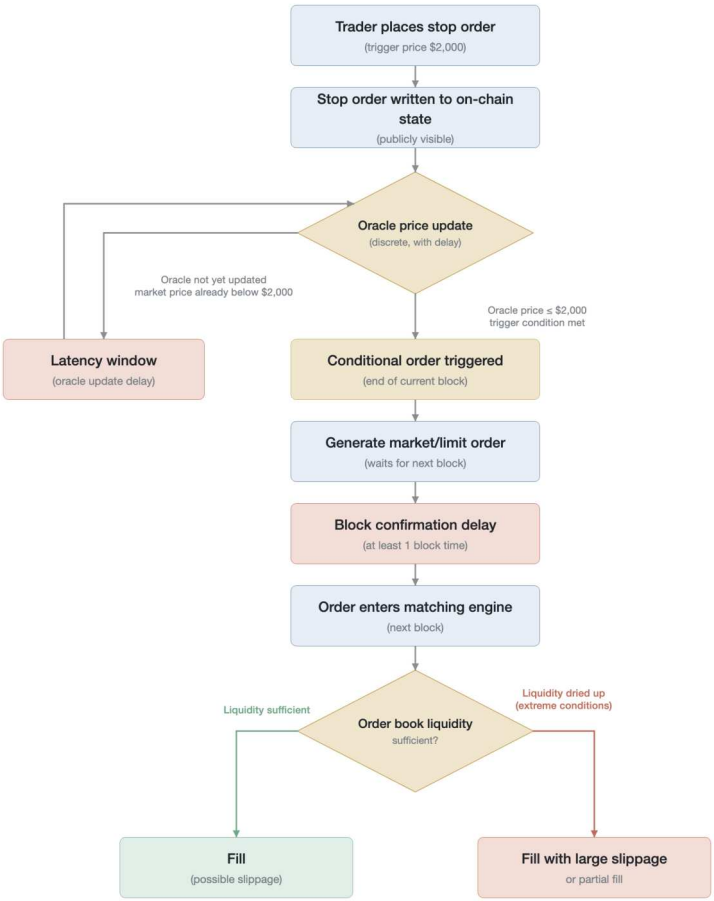

Figure 7-18. The trigger and execution path of an on-chain stop-loss order (on-chain stop-loss trigger-execution mechanism illustration: the $2,000 trigger price is an illustrative value, not empirical; the "at least 1 block" is per the dYdX EndBlocker [22]; the 5%/10%/20% slippage tiers are discussed in the text)

Figure 7-18 uses a timeline to show, in full, all the stages of an on-chain stop-loss order from dormancy to final fill. The time interval between each stage may introduce

slippage, and in extreme conditions the compounding of these intervals may cause a deviation of hundreds or even thousands of basis points between the final fill price and the trigger price.

7.6.5 The order-matching mechanism

On a centralized exchange, the matching engine uses a continuous-time limit-order-book model, matching orders at the instant they are received according to the "price priority, time priority" principle. Between two orders at the same price, the one that arrives a fraction of a microsecond earlier gains priority to fill. This continuous-matching mechanism updates the order-book state in real time as each new order arrives, and the price-discovery process appears as a smooth, continuous trajectory.

The discrete-time nature of blockchain fundamentally changes this matching paradigm. Because state updates proceed in units of blocks, the minimum time resolution is no longer the microsecond but the duration of one block. On the Ethereum mainnet this interval is about 12 seconds; on an application chain such as Hyperliquid, about 200 milliseconds. All orders arriving within the same block are treated as "submitted simultaneously" on the time dimension, and priority cannot be established by arrival time. Budish, Cramton, and Shim (2015) note that such discretization can, in theory, transform speed-based competition into price-based competition [25], and the block-time nature of blockchain bears a structural resemblance to that conception.

The matching implementations of current on-chain perpetual futures order books fall mainly into three modes, each representing a different response strategy to the discrete-block constraint.

dYdX v4 adopts a proposer-matching mode: the order-book state is maintained in the validators' memory, the matching process is completed off-chain by the proposer during the block-proposal stage, and the matching result is then submitted as part of the block to the other validators for consensus verification [22]. This design keeps the matching logic itself following the price-time priority principle, but the arrangement order of orders within a block is determined by the proposer rather than strictly fixed by arrival time.

Hyperliquid adopts a validator-embedded-matching mode: its validator nodes simultaneously play the role of the matching engine, orders enter the matching queue at sub-second latency after arriving at a validator, and through high-frequency block production (about 200 ms/block) and a first-in-first-out ordering rule, the matching behavior approaches the CEX's continuous model on the time-granularity dimension [14]. However, "first-in-first-out" is an ill-defined concept in a distributed system: when multiple validators receive orders submitted by different traders at nearly the same time, the definition of "arrived first" depends on the local timestamp of the leader validator (the block proposer) rather than on a globally verifiable objective order. In the absence of a verifiable ordering proof, the credibility of a FIFO claim ultimately depends on trust in the honest behavior of the current leader validator—which is no fundamentally different from the trust model of a CEX matching engine.

Injective adopts a frequent-batch-auction mode, whose design logic is fundamentally

different from the previous two. Within each block's time window (about 1 second), all submitted orders are sealed—neither disclosed publicly nor entered into a visible order book. At the end of the block, the protocol performs a uniform clearing of all crossing buy and sell orders within that window: the system computes a single clearing price that maximizes traded volume, and all filled orders execute at that price [26]. When the resting quantities of buyers and sellers at the clearing price are asymmetric, the smaller side fills in full and the larger side fills proportionally in part. This mechanism makes the submission order of orders irrelevant to the fill price, thereby transforming the competitive dimension from "who is faster" to "whose price is better," and eliminating at the protocol layer the economic basis for ordering- and speed-based front-running within a block (though cross-block and cross-venue informational front-running, and the potential peeking at sealed orders by validators, are not covered by this mechanism). The frequent-batch-auction theoretical framework proposed by Budish, Cramton, and Shim (2015) [25] is precisely the academic precursor of this design (a derivatives batch-auction mechanism is functionally equivalent to a traditional exchange's call auction and may, in jurisdictions such as the United States, trigger exchange-registration requirements and related compliance obligations). This theory originally targeted the high-frequency-trading arms race in equity markets, and its core assumptions do not necessarily hold in full in the crypto perpetual futures market; the boundaries of its applicability deserve attention when it is cited across domains. Specifically, the model of Budish et al. assumes the following conditions, all of which face challenges in the on-chain perpetual futures market: (1) homogeneous competition among a large number of market makers, whereas the number of active market makers on an on-chain DEX is in fact far smaller than on a traditional securities exchange; (2) discrete arrival of fundamental information through public news, whereas the information sources of the crypto market are dispersed and include the distinctive dimension of oracle latency; and (3) arbitrage activity occurring mainly among different trading venues for a homogeneous asset, whereas cross-chain arbitrage in the crypto market involves additional complexities such as bridging latency and settlement finality.

The three modes exhibit a gradient of difference in matching fairness. In the dYdX v4 architecture, because the block proposer has discretion over the ordering of transactions within a block, the execution order of orders within the same block is not fully deterministic, which affords the proposer a certain ordering advantage. Hyperliquid, by embedding the matching logic in the consensus-protocol layer and adopting a first-in-first-out rule, narrows this ordering-discretion space, but validators still have the ability to fine-tune the orders they receive. Injective's frequent batch auction, through its uniform clearing price and sealed-order mechanism, provides the strongest guarantee of ordering neutrality among the three, and the economic value of ordering power approaches zero under the uniform-clearing mechanism. The cost of this design is a sacrifice of matching time-granularity: traders cannot obtain immediate fill feedback within the auction window, and all orders must wait until the window closes to be processed uniformly.

Another layer of impact that discrete block time has on the matching mechanism is reflected in the order book's update frequency. On a CEX, every minute change in the order book can be observed in real time, and market makers can adjust their

quotes at the microsecond level. In an on-chain environment, however, the order-book state updates only at block boundaries, and between two blocks the order book is "frozen." This means on-chain market makers cannot precisely manage inventory risk and spreads through high-frequency fine-tuning as on a CEX, but must submit their quoting strategy all at once within each block window. This constraint directly affects the depth structure and spread levels of the on-chain order book, which the next chapter analyzes further from the perspective of order-book microstructure.

7.6.6 State-management constraints

The costly state-storage resource of blockchain imposes strict physical constraints on order-book design. On a CEX, a trader can maintain thousands of active limit orders simultaneously at no extra cost. In an on-chain environment, however, every active order occupies precious state space, and the scarcity of storage resources gives rise to a series of design limitations absent on a CEX.

The most direct constraint is a limit on the number of orders. To prevent state bloat and denial-of-service attacks, on-chain protocols must set clear boundaries on trader behavior. Paradex, for example, explicitly stipulates that each trader can maintain at most 100 unfilled resting orders in a single market [27]. On platforms with a higher market share, Hyperliquid sets an upper limit on the number of active orders per address in a single market (the specific value is dynamically adjusted by market and account tier), and dYdX v4 likewise sets an upper limit on the number of active orders per subaccount (typically on the order of hundreds). This hard limit forces market makers to manage their order flow more precisely, abandoning the strategy—common on a CEX—of densely posting orders across dozens of price levels, in favor of a more concentrated and efficient quoting approach.

In addition, the on-chain order book faces a distinctive "dust attack" threat. Usman (2025), in Hacken's security research, describes this attack vector in detail [28]: an attacker uses transactions of an extremely small amount (such as 1 wei, the smallest divisible unit) to partially fill a target order. Because the smart contract must perform complex rounding and state updates when handling a partial fill, this tiny fill may cause a variety of problems: loss of computational precision, invalidation of the remaining order amount when it falls below the minimum trade unit, or even—in a poorly designed protocol—the state of the original large order being erroneously marked as "completed," nullifying the limit-order provider's liquidity. The dust attack is merely the tip of the iceberg of the smart-contract security surface facing on-chain order books. Broader attack vectors also include: reentrancy attacks (repeatedly triggering state updates within an order-fill callback), integer overflow/underflow (producing unexpected results in high-precision price and quantity computations), and state-bloat denial-of-service (creating large numbers of tiny orders to push the contract's storage and computation costs beyond the gas limit). Protocol developers should consult the on-chain-order-book audit reports published by professional security-audit firms (such as Trail of Bits, OpenZeppelin, and Hacken) to systematically assess and defend against these attack surfaces.

To defend against attacks that exploit state-management vulnerabilities, protocol de-

velopers must introduce additional defensive mechanisms: mandating a minimum order size (such as $10 equivalent in tokens), setting a minimum fill ratio (such as at least 1% of the order's remaining amount), automatically zeroing out an order when its remaining amount falls below a specific threshold, or charging an extra processing fee for partial fills of extremely small amounts. This logic, added to adapt to the on-chain physical environment, further increases the complexity and audit difficulty of the smart contract.

> State bloat is the core challenge of the on-chain order book. All mitigations (order expiry, quantity caps, minimum size) weaken, to varying degrees, the competitiveness of the on-chain order book relative to the CEX. Application chains mitigate this problem through higher throughput and lower state cost, but cannot eliminate it entirely.

The table below summarizes the behavioral differences of the core order types across the three execution architectures, providing traders with an intuitive reference framework for choosing order strategies in different environments:

Order type/property	Centralized exchange	Fully on-chain DEX	Application-chain DEX
Limit-order lifecycle	GTC, valid permanently	Must use GTT/GTD	Short-term GTB / long-term GTBT or GTC
Limit-order cancellation	Instant and free	Requires sending a transaction, paying gas, awaiting confirmation	Short-term best-effort free / long-term requires an on-chain transaction
Market order	Instant fill, low slippage	High slippage + MEV sandwich risk	Medium slippage, lower MEV risk
Post-Only	Standard support	Requires smart-contract logic checks	Standard support
IOC	Standard support	Complex to implement, high gas cost	Standard support
FOK	Standard support	Complex to implement	Standard support
Stop-loss market order	Based on internal fill price, instant trigger	Based on oracle, at least 1-block latency	Based on oracle, at least 1-block latency
Trailing stop	Standard support	Extremely complex to implement, generally unsupported	Partially supported
TWAP	Via API or third-party tools	Generally unsupported	Some native support
Iceberg order	Standard support	On-chain transparency renders it ineffective	Possibly supported (depends on the order-visibility design)
Maximum active orders	No practical limit	Constrained by gas and state storage	Clear upper limit (such as 100 per market)

Table 7-11. The behavioral differences of the core order types across the three execution architectures (Data source: compiled by the author)

The core conclusion of Table 7-11 is that the application-chain DEX has approached the functional completeness of the CEX for the vast majority of order types, but a

gap remains in advanced functions such as trailing stops, TWAP, and iceberg orders. Constrained by gas cost and state-storage limits, the fully on-chain DEX has difficulty implementing order types that require immediate feedback, such as IOC and FOK. This functional difference directly affects the platform choices of different types of traders: high-frequency market makers tend toward the application-chain DEX, whereas traders with a strict need for censorship resistance may still have to choose a fully on-chain protocol.

7.7 The order strategies of market participants

Orders do not exist as isolated technical instructions; they are the tools with which different market participants express intent, compete for advantage, and manage risk within a shared trading grammar. In the ecosystem of the decentralized perpetual futures market, market makers, arbitrageurs, speculators, hedgers, and liquidators each play a key role, bear different risks, and pursue different return objectives. The impact of an order radiates outward along four dimensions: funding-rate transmission, the liquidation chain, microstructure signals, and on-chain MEV risk exposure. Understanding the order preferences of different participants not only helps illuminate the operating mechanics of market microstructure but also makes it possible to infer, in reverse, the current market state and the dominant forces.

This section analyzes the characteristics of five core classes of market participant, examines how they use different order types and strategies to achieve their business objectives, and finally shows how the dominant participants in a market can be identified through order-flow analysis.

7.7.1 The order strategies of market makers

Market makers are the primary providers of liquidity on decentralized exchanges and a core component of order-book depth and market continuity. Their core business model is to earn the bid-ask spread and the liquidity incentives provided by the exchange (such as maker-fee rebates or token rewards) by simultaneously providing quotes on both the bid and ask sides. Because market makers generally remain market-neutral and do not actively take directional risk, their order strategies depend heavily on low latency and the ability to adjust at high frequency.

In an on-chain environment, a market maker's most core tools are the limit order (especially with the Post-Only attribute) and the short-term order. The Post-Only attribute (see Section 7.3.3) is decisive for market makers: it not only guarantees that they always enjoy the maker-side fee benefit (on many DEXs the maker fee is zero or even negative) but also avoids the unexpected slippage that arises when a rapid market price movement causes a limit order to "cross" and become a market order.

Market makers densely place limit orders at multiple price levels on the order book, forming a multilayered quote structure to build market depth. When the net position deviates from neutral, a market maker widens the spread on one side, thickens the resting orders on the other side, or uses small aggressive orders to return quickly to neutral. To cope with rapid market-price fluctuations, market makers need to cancel

old orders and place new ones frequently. As discussed in the previous section, on DEXs with an application-chain architecture (such as dYdX v4), market makers make heavy use of short-term orders that expire based on block height [22]. Such orders exist only in memory and expire automatically within tens of seconds, significantly reducing the risk of "stale orders being targeted for attack" due to network latency or congestion.

In the perpetual futures market, market makers also face a distinctive dual inventory risk: not only the directional risk from movements in the underlying asset's price but also the position-carrying-cost risk from the funding rate. If a market maker holds a large long position and the current funding rate is negative (longs pay shorts), the continuously paid funding will erode market-making profit. A more common practice, therefore, is "perpetual market-making + spot hedging"—providing liquidity in the perpetual futures market while establishing an opposite-direction position in the spot market, thereby isolating directional risk. This hedging strategy, however, faces several non-negligible execution risks in practice. The first is basis risk: the basis between the perpetual futures price and the spot price fluctuates continuously, so the hedge is not perfect. The second is cross-platform margin lock-up: when the perpetual leg is in profit while the spot leg is at a loss (or vice versa), the funds on the profitable leg cannot be reallocated in real time to the losing leg to top up margin, potentially causing one leg's position to be liquidated while the "hedge" on the other leg fails. Most serious is the operational risk during a crisis: an exchange outage, a withdrawal delay, or a cross-chain-bridge failure may prevent the spot-leg position from being adjusted in time, leaving the perpetual position unprotected at precisely the moment hedging protection is most needed. In addition, market makers make wide use of algorithmic strategies such as time-weighted average price or iceberg orders, splitting large liquidity into multiple small orders to hide their true position intent.

7.7.2 The order strategies of arbitrageurs

Arbitrageurs are a key force maintaining cross-market price consistency, playing the role of "price calibrator" in market microstructure. By capturing minute price differences of the same asset across different exchanges (such as between a CEX and a DEX, or between different DEXs), they buy low and sell high to obtain risk-free or low-risk profit. Arbitrage opportunities are typically fleeting, so speed and execution certainty are the arbitrageur's core requirements.

An arbitrageur's preferred tools are the market order and limit orders with the immediate-or-cancel or fill-or-kill attribute. The market order offers the strongest fill certainty: regardless of the current order-book state, a market order immediately takes the available liquidity. An IOC order takes the liquidity within the fillable depth and then automatically cancels the unfilled remainder, avoiding the one-sided-exposure risk the arbitrageur would face if one leg fills while the other does not. An FOK order is stricter, requiring the order to fill in full or else cancel entirely, guaranteeing the atomicity of the arbitrage strategy.

In the perpetual futures market, arbitrageurs enjoy a rich variety of opportunity sources: basis arbitrage between perpetual futures and spot, cross-exchange price-difference arbitrage, and a cross-chain combination of price-difference and funding-rate-difference

arbitrage. When an arbitrage bot detects that the price on an on-chain DEX lags that on a CEX, it immediately sends an IOC order to the DEX. If network latency means the price has already moved unfavorably by the time the order arrives, the IOC attribute ensures that the portion unable to fill immediately is automatically canceled, preventing a failed arbitrage from turning into one-sided exposure.

The on-chain environment, however, has rewritten the arbitrageur's profit model. Gas cost becomes a non-negligible fixed cost: every arbitrage transaction incurs a gas fee, which means only arbitrage opportunities whose price gap exceeds the gas cost are worth executing. More seriously, MEV front-running may cause an arbitrageur to pay gas yet fail to fill, or to fill after the price has already been pushed to a worse level. On-chain arbitrageurs are therefore increasingly turning to private transaction channels to protect their arbitrage intent. The two must be distinguished. MEV-protection infrastructure on Ethereum (such as Flashbots Protect and MEV-Share) applies only to Ethereum and its Layer 2 ecosystem, and its trust model is built on the competitive mechanism of the block-builder market. On application-chain DEXs (such as Hyperliquid and dYdX v4), the relevant MEV-protection mechanisms are the validator private mempool and protocol-level deterministic ordering, whose trust model is entirely different, relying on trust in the honest behavior of a small number of validators rather than on market competition (see the detailed analysis in Section 7.5.4). Conflating the two would mislead practitioners.

7.7.3 The order strategies of speculators

Speculators, often called directional traders or retail traders, are the primary contributors of market volatility and trading volume. Based on analysis of market fundamentals, technicals, or macroeconomic events, they actively take directional risk in the hope of obtaining leveraged gains from a price rise or fall. Speculators are the most active and diverse group of participants, and their core constraints include not only structural factors (informational disadvantage, slippage cost, the chain effect of stop-loss triggering, and on-chain MEV exposure) but also behavioral factors: revenge trading (rushing to "win it back" after a loss by increasing position size and leverage), FOMO-driven chasing (buying in with a market order during a sharp price surge for fear of missing out), and the endowment-effect-driven refusal to close losing positions (treating an "unrealized loss" as a "loss not yet confirmed" rather than an economic loss that has already occurred). These behavioral biases systematically undermine the speculator's risk-management discipline.

The order strategies of speculators are the most varied, but their core demands can be summarized in two keywords: "entry" and "risk control." To capture market trends quickly, speculators frequently use market orders to take liquidity directly (as takers). Mature speculators, however, are more inclined to use conditional orders—especially stop-loss and take-profit orders—to achieve automated risk management.

In on-chain perpetual futures trading, because they cannot monitor the market 24 hours a day, speculators rely heavily on stateful conditional orders to protect their leveraged positions. For example, when going long on Ethereum, a speculator simultaneously sets a stop-loss order with a trigger price below the current market price. Once the

oracle price falls below that threshold, the stop-loss order is activated and converts into a market order, forcibly closing the position to prevent losses from widening. This "set-and-forget" strategy is generally implemented on an application-chain DEX through a months-long GTBT stateful order.

The special risks speculators face in an on-chain environment cannot be ignored. They are the primary source of MEV's "extractable-value order flow": their market orders and trigger orders are visible on-chain and more easily fall prey to sandwich attacks. The final fill price of an on-chain market order depends not only on order-book depth but also on the outcome of the game among MEV bots in the same block. Typical countermeasures include: using MEV-resistant routing (such as submitting transactions through a private mempool), setting reasonable slippage-protection parameters, and choosing an application-chain DEX with a protocol-level MEV-protection mechanism.

7.7.4 The order strategies of hedgers

Hedgers participate in the perpetual futures market not to obtain absolute returns but to transfer or hedge their risk exposure in the spot market or other lines of business. Typical hedgers include miners (hedging the price risk of mining revenue), token project teams (hedging the value volatility of treasury assets), cross-chain-bridge operators (hedging the exchange-rate risk of liquidity pools), and institutional investors holding large spot positions.

Hedgers typically trade in large sizes and are highly sensitive to the execution price but have relatively low requirements for execution speed. Hedgers therefore rarely use market orders to strike the order book directly, because a large market order would produce considerable market impact and slippage. Instead, they are more inclined to use limit orders (GTC or GTBT) and algorithmic orders (such as TWAP and VWAP).

By splitting a large hedging need into smaller child orders and executing them gradually over a longer time window, a hedger can minimize the impact of their trading on the market price. The splitting logic of TWAP and VWAP was detailed in Section 7.3.4 (the former splits evenly by time, the latter weights by the historical volume distribution) and is not repeated here.

In the perpetual futures market, the two most common structures for hedgers are: spot long + perpetual short (the standard hedging structure for miners and institutions) and the funding-rate trade (when the funding rate is high, shorting perpetual futures while going long spot to earn the rate differential). In addition, the Reduce-Only attribute is especially important for hedgers: it ensures that an order can only reduce an existing position and will not accidentally increase speculative exposure, preventing the creation of new risk exposure due to an operational error when adjusting the hedge ratio.

7.7.5 The order strategies of liquidators

Liquidators (or the liquidation mechanism) are key participants in the decentralized leveraged-trading ecosystem and the core executor of the solvency-safeguard mechanism. When a trader's margin ratio falls below the maintenance-margin requirement, the liquidation mechanism forcibly takes over and closes the defaulting position, thereby

protecting the protocol from bad-debt risk. The liquidation architecture of current on-chain derivatives protocols, however, comes in two starkly different modes that must be distinguished.

The first is the external-liquidator-competition mode, seen mainly in DeFi lending protocols (such as Aave and Compound) and early derivatives protocols (such as dYdX v3). In this mode, liquidators are independent third-party participants who must monitor the health factor of all on-chain accounts in real time and, the moment they find an account whose margin ratio has fallen below the liquidation threshold, call the protocol's liquidation function as fast as possible. This liquidation operation is, in effect, equivalent to a forced market order. In return, the liquidator generally receives a portion of the liquidation penalty as a profit incentive. The behavioral pattern of liquidators closely resembles that of arbitrageurs: both are highly time-sensitive participants who pursue execution certainty.

The second is the protocol-built-in-liquidation-engine mode, adopted by current mainstream application-chain DEXs. Hyperliquid uses an internal liquidation engine: when an account's margin ratio falls below the threshold, the protocol automatically assigns the defaulting position to a backstop liquidity pool for handling, without the participation of external liquidators bidding. dYdX v4's liquidation is likewise executed automatically by the protocol during block processing: validators check the margin status of all accounts during each block's EndBlocker stage and automatically initiate liquidation for accounts that fail to meet the maintenance-margin requirement. In this mode, the concept of the "liquidator" is internalized as the protocol's automated risk-management module rather than an external competitor.

Among protocols on general-purpose public chains that use the external-liquidator-competition mode (such as Ethereum-based DeFi lending protocols), competition among liquidators is especially fierce during violent volatility. Large numbers of accounts hit their liquidation lines simultaneously, and liquidation opportunities emerge and vanish within an extremely short time. To be the first to complete a liquidation, liquidators participate in MEV bidding, raising the gas fee to ensure their liquidation instruction is packed first. On Ethereum, the competition mainly takes the form of fierce gas bidding; on high-throughput chains such as Solana, it takes the form more of a latency race and infrastructure competition. On application-chain DEXs that use a protocol-built-in liquidation engine, the liquidation process is executed automatically by the protocol, eliminating competition and gas bidding among external liquidators; but its processing capacity may face a throughput bottleneck in extreme conditions: when the number of accounts that need liquidation within a single block exceeds the engine's processing limit, some liquidations may be deferred to subsequent blocks.

Whatever liquidation architecture is used, forced liquidation raises several unresolved legal issues. Under the consumer-protection framework of traditional finance, forced position closure generally requires specific contractual authorization, prior notice, and a grace period. The automated liquidation of on-chain protocols lacks a notice mechanism and a grace period, and the fairness of the liquidation penalty likewise lacks regulatory review. As frameworks such as MiCA gradually bring crypto-asset service providers within the scope of consumer-protection obligations, the legal status of forced

liquidation (including the boundary of the protocol's fiduciary duty to users and the reasonableness of the liquidation penalty) is becoming a frontier topic in regulatory discussion.

7.7.6 Participant identification based on order flow

In a fully transparent on-chain order book, the behavioral patterns of different participants leave clear and traceable digital footprints. Unlike the opaque environment of a CEX, the on-chain environment allows anyone to infer the current market's dominant participants and their intent by analyzing the characteristics of the order flow. This analytical capability is a distinctive advantage brought by the transparency of on-chain finance.

Through a combined analysis of the type, survival time, cancellation frequency, and fill pattern of orders, as well as their correlation with market-price movements, the following typical behavioral patterns can be identified:

- Market-maker activity signal: a dense, symmetric distribution of limit orders paired with an extremely high cancellation rate and frequent two-sided quoting generally means that market makers are actively providing liquidity and that the market is in a relatively stable state.
- Arbitrageur execution signal: a large order sweeping through multiple price levels at once, appearing simultaneously in opposite directions across two markets, is generally the signal of an arbitrageur executing a two-leg hedge strategy.
- Retail activity signal: a continuous inflow of small market orders suggests that the activity of retail speculators is rising.
- Event-driven shock: the sudden appearance of a large market order eating through several price levels is generally related to a major news event or a large on-chain liquidation.
- Stop-loss cascade signal: successive market impacts as stops are triggered reflect the coupling effect between the speculators' stop-loss chain and the liquidation engine.
- Risk-perception signal: a sudden widening of the bid-ask spread means that market makers have perceived an increase in risk and adjusted their quotes accordingly.
- Institutional execution signal: slow, tranched filling over a long period is a typical feature of a hedger or institution using an algorithm such as TWAP to execute a large order.

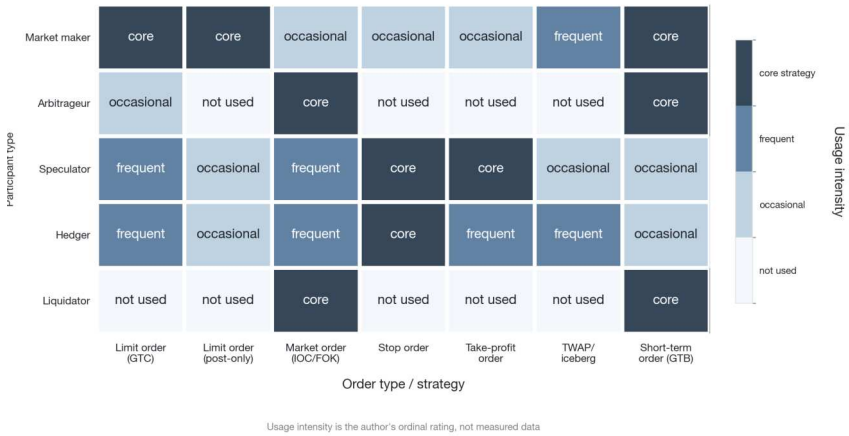

Figure 7-19. A heatmap of the order-strategy usage of different market participants (author's qualitative rating heatmap; "not used/occasionally/frequently/core" reflect the author's judgment, not empirical data; consistent with Table 7-12)

As Figure 7-19 shows: market makers' orders are highly concentrated in Post-Only limit orders and short-term orders; arbitrageurs concentrate on IOC and FOK (reflecting a need for execution atomicity); speculators' tool usage is the most dispersed (covering market orders, stop-loss orders, take-profit orders, and more, reflecting both strategic diversity and an emphasis on risk management); and liquidators concentrate on the equivalent of market orders and short-term trigger orders, reflecting their passive execution mode driven by protocol rules.

Table 7-12 systematically summarizes the order strategies of the five classes of participant along five dimensions: core objective, typical order types, reason for preference, main risks, and on-chain-specific countermeasures:

Participant	Core objective	Typical order types	Reason for preference	Main risks and costs	On-chain-specific countermeasures
Market maker	Earn the spread and maker rebates	Post-Only limit orders, layered quoting, short-term orders	Ensure maker status, build multilayered depth	Adverse selection, inventory skew, cancellation-latency cost	Widen spreads, shorten order lifespan, perpetual + spot hedging
Arbitrageur	Capture risk-free spreads	Market orders, IOC, FOK	Ensure fill certainty and two-leg consistency	Slippage, naked single leg from an unfilled order	Account for gas and MEV costs, use private transaction channels
Speculator	Directional leveraged returns	Market orders, stop-loss orders, take-profit orders, trailing stops	Quickly express a directional view and manage risk	Sandwich attacks, stop-loss cascades, slippage amplification	MEV-resistant routing, reasonable slippage protection, choose application-chain DEXs
Hedger	Reduce portfolio risk exposure	Limit orders, TWAP, VWAP, Reduce-Only	Reduce market impact and prevent operational errors	Long execution cycle, missing the optimal timing	Tranched execution, cross-market hedging, funding-rate trades
Liquidator	Obtain liquidation rewards	Liquidation-function calls (equivalent to market orders), IOC	Driven by system rules, seizing execution priority	Gas cost of losing the competition, on-chain congestion	Gas bidding, latency racing, private liquidation channels

Table 7-12. A comparison matrix of the order strategies of the five classes of market participant (Data source: constructed by the author)

By understanding "who says what with which tool," we can better understand the microstructure behind the decentralized perpetual futures market. Each class of participant's order choice is not random but a rational trade-off around cost, certainty, and risk exposure under their specific constraints. In the decentralized derivatives market, every order instruction is not only a carrier of value transfer but also a direct expression of each party's interests and strategic maneuvering. A systematic analysis of order flow not only helps traders devise more targeted counter-strategies but also provides important data support for DEX protocols to optimize their fee structures, improve their matching mechanisms, and guard against malicious attacks.

7.8 A three-dimensional framework for risk analysis

In the crypto derivatives market, the risk and cost of an order are not static attributes but dynamic variables determined by the execution environment. As discussed earlier, the slippage of a simple market order may differ by hundreds of times between a normal market and an extreme crisis, and the MEV risk it faces differs starkly between a centralized exchange and a fully on-chain decentralized exchange. To comprehensively assess the potential risks in trade execution, we need to go beyond single-dimensional consideration. This section integrates the three dimensions of order type, market state, and execution architecture into a unified analytical framework, providing traders with a practical tool for decision-making in complex market environments.

7.8.1 Defining the three dimensions

The formation of trading risk is a multivariable, interactive process. In this three-dimensional analytical framework, each dimension represents a major driver of risk, and the cross-combination of the three determines the ultimate risk level.

Dimension one: order type (microstructure role). The order type determines the role the trader plays in market microstructure: the limit order, as a liquidity provider, has as its core risks adverse selection and execution uncertainty—just as Copeland and Galai (1983) argued that "a limit order is equivalent to giving the market a free option" [4] (the full mechanism of this causality appears in Section 7.1.3); the market order, as a consumer, mainly bears market-impact cost and slippage risk; and the stop-loss market order is the most distinctive, as it may encounter a liquidity vacuum when triggered and even become a catalyst for a liquidation cascade (see Section 7.2).

Dimension two: market state (macro liquidity environment). The market state reflects the macro liquidity environment and is generally divided into three types—normal, high-volatility, and extreme-crisis: under a normal state, order-book depth is ample and spreads are tight; as the state evolves toward high volatility and then extreme crisis, liquidity becomes thin and fragile, and risk exhibits nonlinear, more-than-proportional amplification. As cited in Section 7.1.4, Kaiko Research (2025) measured that under extreme conditions order-book depth plunged by more than 90% and market-order slippage spiked from a few basis points to 5% or even 10% [10].

Dimension three: execution architecture (underlying infrastructure). The differences in execution architecture determine the transmission path and ultimate impact of risk: the CEX has extremely low latency (sub-millisecond) and zero order cost, but its opacity may conceal counterparty risk; the fully on-chain protocol has the highest transparency and censorship resistance, yet faces significant MEV risk due to high gas costs, slow block confirmation, and a public mempool; and the application-chain DEX (such as Hyperliquid and dYdX v4) seeks a balance between the two through a sovereign, customized blockchain [21] (the full comparison of the three architectures appears in Section 7.6.1).

These three dimensions together constitute a three-dimensional risk space, as shown in Figure 7-20. In this three-dimensional coordinate system, the X-axis is the order type, the Y-axis is the market state, and the Z-axis is the execution architecture, and

any order can be located by its three-axis coordinate to determine its risk level. The color gradient in the figure indicates that risk does not grow linearly as the coordinate moves, but may exhibit a more-than-proportional amplification effect when all three dimensions trend toward the extreme simultaneously. Two caveats apply. First, the "more-than-proportional" pattern rests mainly on the slippage-depth pairing observed in a few extreme events such as October 2025; it still lacks a linear-superposition baseline rigorously defined within the framework, so it should be treated as an empirical observation awaiting testing against more cross-event evidence rather than a proven law. Second, the three dimensions are not fully orthogonal—the execution architecture already endogenizes most of the risk drivers of order type and market state, so the framework more closely resembles a hierarchical structure of "architecture as the main factor, with order type and market state as moderating factors," and the three-dimensional coordinate system is merely an approximation for ease of visualization. For example, the risk level of a stop-loss market order executed through a fully on-chain DEX in an extreme crisis far exceeds the simple sum of the three single-dimensional risks.

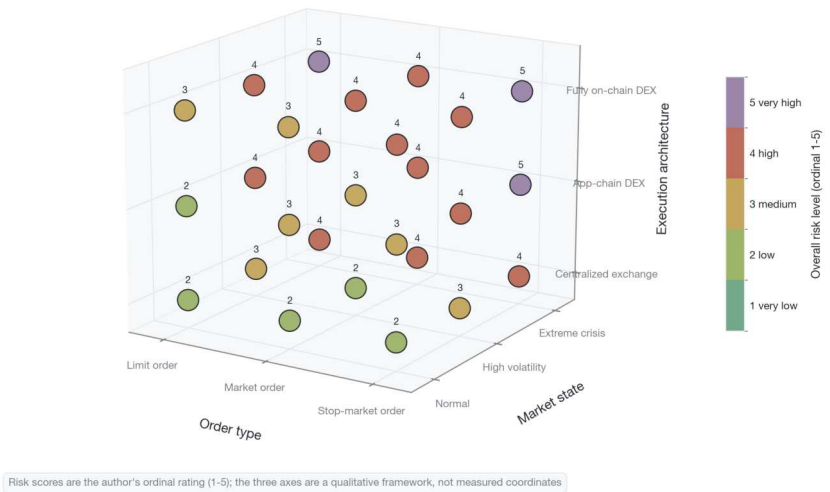

Figure 7-20. A three-dimensional analytical framework for trading risk (author's composite risk-rating 3D scatter; the ordinal 1–5 reflects the author's composite judgment, not empirical data; sources: Ali 2025 [9], Copeland & Galai 1983 [4], EigenPhi [19], dYdX Foundation [21][22])

7.8.2 Applying the three-dimensional risk matrix

To show more intuitively how these three dimensions interact and affect the ultimate execution risk, we can map the three-dimensional space onto a concrete risk matrix. Table 7-13 details the specific risk characteristics that different order types face under various market states and execution architectures.

Order type	Market state	Centralized exchange	Fully on-chain DEX	Application-chain DEX
Limit order	Normal	Low adverse-selection risk	Medium adverse-selection risk	Low-to-medium adverse-selection risk
	High volatility	High adverse-selection risk	Very high adverse selection + costly cancellation	High adverse selection + cancellation latency
	Extreme crisis	Order may fail to fill	Fails to fill + cancellation fails due to network congestion	May fail to fill
Market order	Normal	Low slippage	Medium slippage + potential MEV risk	Low-to-medium slippage, lower MEV risk
	High volatility	Medium slippage	High slippage + high MEV exposure	Medium slippage
	Extreme crisis	Very high slippage	Extreme slippage	High slippage
Stop-loss market order	Normal	Low trigger slippage	Medium trigger slippage + oracle latency	Low-to-medium + oracle latency
	High volatility	Medium trigger slippage	High trigger slippage + oracle latency	Medium + oracle latency
	Extreme crisis	High trigger slippage + may cause a cascade	Extreme slippage + risk of trigger failure	High trigger slippage + may cause a cascade

Table 7-13. The three-dimensional risk matrix from the user's perspective (Note: order-of-magnitude reference for the qualitative risk levels in the table: "low slippage": <10 bps; "medium slippage": 10–50 bps; "high slippage": 50–200 bps; "very high/extreme slippage": >200 bps. "Low adverse-selection risk": market-maker spread <5 bps; "high adverse-selection risk": spread widening to >20 bps. These values are the typical order of magnitude for mainstream trading pairs under the corresponding market state; the specific values vary by underlying, time period, and platform.) (Data source: compiled by the author)

Analyzing this matrix, we can identify several key regularities.

Under a normal market state, the CEX has a clear advantage in execution efficiency and cost, especially for market orders and stop-loss orders, whose low slippage and instant triggering are difficult for on-chain protocols to match. On a fully on-chain DEX, however, even in the normal state, a market order must bear medium slippage and potential MEV risk, and a limit order must pay a gas fee when canceled. The application-chain DEX performs close to the CEX in the normal state, but oracle latency remains an inherent constraint on conditional-order triggering.

When the market enters a high-volatility state, the risk exposure of on-chain protocols increases sharply. High cancellation costs and network congestion make it difficult for market makers to adjust their quotes quickly, resulting in very high adverse-selection

risk. At the same time, MEV searchers are more active in this environment, and market orders face a very high probability of being sandwich-attacked. The application-chain DEX shows a degree of resilience in this state: its lower cancellation cost and faster confirmation speed mitigate these risks to some extent, but it still cannot entirely eliminate the stop-loss-triggering lag caused by oracle latency.

Most noteworthy is the performance under an extreme-crisis state. At this point, all execution architectures face challenges, but the form the risk takes differs. On a CEX, the slippage of a market order may reach a very high level, and the mass triggering of stop-loss orders may become a catalyst for a liquidation cascade—precisely the concrete manifestation of the procyclicality of cross-margin in the October 2025 liquidation cascade described by Ali (2025) [9]. On a fully on-chain DEX, the situation can become extremely severe: a market order may face enormous slippage, and a stop-loss order, owing to oracle-update latency and network congestion, may even face the risk of trigger failure. This nonlinear widening of the "intent-execution gap" during a crisis is a systemic risk that traders must fully recognize. Especially worth guarding against is the correlated failure mode in which all protective layers fail simultaneously: in an extreme crisis, a stop-loss order fails to fill at an acceptable price because of a liquidity vacuum, the liquidation engine is delayed because its processing queue is overloaded, and the oracle price feed lags the actual market price because of latency in the underlying data source itself. When these three lines of defense fail at once, a trader's position can persist at a level far beyond the liquidation price, producing bad debt that exceeds the margin. At this point the insurance fund is called upon to absorb the bad debt; and if the insurance fund is exhausted, the protocol generally activates the auto-deleveraging (ADL) mechanism, forcibly closing the corresponding positions of the profitable side to digest the loss. This comprehensive failure of defense-in-depth is rare, but it is precisely the extreme tail scenario that systemic-risk assessment must consider.

7.8.3 Practical implications for risk management

The three-dimensional risk framework is not merely a theoretical model; it can also provide concrete guidance for a trader's actual operations. Based on the analysis above, we can draw the following practical implications for risk management.

There is no universally "optimal" execution architecture, only the architecture "best suited" to a specific scenario. Traders should choose an execution platform according to their own strategic needs, order size, and tolerance for different types of risk. Under a normal market environment, a high-frequency trader pursuing extremely low slippage may lean toward a CEX; whereas for a trader who highly values self-custody of funds and censorship resistance, a fully on-chain protocol is the preferred choice. The application-chain DEX offers a highly attractive option for those traders who wish to find a compromise among speed, cost, and decentralization. This judgment echoes the core argument of Chapter 5 regarding the "impossible trinity": every architecture choice is a specific trade-off among performance, decentralization, and security.

One must recognize the nonlinear character of risk growth. As discussed in Section 7.8.1, from a normal market to high volatility and then to extreme crisis, slippage and adverse-selection risk amplify nonlinearly and more than proportionally, rather

than increasing proportionally. When devising a strategy, therefore, a trader cannot backtest based only on normal-market parameters but must incorporate the nonlinear risk under extreme conditions. As discussed in Chapter 1 with the concept of "risk-surface transformation," high-frequency variable shocks are the theoretical basis for the nonlinear amplification of risk.

At the operational level, the following principles deserve special attention. For large trades, whatever platform they are executed on, it is strongly recommended to use algorithmic orders such as time-weighted average price or volume-weighted average price for splitting, so as to effectively reduce market impact and signal leakage. Stop-loss orders must be used with extreme care; never "set and forget." When using stop-loss orders in an on-chain environment, one must fully understand the inherent lag brought by oracle latency and block confirmation. Traders should treat MEV loss as an implicit trading cost and include it when assessing a strategy's profit and loss. By diversifying asset allocation across the CEX and on-chain protocols, one can simultaneously hedge the trust risk of centralized platforms and the technical risk of decentralized protocols, achieving more robust overall risk management. However, the diversification strategy itself also introduces new risks: cross-platform rebalancing operations carry latency (especially during a crisis, when cross-chain transfers and exchange withdrawals may lag severely), capital efficiency declines because funds are dispersed, and in extreme conditions multiple platforms may experience liquidity depletion or technical failure simultaneously, weakening the expected protective effect of diversification.

The three-dimensional framework above analyzes the static risk characteristics of a single order in a specific environment. In an actual market, however, risk evolves dynamically: thousands upon thousands of orders pour into the market as a continuous flow, and the orders of different participants intertwine, superimpose, and hedge one another. To understand this dynamic process, one must rise from the static analysis of a single order to the dynamic examination of order flow.

7.9 Order-flow analysis

If a single order is a "word" in the language of trading, then a continuous order flow is a sequence composed of these orders. The information content of order flow and its compositional structure fundamentally determine a market's price-discovery efficiency, the quality of its liquidity, and the distribution of profit among different participants. This section transitions from the static analysis of a single order to the dynamic examination of order flow, establishing a conceptual bridge to understanding the market's information ecosystem and laying the groundwork for the next chapter's discussion of the order book that order flow aggregates into.

7.9.1 The composition of order flow

The order flow in a market is not a homogeneous whole but a composite structure formed by the confluence of different sources. Each source represents the trading intent of a specific participant, carries a different type of information, and produces a distinctive impact on market microstructure. We can classify these order flows into

four main types, as shown in Figure 7-21.

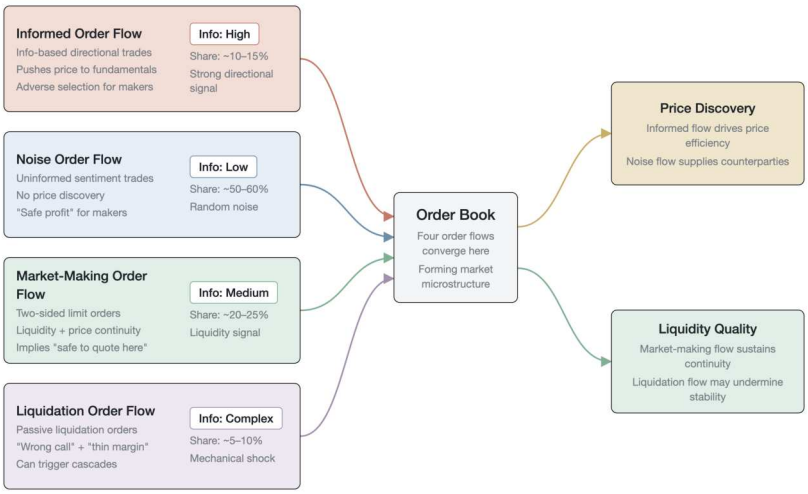

Figure 7-21. The four sources of order flow and their information content (illustration of the information content of the four classes of order flow: the shares of about 10–15% / 50–60% / 20–25% / 5–10% are the author's order-of-magnitude estimates, not empirical, and are affected by the macro cycle; per Easley et al. 2012 VPIN [29], Copeland & Galai 1983 [4], Ali 2025 [9])

Figure 7-21 divides order flow into four classes—informed, noise, market-making, and liquidation—in descending order of information content; the characteristics of each are analyzed in turn below.

Informed order flow is initiated by traders who possess information not yet fully priced into the market. These traders make directional bets based on their informational advantage, and their order flow has extremely high information content. The PIN/VPIN literature of market microstructure (Easley et al.) estimates that in a typical mature market, informed order flow accounts for about 10% to 15% of total order flow, but its influence on price far exceeds its share by count [29]. Informed order flow is the core force driving price toward fundamental value, promoting the market's price-discovery efficiency. For the market makers who provide liquidity, however, informed order flow is the direct source of adverse-selection risk (the mechanism by which market makers accordingly widen the bid-ask spread to compensate for potential losses appears in Section 7.1.3).

Noise order flow comes from participants who lack an informational advantage and trade on the basis of emotion, liquidity needs, or mistaken beliefs. This class of order flow has extremely low information content, generally manifesting as random buying and selling that does not exert a long-term directional push on price. Yet noise order flow plays an important role in the market ecosystem: it provides market makers with a relatively safe counterparty and is the primary source of their spread profit, thereby indirectly supporting the market's overall liquidity. In the crypto derivatives market, because of the heavy participation of retail speculators, the share of noise order flow is generally higher than in traditional equity markets; the author's preliminary order-of-magnitude estimate, based on public data, is about 50% to 60% of total order flow.

This ratio, however, carries a high degree of methodological uncertainty and depends heavily on the macro cycle: in a bull market, retail speculative activity surges and the noise-flow share may rise significantly; in a bear market, retail participation ebbs and the share contracts sharply. In addition, the original study of the PIN model by Easley et al. (2012) [29] targeted the U.S. equity market, and directly transplanting its informed-flow ratio to the crypto perpetual futures market requires caution, because the two markets differ fundamentally in participant composition, information-propagation speed, and regulatory environment. Although the precise figure is hard to determine, the higher share of noise flow remains an important reason for the relatively high market-making profit margin in this market.

Market-making order flow consists mainly of the two-sided limit orders submitted by market makers, estimated to account for about 20% to 25% of total order flow in mainstream trading pairs (based on the publicly disclosed market-share data of market makers on top exchanges). This class of order flow does not itself contain strong directional information; its core function is to provide liquidity and maintain price continuity. If market-making order flow conveys any information, it is that "market makers regard providing liquidity at the current price level as relatively safe." When market makers perceive an increase in market risk (for example, anticipating an imminent surge of informed order flow), they quickly withdraw or adjust their quotes, and the sudden widening of the bid-ask spread and the sharp drop in order-book depth themselves constitute a strong signal of a change in market state.

Liquidation order flow is a class distinctive to, and extremely important in, the crypto derivatives market. It consists of passive orders forcibly triggered by the protocol's risk engine when a trader's margin is insufficient, generally entering the market in the form of market orders. The information content of liquidation order flow is quite complex: it may merely reflect a single trader's poor leverage management (a purely mechanical trigger, with no directional information), or it may hint at a reversal of the market trend that has caught large numbers of traders on the wrong side. A liquidation cascade, moreover, is generally not confined to a single market: the forced selling pressure produced by a large-scale liquidation of BTC perpetual futures spills over to related assets such as ETH and SOL, triggering a cross-asset "correlation spike" and in turn setting off liquidation cascades in those assets themselves, forming a cross-market systemic contagion. More critically, large-scale liquidation order flow produces a strong mechanical price impact and may even trigger a chain of liquidations (a liquidation cascade), undermining the stability of market liquidity [9]. During the normal operation of a typical perpetual futures market, liquidation order flow is estimated to account for about 5% to 10% of total order flow (extrapolated from the frequency of on-chain-observable liquidation events), but in extreme conditions this ratio may spike sharply, becoming the core force dominating the market's short-term movement [9].

7.9.2 Order-flow toxicity and VPIN

Having understood the composition of order flow, the core challenge facing market makers and quantitative traders is how to assess in real time the information content of incoming order flow—the so-called "order-flow toxicity." Highly toxic order flow means

that informed traders are actively entering, and if market makers do not adjust their strategy in time, they will face serious adverse-selection losses.

> VPIN is a classic indicator for measuring order-flow toxicity, proposed by Easley, Lopez de Prado, and O'Hara (2012). Its core intuition is that when buyer-initiated volume and seller-initiated volume exhibit a significant and sustained imbalance over a short period, it very likely means that informed traders are actively building positions using their informational advantage [29].

VPIN is computed as follows: total volume is divided equally into n volume buckets, each containing a fixed volume V. For the i-th bucket, a bulk-classification algorithm divides the volume into buyer-initiated volume V_i^B and seller-initiated volume V_i^S. VPIN is defined as:

$$\text{VPIN} = \frac{\sum_{i=1}^{n} |V_i^B - V_i^S|}{n \cdot V}$$

where $n \cdot V$ is the total volume within the window, so VPIN falls in the interval $[0, 1]$. This volume-based rather than time-based sampling method can capture microstructural anomalies that are hard to detect with traditional time-period-based data. When VPIN approaches 1, it indicates that the order flow is almost entirely one-directional and toxicity is extremely high; when it approaches 0, it indicates that buying and selling are roughly balanced and toxicity is low. In practice, a sharp rise in VPIN often precedes large market swings, so it is widely used as an early-warning indicator.

However, one must be especially cautious when applying VPIN or similar indicators in the perpetual futures market. This is because order-flow imbalance in the perpetual futures market may arise not only from informed traders' directional bets but also from a liquidation cascade. When large numbers of long positions are forcibly closed, an enormous volume of sell market orders suddenly emerges, which appears in the data as a significant seller imbalance—highly similar in feature to "informed traders shorting heavily." In reality, however, these liquidation orders are "forced to sell" and contain no predictive information about future prices; they are mechanical, not informational.

Accurately distinguishing information-based toxic flow from mechanism-based liquidation flow is key to high-frequency trading strategies and market-making strategies in perpetual futures. Research by Bieganowski and Ślepaczuk (2026) further shows that by analyzing the microstructural features of order-flow imbalance (such as the duration of the impact and the accompanying pattern of OI changes), one can distinguish these two different kinds of order flow to some extent [7]. Later chapters further explore how market makers quantify and manage the information content of order flow (see the "toxic-flow spectrum" framework in Chapter 19); this section only establishes the basic recognition.

7.9.3 The distinctive signals of perpetual futures order flow

Compared with the traditional spot market, the order flow of perpetual futures carries some distinctive signals derived from its derivative mechanisms. These signals offer the keen observer valuable clues for predicting short-term price dynamics.

Because perpetual futures allow high-leverage trading, traders' liquidation prices tend to cluster in specific price ranges, forming so-called liquidation-price clusters. In an on-chain environment, these liquidation prices are even publicly visible. When the liquidation prices of large numbers of positions cluster near the current price, a potential zone of concentrated risk forms, as shown in Figure 7-22.

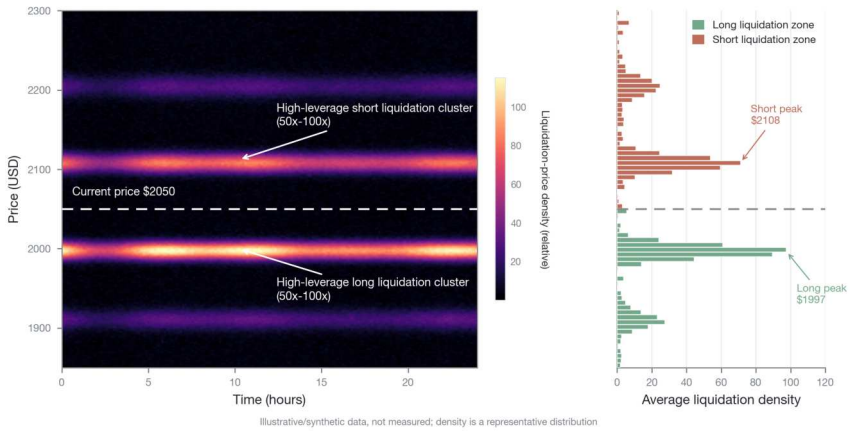

Figure 7-22. A heatmap of liquidation-price clusters (conceptual illustration: $2,050/$1,997/$2,108 and the like are synthetic representative values, not empirical; the distribution pattern is per Ali 2025 [9] and public statistics from CoinGlass/Bybit/Binance)

A liquidation-price cluster is a signal with a strong self-reinforcing property. It signals to the market: "if the price reaches this level, it will trigger a large number of forced market orders." When enough participants observe this signal, speculative capital may strategically push the price toward the cluster (the so-called deliberate triggering of stop-losses or deliberate triggering of liquidations), in the hope of setting off a liquidation cascade and profiting from it. The triggering of a liquidation cascade, however, does not depend solely on deliberate manipulation by large players: as the price approaches a publicly visible liquidation cluster, panic-driven early exits (traders proactively selling to avoid being liquidated) accelerate the price's move toward the liquidation zone, forming a self-fulfilling prophecy. The real-time spread of social media further amplifies this effect—the wide dissemination of liquidation heatmaps makes the liquidation zone common knowledge, accelerating herd behavior and increasingly blurring the boundary between deliberate hunting and the spontaneous cascade caused by collective panic. Methodological clues for distinguishing a deliberately manipulated trigger from a natural swing touching a liquidation cluster include: anomalous order-flow patterns (whether large one-directional orders inconsistent with normal trading activity appear before the trigger), the price-recovery shape (deliberate manipulation is generally accompanied by a rapid V-shaped reversal after the trigger, whereas a trend-driven trigger shows a sustained decline), and the pattern of change in open interest (a deliberate manipulator has generally established a reverse position before the trigger, so the change in OI exhibits a special temporal relationship with the price direction). This fragility, brought by the transparency of the mechanism design, significantly affects the short-term microstructure of the perpetual futures market and is a concrete manifestation, at the order-flow level, of the "transparency-fragility paradox" discussed

in Chapter 4.

The anticipatory trading behavior around funding-rate settlement (whose mechanisms of anchoring to spot and settling every 8 hours appear in Section 7.4.3 and Chapter 10) constitutes another class of distinctive signal. Around the moment of funding-rate settlement, order flow often exhibits an observable systematic pattern, reflecting traders' expectations of the direction and magnitude of the rate. For example, if large amounts of short-position-building order flow suddenly appear just before a funding-rate settlement, this may mean that the market broadly expects the next period's funding rate to be positive (longs pay shorts), so speculators are "positioning in advance" to collect the rate. By analyzing the order-flow dynamics before and after settlement, one can infer the trade-off strategies market participants are making between directional gains and rate gains.

The direction of order flow, paired with changes in open interest, can provide a richer signal than a bare price rise or fall—this is precisely the informational value embedded in changes in open interest. An increase in open interest means new capital is entering the market to establish positions; a decrease means existing positions are being closed. Cross-analyzing the price direction with the change in open interest can distinguish four combination patterns with different market implications.

Price direction	OI change	Market implication	Signal strength
Up	Increase	New long capital actively building positions	Strongly bullish
Up	Decrease	Short covering (shorts closing) driving the rise	Weakly bullish
Down	Increase	New short capital actively building positions	Strongly bearish
Down	Decrease	Longs closing (long stop-losses) driving the decline	Weakly bearish

Table 7-14. Interpreting the signals of price direction and changes in open interest (Data source: compiled by the author)

The most noteworthy contrast in Table 7-14 is the difference between "up + OI increase" and "up + OI decrease": the former indicates that new long capital is actively entering, constituting a strongly bullish signal; the latter merely reflects short covering, with weak upward momentum. Likewise, "down + OI increase" indicates that new short capital is entering and is a strongly bearish signal, whereas "down + OI decrease" merely reflects long stop-losses, with limited downward pressure. This distinction has practical value for judging the persistence of a price movement.

In the 24/7, high-leverage perpetual futures market, this interaction between OI and order flow changes more rapidly and violently. Especially during a liquidation cascade, a sharp drop in OI accompanying a one-directional price plunge is a typical feature of "mechanical volatility" (rather than "informational volatility") (see the detailed analysis

in Chapter 22).

7.9.4 From orders to the order book

In this chapter, we have deconstructed the "words" of the trading language—the order—in detail. We have explored the dual function of an order (trading and signaling), the strategic implications of different order types, the three-dimensional extension that perpetual futures confer on orders, and how the underlying execution architecture reshapes the physical properties of orders. We have seen that even the simplest market order or limit order conceals complex maneuvering and trade-offs behind it.

A market, however, is not composed of isolated orders. As this section has shown, thousands upon thousands of orders carrying different intents from different participants converge to form a continuous order flow. These order flows interact, match, or rest within the matching engine, ultimately aggregating into a real-time-updated data structure—the order book.

The order book is "the real-time record of the market's conversation." Its state at every microsecond is the cumulative result of all prior order submissions, cancellations, fills, and liquidations. The shape, depth, and buy-sell asymmetry of the order book, and its resilience when struck by new orders, embed rich information about the market's current liquidity conditions and future price direction. The next chapter raises the line of sight from the level of "words" and "sentences" to that of "discourse," dissecting the structural dynamics of the order book and establishing a complete analytical framework for understanding the evolution of market microstructure.

7.10 Chapter summary

The order is the most basic building block of market microstructure and the only interface through which a trader interacts with the market. In the highly complex, round-the-clock, and strategically charged environment of the crypto derivatives market, understanding the meaning of an order is a precondition for every participant seeking to build an effective strategy. This chapter has systematically deconstructed the concept of the "order," establishing for the reader—from several core perspectives—an analytical framework for mastering this fundamental toolkit of trading.

The foundation of understanding microstructure lies in recognizing that the order is a signal. While every order performs its surface "trading function," it inevitably also exercises a "signaling function," leaking to the market clues about the submitter's urgency, capital base, and information content. The choice of order type is, in essence, the process by which a trader finds the optimal trade-off position between "execution certainty" and "information leakage"; and it is precisely by reading these signals that market makers manage adverse-selection risk, which constitutes the microfoundation of bid-ask spread formation [4].

The emission of a signal, however, is only the starting point. Between a trader's original intent and the final fill outcome lies an intent-execution gap composed jointly of slippage, latency, MEV, information leakage, and liquidation risk. The width and composition of this gap differ fundamentally across execution architectures: on a centralized exchange,

the gap is generally narrower but contains a hard-to-quantify implicit risk of information exploitation; on an on-chain protocol, the gap may be wider, but every component of it is transparent and auditable. Especially worth guarding against is that, under an extreme-crisis state, this gap undergoes a sharp nonlinear widening [10]—a tail event that risk management must guard against.

Building on this, the distinctive mechanisms of perpetual futures further intensify the complexity of order decisions. Order decisions in the traditional spot market revolve mainly around price, quantity, and time, whereas perpetual futures add three important dimensions: leverage (every order changes the effective leverage and liquidation distance), liquidation (the complex interaction between the stop-loss order and the forced-closure mechanism), and time (the funding-rate settlement cycle creates new strategic timing). This multidimensional complexity is the microfoundation of the perpetual futures market being "simple to operate but complex to decide," and it is an important reason for the systematic losses of many ineffective traders [9].

At the same time, when these orders are submitted to an on-chain environment, their nature undergoes a fundamental transformation: on a centralized exchange, an order is a private expression of intent that can be canceled at any time at zero cost, but on an on-chain central limit order book, every order becomes a "public commitment" observable by the entire world. This transparency is a mechanism with both positive and negative effects: on the one hand it provides verifiable, trustless liquidity; on the other, it fully exposes the trader's strategic intent, making key levels such as the stop-loss order easy targets for sniping [20].

More fundamentally, the physical constraints of blockchain reshape the economic semantics of orders from the ground up: state-storage cost forces permanently valid orders to be replaced by orders with a lifecycle; the consensus mechanism turns cancellation from free and instant into costly and latent; oracle dependence introduces an inherent lag into the triggering of conditional orders; and discrete block time transforms continuous matching into a batch auction. Understanding how these underlying architectures change the behavioral characteristics of orders is the key entry point for understanding the distinctiveness of on-chain finance.

It is thus clear that an order is by no means merely a button on a software interface or a string of code in an API, but a complex carrier of intent, risk, and information. This chapter has completed a systematic dissection of the "words" of the trading language; the next chapter raises the perspective to the level of "sentences" and "narrative," analyzing the core data structure that order flow aggregates into—the order book—and revealing its structural dynamics, its information content, and how it drives the evolution of the entire microstructure ecosystem as the real-time record of the market's conversation.

The Perpetual Futures Order Book and Market Microstructure

On October 10, 2025, the cryptocurrency market experienced a flash crash of unprecedented scale. Every extreme market event unfolds along a three-stage chain of preconditions, triggers, and amplification mechanisms: a contraction in global risk appetite and a turn in the monetary policy cycle constituted the preconditions for systemic fragility; specific selling pressure served as the trigger; and defects in the market microstructure supplied the amplification mechanism. According to post-mortem reports from FTI Consulting and Amberdata, more than $9.89 billion in leveraged positions was forcibly liquidated within just 14 hours. This forced-liquidation volume represented roughly 6% to 7% of the total open interest in perpetual futures across the market at the time (approximately $9.89 billion against roughly $146.7 billion in open interest) and exceeded the roughly $8.6 billion liquidated during the May 2021 crash, with about 70% of the damage concentrated within 40 minutes [1] (a clarification is warranted: the $9.89 billion figure refers to the core window of roughly 14 hours under the perpetual-futures forced-liquidation measure; if one measures the evaporation of market-wide leverage and open interest, and includes voluntary position closures and position transfers, the entire deleveraging round reached roughly $19 billion over about a day. The two figures differ because of differences in statistical measure and time window [2]). Yet the fundamental reason this crisis escalated from a routine price correction into a systemic collapse lay not in any single price shock but in the underlying architecture of the market microstructure. Comparing three snapshots of this perpetual futures order book (such as BTC-USDT) — 24 hours before the crisis, at the moment it erupted, and 24 hours afterward — systematically reveals the evolution of the liquidity illusion and of systemic fragility.

Comparing three snapshots of the BTC-USDT perpetual futures order book before and after the crisis makes this process clearly observable. In the 24 hours before the crisis, the order book displayed a textbook equilibrium: depth on both the bid and ask sides was ample and approximately symmetric, the best bid-ask spread was as low as 0.02 basis points, and visible liquidity (defined as the cumulative two-sided resting depth within $\pm 2\%$ of the best bid and ask) reached as high as $103.6 million [1]. Even so, bid-side depth already showed a pronounced "depth cliff" near the dense liquidation zone below the prevailing price, as market makers, foreseeing that this region would generate a toxic flow of liquidation orders, had withdrawn in advance. At 20:50 UTC on October 10, after sustained selling pressure had driven the price to the liquidation threshold, the

order book underwent a violent structural change within minutes. At the peak moment of 21:15 UTC, $3.21 billion in positions was forcibly liquidated within 60 seconds (93.5% of it forced selling), visible depth shrank from $103.6 million to just $170,000 (a decline of about 99.8%), and the spread widened from 0.02 basis points to 26.43 basis points (both figures are instantaneous snapshot values rather than time-weighted averages, and the 26.43 basis points was the peak spread recorded at 21:15 UTC) — a widening of roughly 1,321-fold. The market sell orders generated by the liquidation engine and the collective retreat of market makers formed a positive feedback loop of "price decline → liquidations triggered → depth consumed → further price decline" [1]. The post-crisis recovery, by contrast, exhibited pronounced asymmetry: the collapse took less than two hours, whereas restoring liquidity required weeks. A CoinDesk report one month after the crisis showed that order book depth remained far below early-October levels and that market makers had undergone a structural retreat [3].

These three snapshots crystallize the central question of this chapter. Chapter 7 analyzed the single order — the basic vocabulary of the language of trading. The object of this chapter is the order book: the dynamically evolving market microstructure formed by the continuous interaction of millions of orders. The order book does more than perform matching; it is a continuously operating information-aggregation device. The high leverage, liquidation mechanisms, funding rates, and around-the-clock trading environment of perpetual futures leave a distinctive set of "four fingerprints" on the order book. When executing a large perpetual futures long position, the choice between a centralized exchange's continuous matching system and an application-chain-based batch-auction mechanism directly determines whether the microstructure can offer genuine protection under extreme market conditions. Analyzing the structure of the order book is the foundation for understanding this choice.

The chapter proceeds as follows. It first defines the order book as an information machine and proposes a joint diagnostic framework of five signal channels, then traces the dual causes of the depth illusion and the methods for quantifying it. A survey of the five institutional mechanisms unique to perpetual futures shows how each reshapes order book behavior. Turning to topology, the analysis distills a morphological classification of the order book and its mapping to market states, and on that basis proposes the "four fingerprints" framework, which translates those institutional mechanisms into observable, quantifiable diagnostic tools. Introducing the time dimension, it then examines the structural disadvantage in order book resilience. The discussion moves next to the infrastructure layer, tracing the evolution of matching-engine architecture and the institutional innovation of matching mechanisms, and closes by contrasting the information ecosystems of on-chain and off-chain order books.

8.1 The order book as an information machine

Traditional finance textbooks typically define the function of the order book simply as "matching buyers and sellers." This is correct but incomplete. Matching is only the mechanical function of the order book; its deeper and more essential function is information aggregation.

In his classic work *Empirical Market Microstructure*, Joel Hasbrouck notes that the order book is the most fundamental institutional arrangement in market microstructure and that its design directly determines the efficiency of price discovery, the quality of liquidity, and the fairness of trading [4]. The order book is an information machine: through continuous price competition, it transforms the private information, expectations, and risk preferences dispersed across many participants into a set of publicly observable state variables. These variables carry rich signals about the current state of the market and its near-term future.

In perpetual futures markets, this information aggregation is pushed to an extreme. Because these contracts have no expiry date and are anchored to the spot price through the funding rate, the order book becomes the central arena in which longs and shorts engage in high-frequency competition over the funding rate, liquidation risk, and macroeconomic expectations. Every order submitted, modified, or canceled broadcasts information: a market maker's cancellation may hint that liquidity is about to dry up, while an abnormal buildup of depth on one side may signal that an institution is establishing a large one-directional position. Treating the order book as an information machine is precisely the analytical starting point for understanding perpetual futures microstructure.

8.1.1 The structure and rules of the CLOB

The central limit order book (CLOB) is the core infrastructure of modern electronic trading markets. Whether in traditional stock exchanges or in emerging cryptocurrency derivatives platforms, the CLOB holds a dominant position. Understanding how this information machine operates requires first dissecting its physical structure.

Structurally, the order book consists of two sides: the bid side and the ask side. Each side is strictly sorted by price: bid orders are arranged from high price to low, and ask orders from low price to high. This ordering reflects the core objectives of market participants: buyers wish to buy at the lowest possible price, while sellers wish to sell at the highest possible price.

The gap between the best bid and the best ask is called the bid-ask spread. The spread is the price of liquidity — the minimum cost a trader must pay to obtain immediate execution. In markets with ample liquidity, the spread is typically very narrow, whereas when liquidity dries up or the market becomes highly volatile, it widens rapidly. The size of the spread reflects not only the current state of liquidity but also market makers' expectations of near-term volatility and their risk premium.

The quantity of resting orders accumulated at each price level constitutes the depth at that level. Depth reflects the market's capacity to absorb the impact of large orders without a dramatic price move. As Larry Harris defines it in *Trading and Exchanges*, the order book is "a dynamic electronic record of all unexecuted limit orders submitted by market participants, displaying the state of market liquidity in real time" [5]. Depth is not merely a static indicator; it also evolves dynamically as participants' expectations change. The distribution of depth is often nonuniform, typically densest near the best bid and ask and thinning progressively as prices move away from the best quotes.

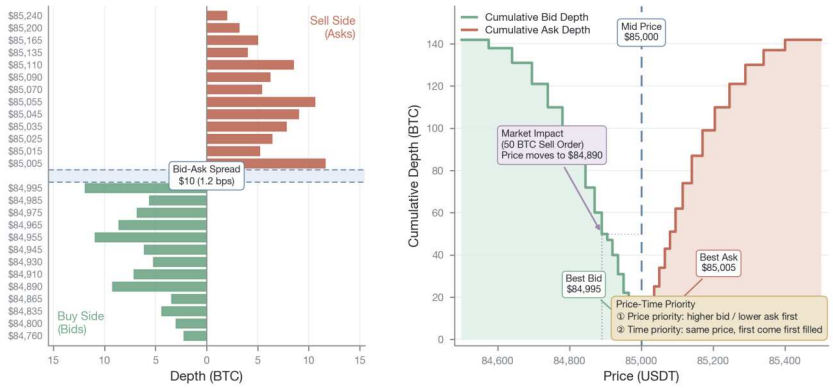

Figure 8-1. Basic structure of the central limit order book and the market impact effect (conceptual structural illustration: the $85,000 mid price, the $10 spread of about 1.2 basis points, and the impact of a 50 BTC sell order down to $84,890 are all illustrative synthetic values, not empirical data; the central limit order book and the price-time priority rule follow Harris 2003 [5])

Order book depth follows an inverted-cone, nonuniform distribution — thick in the middle and thin at both ends. The key insight lies in the cumulative depth curve in the right panel: when order size is small, the slope of the curve is gentle and price impact is limited, but once size exceeds the capacity of the near-touch liquidity, the curve turns sharply upward, and the price slippage induced by each additional unit of size is significantly amplified. This nonlinearity is precisely the microstructural basis for understanding the execution cost of large trades and extreme market events.

With respect to matching priority rules, the vast majority of CLOBs follow the principle of price-time priority, which is key to understanding the microdynamics of the order book. Price priority means that a higher bid receives higher priority among buyers, and a lower ask receives higher priority among sellers. This principle ensures that the market always matches in the direction most favorable to traders. It is the cornerstone of the price discovery mechanism, encouraging participants to offer more competitive quotes and thereby narrowing spreads and improving market efficiency. When prices are equal, time priority applies: the order that reaches the system first receives priority for execution, which is intended to ensure fairness of processing. In the modern high-speed electronic environment, however, time priority has spawned intense speed races and latency arbitrage. High-frequency trading firms invest heavily in optimizing network connectivity and the response speed of matching engines, all to arrive at a given price level a few microseconds ahead of their competitors. This is explored in depth in the later section on the evolution of matching engines. In perpetual futures markets, the widespread use of APIs further intensifies this time-based competition.

With the priority rules in place, consider how a market order consumes the book level by level. When a newly arriving market buy order enters the system, it consumes resting orders starting from the lowest ask, level by level. If the size of the market order exceeds the available depth at the first level, it continues to consume the resting orders at the second level, the third level, and so on, until the order is fully filled or the order book depth is exhausted. The price movement produced by this process is called

market impact.

The magnitude of market impact depends on the ratio of order size to available depth. Kyle's (1985) seminal model predicts a linear price impact function, $P = P_0 + \lambda x$, in which the parameter λ characterizes market depth (depth equals $1/\lambda$; that is, the larger λ is, the shallower and less deep the market, the two being inversely related), so that an order of any size bears a price impact proportional to its size [6]. Subsequent empirical research, however, has systematically revealed the limitations of this linear prediction. Almgren and Chriss (2001) introduced a nonlinear impact function within an optimal-execution framework [7], and Bouchaud, Farmer, and Lillo (2009), analyzing large-scale empirical data, found that the price impact of large orders exhibits pronounced concavity — the so-called square-root law, whereby the magnitude of impact is proportional to the square root of order size rather than to size itself [8]. This implies that although the actual impact of small orders roughly matches the linear prediction of the Kyle model, the impact of large orders grows more slowly as size increases, even as its absolute level still far exceeds a linear extrapolation. In perpetual futures markets, this nonlinear impact effect is especially pronounced. Because of the high leverage present, the impact of a large market order not only consumes liquidity but may also trigger other participants' stop-loss orders or forced liquidations, setting off a chain reaction. This nonlinear price jump induced by liquidity consumption is central to understanding the microstructural mechanics of extreme market events such as flash crashes.

8.1.2 The five signal channels of the order book

If the order book is viewed as an information machine, its various observable parameters constitute the analytical dimensions for extracting market signals. Traditional microstructure analysis often studies the spread or depth in isolation. This chapter systematizes these dimensions into a joint diagnostic framework of five core signal channels (Table 8-1). These five channels do not exist in isolation; together they depict a multidimensional picture of the market.

Signal channel	Observable variables	Core information conveyed	Correspondence with Chapter 7
Spread channel	Absolute and relative values of the bid-ask spread	The market's immediate transaction cost; market makers' pricing of adverse-selection risk; a real-time indicator of market "tension."	Corresponds to Section 7.2.4 (the maker-taker game and the economics of the spread). The spread is not only a transaction cost but also compensation to market makers for the risk of information asymmetry.
Depth channel	Resting order quantity at each price level and the cumulative depth curve	The market's capacity to absorb impact without a significant price move; the thickness of liquidity. An imbalance in depth between the bid and ask sides (order imbalance) is one of the strong predictors of short-term price movement [9].	Corresponds to Section 7.2.2 (limit orders as the supply of liquidity). The thickness of depth directly determines the market's capacity to withstand impact.
Slope channel	The rate at which depth decays with distance from the mid price	Participants' "confidence distribution" regarding price deviations from the current level; the steeper the slope, the more concentrated liquidity is at the current price.	Reflects the market's expectations of extreme price movements. A steep slope means the market regards a large price deviation as highly improbable.
Flow channel	The number of trades and the trading volume per unit of time	The market's "activity" and "urgency"; a high trade rate means the market is reacting intensely to new information.	Corresponds to Section 7.6 (the order-flow information ecosystem). Flow is the most direct manifestation of information entering the market.
Dynamics channel	The update frequency and cancellation rate of quotes	Market makers' "tension"; a rising cancellation rate is an early-warning signal that market makers' confidence is declining and that they are preparing to retreat.	Corresponds to Section 7.1.2 (the signal-strength spectrum). A high cancellation rate often foreshadows an imminent sharp market move.

Table 8-1. The five-signal-channel matrix of the order book as an information machine (Data source: constructed by the author)

These five signal channels are not mutually independent; they exhibit significant cross-

correlations. For example, a rise in the quote cancellation rate in the dynamics channel often precedes a widening of the bid-ask spread in the spread channel, while a one-sided contraction of liquidity in the depth channel typically accompanies an intensifying asymmetry in the rate of depth decay in the slope channel. Consequently, jointly monitoring the five channels — for instance, observing an abnormal climb in the cancellation rate even as the spread remains superficially stable — provides far greater diagnostic value than observing any single channel in isolation. This cross-channel joint-analysis framework is precisely the key methodological foundation that elevates the order book from a simple record of quotes into a systemic risk-warning tool.

Figure 8-2 provides a visual mapping of the core observable variables of the five signal channels and their analytical dimensions, showing how they capture market microstructure information from different angles and converge into a comprehensive assessment of the market's overall state, thereby transcending isolated reliance on any single indicator.

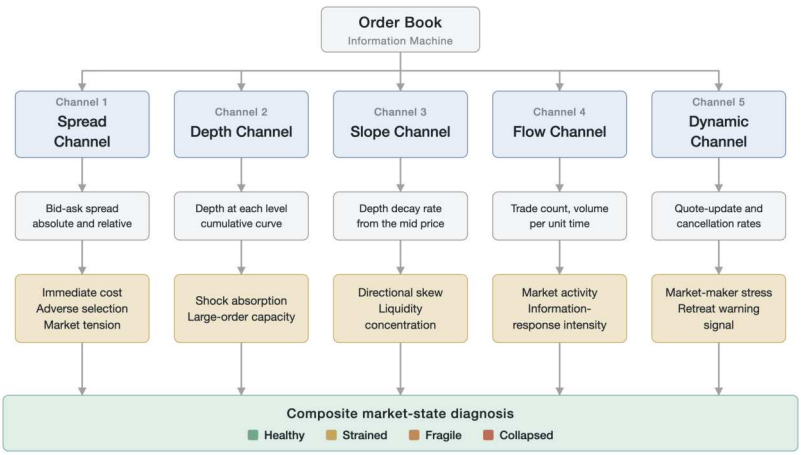

Figure 8-2. The five signal channels of the order book and the integrated diagnostic process (illustration of the integrated diagnostic process across the five signal channels; not empirical data)

The combined patterns across these five channels yield a comprehensive reading of the market state. Analyzing the signals jointly, rather than watching any single indicator in isolation, is what makes systematic diagnosis possible.

For example, in a superficially calm market with a narrow spread and thick depth (channels 1 and 2 healthy) but a sudden surge in the cancellation rate (channel 5 anomalous), the reading is often an early signal that high-frequency market makers have detected toxic order flow and are beginning to retreat. If the slope channel (channel 3) suddenly steepens while the depth channel shows a cliff at a particular price level, this strongly suggests that participants are preparing for a price breakout or a liquidation event. Such subtle structural changes often reveal the market's underlying trajectory earlier than price or volume indicators do.

8.1.3 Signal timeliness and information decay

The signals broadcast by the order book have one key characteristic: their information value decays sharply over time. In perpetual futures markets, this decay is especially rapid.

The depth consumption and price impact caused by a large market order may be filled within seconds — or even hundreds of milliseconds — by high-frequency market makers' quote updates; an abnormal asymmetry in bid and ask depth may return to balance within tens of seconds as arbitrageurs step in. Perpetual futures markets operate around the clock, which means that signals have no cross-day accumulation effect but instead exist in a perpetual cycle of continuous generation and rapid decay. This continuous high-frequency interaction keeps the order book in a dynamic-equilibrium steady state, in which any anomalous signal that deviates from the steady state is quickly smoothed away by market forces.

In the modern crypto market dominated by high-frequency market makers, orders are updated and canceled at extremely high frequency. This extremely short information half-life carries an important methodological implication: the time granularity of any analysis based on order book data must match the half-life of the signal. Using daily or even hourly data to analyze the order book produces a severe mismatch between temporal resolution and signal half-life, causing the analysis to miss almost every meaningful microstructural signal. In the millisecond-scale micro-world, liquidity may have vanished and reformed countless times, and these changes are entirely invisible on minute- or hour-level candlestick charts.

This mismatch in time granularity is precisely why many traditional macro analysts produce inaccurate results in crypto-market analysis. They attempt to explain the market's microdynamics using minute- or even hour-level candlestick charts, overlooking the fact that within these time windows the order book may already have undergone thousands of reconstructions and rebalancings. For instance, a momentary liquidity vacuum triggered by a liquidation may cause the price to plunge and rebound within seconds, leaving only a long lower shadow on the hourly chart. Without descending to the level of tick-by-tick order book data, one cannot understand the true driver of such a price anomaly.

A further distinction is needed: not all price impacts share the same decay characteristics. The microstructure literature decomposes impact into temporary impact (driven by liquidity consumption and market makers' inventory adjustments, which reverts within a relatively short time) and permanent impact (which reflects the incorporation of genuine information into the price and does not revert). In perpetual futures markets, because the liquidation of a leveraged position itself conveys genuine information about market direction (being liquidated means the market's tolerance for positions in that direction has been exhausted), the proportion of permanent impact within total impact may be systematically higher than in traditional spot markets. This distinction has a direct implication for the analysis of signal decay: if an impact is primarily permanent, then waiting for a "reversion" is itself a mistaken expectation.

This explains why, in practice, order book analysis remains the exclusive domain of a small number of professional quantitative institutions. The capacity to acquire, store,

and process millisecond-level or tick-by-tick order book snapshot data constitutes a natural technological and informational barrier. This phenomenon confirms the transparency paradox discussed in Chapter 1: although the crypto market is fully public and transparent at the level of data, the sheer volume of data and the rapid decay of information mean that genuine insight remains in the hands of a small number of institutions commanding top-tier computing resources. These institutions can monitor and parse minute changes across the five signal channels in real time, allowing them to act before the market undergoes a structural shift.

8.1.4 From single signals to state diagnosis

By integrating the five signal channels, we can construct an order book state dashboard that divides the market's microstructural state into four typical, continuous phases: healthy, tense, fragile, and collapsed. It formalizes the "three snapshots" of the introduction and previews, at the order-book level, the liquidity-fragility model of Chapter 20. The specific characteristics of each state across the five channels will be mapped in detail in Section 8.4.4 in conjunction with order book morphology. Here we merely outline the core logic: the transition from "healthy" to "collapsed" is not a sudden event but a traceable, continuous process of deterioration, manifested as a gradual widening of the spread, a contraction of depth from symmetric to one-sided thinness, and a rise in the market-maker cancellation rate from steady climbing to full retreat. The flash crash of October 2025 is a textbook case that evolved precisely along this path.

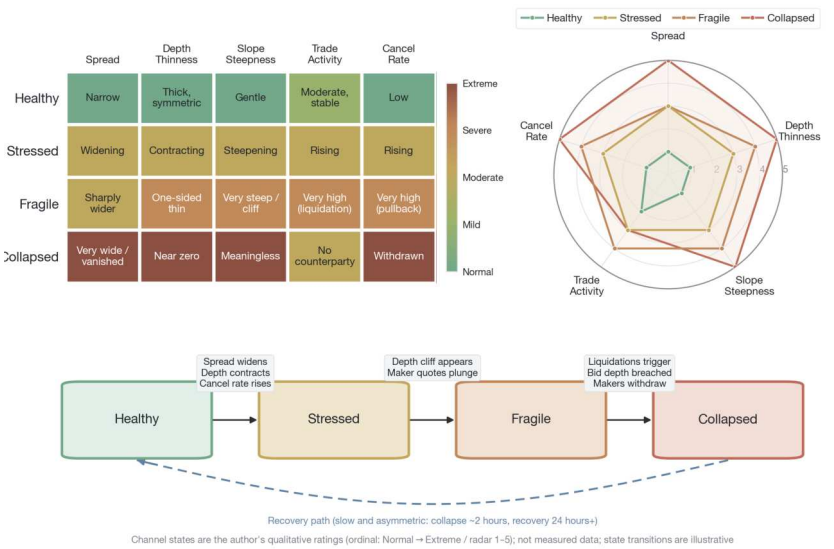

Figure 8-3. The order book state dashboard (the author's state-diagnosis framework: the four states — healthy, tense, fragile, and collapsed — and the 1–5 severity scale are the author's qualitative ordinal ratings, not empirical data; the recovery path of "collapse in about 2 hours / recovery in more than 24 hours" is a representative time scale)

The upper half of Figure 8-3 presents, in matrix form, the typical behavior of the five

signal channels across the four states, while the lower half shows the state transitions from healthy to collapsed and the recovery path. The latter is markedly asymmetric: the deterioration path is short and steep, whereas the recovery path is long and gradual. The correspondence between each state's behavior across the five channels and order book morphology is refined in Section 8.4.4.

This diagnostic capability constitutes the core of modern quantitative trading and risk management. By continuously monitoring the order book's state transitions, traders can dynamically adjust their position sizes and leverage, while exchanges can trigger circuit breakers or liquidity-protection mechanisms in advance. Yet even if we could read these signals perfectly, we would still confront a cognitive bias: is the depth we "see" in the order book truly the depth we can "use"? This question leads to the subject of the next section — the depth illusion.

8.2 The depth illusion

In cryptocurrency markets, and especially in perpetual futures trading, one of the most common errors traders make is to equate the resting order quantity visible on the order book with the trading size the market can genuinely absorb. The depth displayed in the order book misleads along two dimensions, and this is no mere technical detail of microstructure: it is the root cause of severe slippage under stress.

A trader who equates visible depth with usable depth may get by in the everyday low-volatility environment, but at the critical moment when the market faces a shock, that trader will often encounter severe slippage. The high-leverage environment, the absence of an expiry date, and the around-the-clock trading mechanism unique to perpetual futures make this depth illusion far more pronounced than in traditional financial markets (such as equity spot markets or traditional futures markets). During the cryptocurrency flash crash of October 2025, post-mortem data showed that within the first few minutes of the price plunge, "the cumulative depth within 5% of the best bid contracted by more than 90%." This figure directly reflects how the depth illusion manifests under extreme stress. Starting from the underlying microstructural logic, this section examines the dual causes of the phenomenon and proposes a set of actionable quantitative methods.

8.2.1 Flickering liquidity and ghost quotes

When we observe the order book of a modern electronic trading platform, what we see is a constantly flickering, rapidly updating matrix of numbers. Beneath this seemingly thriving appearance of liquidity, however, hides a large volume of what is called flickering liquidity. The quotes of high-frequency market makers and algorithmic traders may exist on the order book for less than a second before being automatically canceled and replaced by the system.

These flickering quotes are counted as valid depth in any static snapshot of the order book at a given instant. In actual trading practice, however, when a market order or an aggressive limit order is submitted to the matching engine, network latency and the market maker's extremely fast cancellation often mean that the quote has already been

canceled before the matching engine processes the order. In other words, the trader "sees" ample depth on the terminal, but by the time it comes to "use" that depth — to submit an order — it is gone. This phenomenon constitutes the first layer of the depth illusion.

Academics have long attended to this phenomenon, usually calling it ghost liquidity or flickering quotes. In studies of traditional equity markets, ample empirical evidence has shown that flickering liquidity accounts for a considerable share of visible depth. In highly electronic markets such as Nasdaq, for example, the prevalence of high-frequency trading has substantially shortened the average lifespan of orders.

In the cryptocurrency perpetual futures market, this phenomenon is not only fully inherited but further intensified by the specific market environment. Market makers in crypto markets face significantly higher adverse-selection risk. In a detailed analysis of crypto-market microstructure, Tiniç et al. (2023) found that the absence of unified regulation and disclosure mechanisms pushes the share of informed trading far above that of traditional markets [10]. This means that when a market maker's passive quote is filled, there is a very high probability that the counterparty is a trader with an information advantage, exposing the market maker to systematic losses.

To cope with this high adverse-selection risk — compounded by the fast and frequent price movements that the crypto market's around-the-clock trading and high leverage produce — the market maker's defensive strategy is high-frequency quote updating. To avoid being "arbitraged" or "sniped" by informed traders, market makers must update their quotes at extremely high frequency, adjusting orders at the millisecond or even microsecond level in response to price signals from other exchanges, changes in on-chain data, or macroeconomic indicators. This directly makes the lifespan of each quote extremely short. Flickering is therefore not only ubiquitous in perpetual futures markets; its scale and frequency far exceed those of traditional markets, making it central to any assessment of liquidity quality in crypto markets.

8.2.2 Conditional depth

If flickering liquidity is a "physical-layer" illusion produced by the microstructural mechanics of high-frequency trading, then a deeper and more destructive illusion lies in the behavioral logic of liquidity providers. Even when certain quotes are "real" (that is, they remain on the order book long enough not to be mere flickering quotes), the existence of that depth is absolutely premised on the implicit condition that market conditions are normal.

In the central limit order book model, the limit order a market maker submits appears on the surface to be a firm commitment to provide liquidity to the market, but in essence it is only a conditional commitment. The market maker's internal logic can be made concrete:

> "As a market maker, I have placed a buy order for 100 ETH at the $2,000 price level, providing liquidity to the market. But note that the effectiveness of this commitment rests on a series of strict implicit preconditions: that the market is currently experiencing no extreme directional volatility, that no signs of an ongoing liquidation cascade have

> been observed, that prices across the major exchanges show no significant divergence, and — most important — that my own inventory risk remains within the manageable range of my internal risk-control model. If any one of these conditions no longer holds and my risk-control threshold is triggered, my algorithm will automatically cancel this order within milliseconds and withdraw from the market."

This internal logic reveals the essence of order book depth: it is absolutely not an unconditional guarantee but a highly conditional commitment. The sole condition for its persistence is that the market state remain within the stable range the market maker's algorithm can tolerate. Once the market state deteriorates — even at the earliest sign of deterioration — these conditional commitments retreat collectively within an extremely short time. This collective retreat causes the seemingly ample visible depth on the order book to vanish rapidly, forming zones of extreme liquidity scarcity.

The discussion in Chapter 2 of "the cost of abolishing the expiry date" clarifies the special nature of this conditional commitment in perpetual futures. Traditional futures contracts have a definite expiry date, so a market maker's inventory risk naturally converges as expiry approaches. The loss of a risk-termination date for perpetual futures market-making, however, means that when providing quotes the market maker effectively bears an open-ended inventory risk. Lacking a risk-release mechanism along the time dimension, market makers become far more sensitive to market volatility. As a result, the liquidity commitments they make in perpetual futures are far more conditional than in traditional markets. Once the market enters a trending move, or volatility rises sharply, market makers — to avoid an indefinite erosion of inventory value — trigger their retreat mechanism at a very low threshold. This structural fragility, arising from institutional design, constitutes the second layer of the depth illusion and is the core reason liquidity dries up during extreme market conditions.

8.2.3 The three-layer decomposition of depth

Given that the depth illusion objectively exists and carries significant destructive power, how can it be identified and quantified in practice? The ILLIQ indicator proposed by Amihud (2002) measures illiquidity through the ratio of the absolute value of the daily return to the trading value, providing a standardized tool for the macro-level measurement of market depth [11]. That indicator, however, is based on daily-frequency data and cannot capture the depth changes at the micro time scale with which this chapter is concerned. To break the cognitive fallacy that "visible equals usable" and to measure the scale of the depth illusion precisely at the order book level, this chapter proposes a three-layer definitional framework of depth (Table 8-2). This layered quantitative framework helps traders and risk managers form more accurate dynamic expectations of the liquidity actually usable under different market states.

Depth layer	Conceptual definition	Measurement and calculation method	Reliability and application scenarios
Nominal depth	The total resting order quantity displayed directly in a static snapshot of the order book at a specific point in time. This is the most intuitive depth an ordinary trader sees on the terminal interface.	$\sum_i q_i$ (where q_i is the resting order quantity at the i-th level, and i ranges over all levels within a set percentage band around the best bid and ask). Typically calculated as the cumulative order size within a certain percentage (such as 1%, 2%, or 5%) of the best bid and ask.	Lowest reliability. It undergoes no filtering and contains a large volume of flickering liquidity and conditional commitments that may be canceled at any time. Suitable only for an extremely stable market environment.
Effective depth	The depth that, after removing high-frequency flickering quotes, is genuinely available with high probability for matching and execution under normal market conditions.	Cannot be read directly from a snapshot. It requires high-frequency historical order-flow data to compute the average lifespan of orders and the actual fill rate, from which a discount coefficient X is calibrated. Effective depth = nominal depth $\times$ X%. The value of X varies significantly by asset class, exchange type, and market state: based on empirical analysis of multiple historical extreme events, the X value for mainstream assets (such as BTC and ETH) on leading exchanges is typically between 60% and 80%, for mid-cap assets between 40% and 60%, and for less liquid long-tail assets possibly as low as 20% to 40%. It must be emphasized that the ex ante measurement of stress depth faces fundamental difficulties; the above ratios are merely empirical estimates based on historical-event retrospection and should not be applied mechanically to future stress scenarios.	Moderate reliability. It reflects the true cost of liquidity in everyday trading, but its premise remains that market conditions are normal, and it cannot withstand extreme shocks.
Stress depth	The depth that actually remains on the order book and is available for execution after market makers retreat collectively when the market faces an extreme shock, volatility spikes, and stress rises sharply.	Can be measured only through ex post retrospective analysis of high-frequency tick-by-tick trade data during historical extreme events (such as flash crashes and liquidation cascades). It measures how much depth truly withstood the test at the moment of crisis.	Highest reliability, but extremely difficult to predict. It is the core indicator for assessing market tail risk and calculating extreme slippage. Stress depth is often only 5% to 15% of nominal depth.

Table 8-2. The three-layer decomposition framework of depth (Data source: compiled by the author)

Through this three-layer division, the scale of the depth illusion can be quantified precisely: the vast gap between nominal depth and stress depth is its absolute magnitude.

Take the crypto-market flash crash of October 2025. The detailed post-mortem report by FTI Consulting (2025) shows that within the first few minutes of the crisis, the nominal depth within 5% of the best bid appeared to be as high as hundreds of millions of dollars, but as liquidation selling pressure surged in and market makers canceled orders instantly, the stress depth that actually supported execution amounted to less than 10% of the pre-crisis nominal depth [2]. This means the reduction from nominal depth to stress depth exceeded 90%. The larger this gap, the more the market's liquidity was built on a highly conditional foundation, and the worse its actual performance under stress relative to how it appeared on the surface. For institutional investors who rely on algorithms to execute large orders, estimating slippage and market impact on the basis of nominal depth will produce execution costs far in excess of expectations.

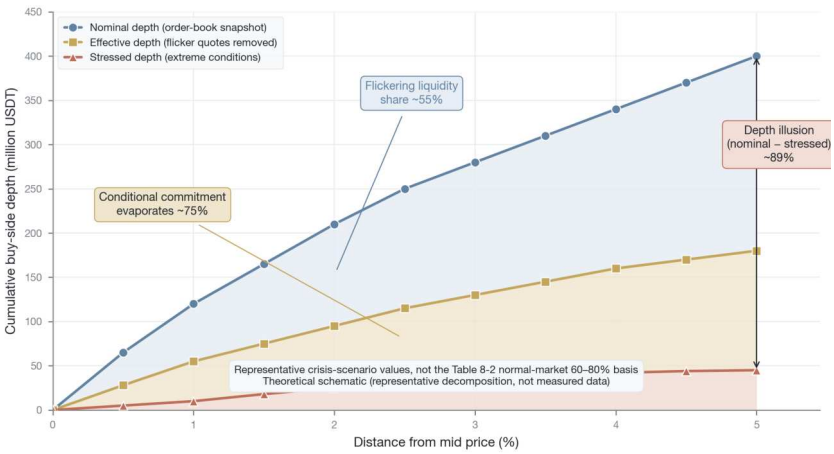

Figure 8-4. A three-layer comparison of nominal depth, effective depth, and stress depth

Note: This figure is a theoretical illustration drawn from the characteristic parameters of the October 2025 flash crash. The flickering, conditional evaporation, and nominal-to-stress depth gap shown are the author's representative decomposition, not empirical data, and are representative values for a crisis scenario rather than the normal-condition measure of Table 8-2 ("effective depth = nominal × 60–80%"); the figure follows FTI Consulting (2025) [2]. Within 5% of the mid price, the reduction from nominal depth to stress depth adopts the same ">90%" measure as Section 8.2 in the main text (the roughly 89% shown is a representative approximation of that reduction), indicating that under extreme market conditions the liquidity a trader can actually rely on is only about one-tenth of the nominal value displayed on the trading terminal. For institutional traders who design large-order execution algorithms, estimating expected slippage on the basis of nominal depth alone will produce execution results that deviate from expectations by an order of magnitude at the moment of crisis.

8.2.4 The amplification mechanisms of the depth illusion

Why is the depth illusion in perpetual futures markets far more severe than in spot markets or in traditional low-leverage markets? The reason is that the underlying

design of perpetual futures embeds two core mechanisms that, under stress, together amplify the depth illusion.

The first amplification mechanism is the anticipation of a liquidation cascade and the resulting defensive order cancellation. In the modern crypto market, market makers possess extremely advanced data-analysis capabilities. On decentralized exchanges (DEXs, such as application chains with an on-chain CLOB architecture), they can precisely calculate the liquidation trigger points across different price ranges by analyzing the fully public on-chain position and liquidation data; on centralized exchanges, they rely on sophisticated machine-learning models and historical experience to estimate the location of dense liquidation zones.

As the price gradually approaches these dense liquidation zones, market makers can clearly foresee the characteristics of the future order flow: "If the price reaches this trigger point, the liquidation engine will automatically take over and submit a large volume of forced sell orders to the market. These orders are highly toxic: they are involuntary, entirely insensitive to price (usually issued as market orders), and, because of the multiplier effect of high leverage, potentially far larger than normal orders."

Faced with this highly certain and enormously destructive anticipation of "toxic order flow," a rational market maker will not remain in place as the counterparty to liquidation orders. Market makers therefore adopt a defensive strategy, sharply reducing — or even entirely withdrawing — their bid quotes near the dense liquidation zone in advance. This anticipation-based collective cancellation forms a liquidity vacuum at specific price levels on the order book, which we call a depth cliff. This preemptive retreat makes the already-thinned depth even more fragile, directly amplifying the destructive power of the depth illusion.

The second amplification mechanism is the compounding effect of high leverage and procyclical retreat. High leverage amplifies not only traders' profits and losses but also the inventory risk market makers face. Market makers inevitably accumulate inventory when providing liquidity. When the market moves in one direction — especially a leveraged one-directional move — the opposing positions market makers hold face accelerating losses.

As discussed in Section 8.2.2 regarding "the cost of abolishing the expiry date," perpetual futures lack a delivery date that would force prices to converge and release risk, so market makers bear an open-ended inventory risk. Layered on top of this is the loss acceleration that leverage brings. Unable to judge how long an adverse trend will last, market makers see their tolerance (threshold) for retreat pressed extremely low.

After analyzing the microstructural data of the flash crash, FTI Consulting (2025) confirmed this point: during the crisis, the speed of market makers' retreat reached the millisecond level, and the scale of the retreat was unprecedented [2]. This reveals a dangerous "procyclicality" in market-maker behavior: precisely when the market is highly volatile and most in need of liquidity to absorb the shock and stabilize prices, market makers instead have the strongest incentive — out of the rational motive of risk avoidance — to withdraw liquidity on a large scale. The superposition of this procyclical retreat and the high-leverage environment exposes the depth illusion to its fullest extent at the most critical moment.

Beyond these two rational mechanisms, the reflexive effect of information transparency constitutes a third amplification channel. In cryptocurrency markets, liquidation data are displayed to the entire market in real time through aggregation platforms such as CoinGlass. This transparency aids price discovery and risk assessment in normal times, but during a crisis it produces a counterproductive accelerating effect: when traders observe on social media and data dashboards that liquidation volume is climbing sharply, these publicly visible liquidation data themselves turn into a panic signal, triggering more participants to close positions voluntarily and thereby generating even larger-scale liquidations. This constitutes a reflexive mechanism: the transparent disclosure of liquidation information in turn accelerates the spread of liquidations, making the crisis self-reinforce far faster than in comparable events under an information-opaque environment.

At the same time, during extreme stress events, arbitrageurs — who ought to perform a stabilizing function — may also fail. Under normal market conditions, arbitrageurs push prices back toward equilibrium by capturing cross-market or cross-asset price deviations. Brunnermeier and Pedersen (2009), however, revealed the mechanism of the liquidity spiral: when the market is highly volatile, arbitrageurs themselves face margin calls and are forced to close out their arbitrage positions to meet funding needs [12]. These forced closures not only fail to narrow the price deviation but instead worsen it, and the force that should anchor prices exits the market at precisely the moment it is most needed. In the high-leverage environment of crypto perpetual futures, arbitrageurs' capital constraints are even tighter, so this "stabilizer failure" is correspondingly more common.

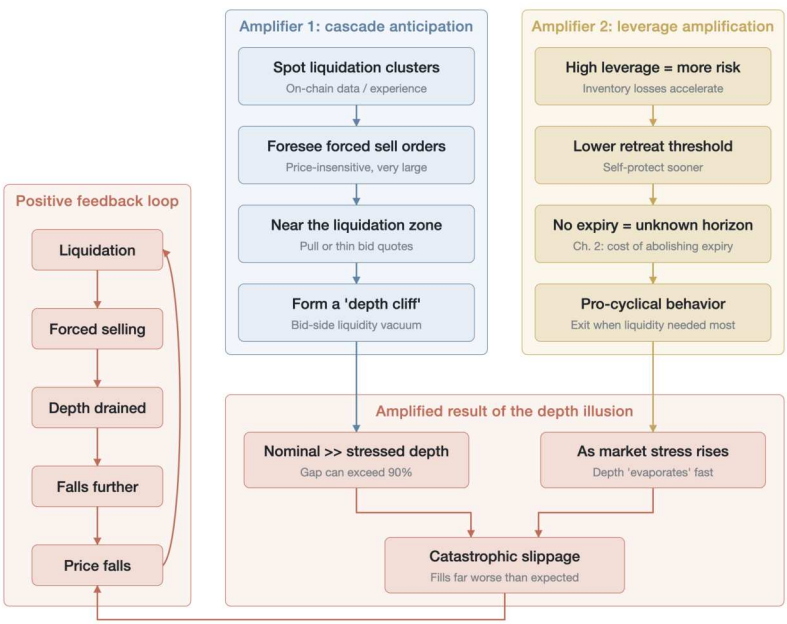

Figure 8-5. The causal chain of the depth-illusion amplification mechanisms (illustration of the mechanism causal chain, not empirical data; this figure focuses on the two rational retreat mechanisms

— liquidation-cascade anticipation and high-leverage procyclicality — while the third amplification channel, the reflexivity of information transparency and the arbitrageur liquidity spiral, is discussed in Section 8.2.4 of the main text, the latter following Brunnermeier & Pedersen 2009 [12]; "2009" is the citation year of that study, not the date of the flash crash)

The left side of the figure shows how market makers' defensive cancellation based on liquidation anticipation forms a depth cliff, and the right side shows the procyclical retreat triggered when high leverage and the absence of an expiry date lower the retreat threshold. The nonlinear interaction of the two (anticipatory cancellation drains the depth buffer at key price levels in advance, while procyclical retreat destroys the residual liquidity when volatility spikes) constitutes a "double vacuum" effect, making the actual severity of the liquidity crisis far exceed what either factor alone would predict.

8.2.5 Case study: the Hyperliquid POPCAT phantom order-wall incident

The preceding analysis focused mainly on the depth illusion caused by market makers' unintentional conditional retreat. The POPCAT incident on the decentralized perpetual futures platform Hyperliquid in November 2025, however, shows that the depth illusion can arise not only passively as an endogenous fragility of the market microstructure but can also be actively constructed and weaponized by a trader to manipulate the market price and transfer risk.

Viewed from a legal perspective, this behavioral pattern (first building a position, then placing a large order with no genuine intent to trade in order to induce others to follow, and subsequently canceling the order for profit) constitutes the classic spoofing conduct of traditional securities law. Under Section 747 of the U.S. Dodd-Frank Act, such conduct is explicitly defined as spoofing — that is, submitting a bid or offer "with the intent to cancel before execution." The 2015 Navinder Sarao case established a precedent for the criminal liability of such conduct, with the court finding that his repeated placement and cancellation of large orders in the S&P 500 futures market constituted market manipulation. On an on-chain decentralized exchange, however, legal enforcement against such conduct faces unique challenges: the manipulator uses anonymous wallet addresses, operates across jurisdictions, and the decentralized protocol itself lacks the monitoring and enforcement obligations of a traditional exchange. This enforcement gap leaves on-chain perpetual futures markets facing a more severe institutional deficit in defending against manipulation than traditional markets.

On November 12, 2025, an anonymous trader withdrew about $3 million in USDC from OKX, dispersed it across 19 wallet addresses, and then built a POPCAT long position on Hyperliquid with total exposure of roughly $26 million to $30 million at about 5x leverage. After completing the position, the trader placed a buy limit order of about $20 million at the $0.21 price level. This order formed a bid-side "order wall" on the order book that far exceeded the normal depth level of that market, transmitting a signal of strong buy-side demand to other market participants [13]. Attracted by this surface depth, other traders followed into long positions, further raising the market's leverage level and long-side concentration.

From a microstructural perspective, the core of the incident is that the $20 million order

wall was, in essence, an artificially manufactured depth illusion. Unlike the flickering liquidity discussed in Section 8.2.1 and the conditional depth analyzed in Section 8.2.2, this order wall was never intended to be filled from the moment it was submitted; its sole function was to manufacture visible depth in order to induce others to follow. Once long positions had accumulated to a sufficient scale, the manipulator withdrew the order wall. The $20 million of nominal depth dropped to zero in an instant, and the high-leverage long positions held by the follower traders who had relied on this visible depth suddenly faced an order book with a severe shortage of real depth. The POPCAT price fell about 43% within minutes (from about $0.21 to about $0.12), triggering about $63 million in platform-wide liquidations. Because the forced sell orders generated by the liquidations far exceeded the true absorptive capacity of the order book, Hyperliquid's community liquidity pool, HLP, ultimately bore about $4.9 million in bad debt [13].

Within Hyperliquid's risk architecture, HLP plays a dual role: it is both the liquidity provider for everyday market-making and the final risk bearer of the liquidation system. When the liquidation engine forcibly closes a position, if the order book lacks sufficient counterparty quotes, the unmatched exposure is first absorbed by the platform's insurance fund. When the insurance fund is insufficient to cover the entire loss, the remaining bad debt is distributed to HLP's liquidity providers through a socialized-loss mechanism. In the POPCAT incident, the insurance fund was rapidly exhausted, and the $4.9 million in bad debt was ultimately borne jointly by HLP's participants in proportion to their contributions. This transmission path (liquidation engine $\rightarrow$ insurance fund $\rightarrow$ HLP socialized allocation) reveals the ultimate destination of risk in a decentralized liquidation system.

From an operational-risk perspective, the incident also exposed multiple defensive deficiencies in Hyperliquid's market monitoring: the dispersed but synchronized position-building across 19 linked wallets (which would typically trigger an alert in the linked-account detection systems of traditional exchanges), the highly concentrated position in a single asset (with total exposure representing a significant share of POPCAT's market-wide open interest), and the $20 million order wall exceeding the normal size distribution. These three anomalies should have triggered, respectively, linked-account, position-concentration, and large-order alerts, yet all failed simultaneously — indicating that decentralized perpetual futures platforms still exhibit a significant institutional lag in the transition from technical architecture to an operational risk-control system.

This incident provides a case of special analytical value for the theoretical framework of the depth illusion. In flickering liquidity and conditional depth, the depth illusion is market makers' spontaneous behavior grounded in their own risk-management logic, intended to protect capital rather than to mislead the market; POPCAT reveals a third form — strategically constructed false depth — in which the manipulator turns the market's default trust in visible depth (the cognitive inertia that "the depth one sees is the depth one can use") into a tool of manipulation. From the perspective of behavioral finance, the $20 million order wall created a strong anchoring effect, causing participants to systematically overestimate the strength of support at that price level and to add leverage accordingly; combined with the availability heuristic (the tendency to rely in decision-making on the most readily available visual information), this explains why followers could gather at large scale in a short time. This strategic

depth illusion is especially dangerous in long-tail-asset perpetual markets: the lower the normal depth, the greater the relative illusion a single large order creates and the stronger its distortion of others' decisions. After the incident, Hyperliquid suspended deposits and withdrawals and launched a risk-control review, becoming a textbook case of the institutional-design challenges that decentralized perpetual platforms face in defending against market manipulation.

8.3 The distinctiveness of the perpetual futures order book

Having dissected the depth illusion, we must further recognize that the perpetual futures order book is not a simple replica of the traditional spot order book. It is deeply reshaped by a series of financial rules unique to the underlying design of perpetual futures. The leverage mechanism, the forced-liquidation system, the funding rate that maintains the price anchor, the dual-track price system (mark price and last traded price), and the vast open interest all give rise, at the microstructural level of the order book, to a series of distinctive phenomena that simply do not exist in spot markets.

This section analyzes systematically how these five core mechanisms shape the dynamic behavior of the order book. This analysis deepens our understanding of market microstructure and lays the empirical and logical groundwork for the "four fingerprints of the perpetual futures order book" framework proposed later in this chapter.

8.3.1 The order book transmission mechanism of the liquidation cascade

In perpetual futures markets, the liquidation order is key to understanding the microstructure of extreme markets. It is a highly unusual order type: it is not actively issued by a human trader or a conventional quantitative strategy based on a market judgment but is executed automatically and compulsorily by the exchange's liquidation engine when a user's margin ratio falls below the maintenance-margin requirement.

This compulsory and special origin gives liquidation orders two microstructural characteristics that carry significant systemic risk. The first is absolute price insensitivity: in order to take over and close the position as quickly as possible to prevent the position from going underwater, the liquidation engine typically throws the position into the market as a market order or an extremely aggressive limit order (such as a bankruptcy-price limit order), executing an immediate fill with no price limit and inflicting a direct and enormous shock on the order book's available depth. Accompanying this is the adverse timing of their appearance: liquidation orders never appear in calm conditions; their triggering is necessarily accompanied by a market that has already moved sharply against the liquidated position. The influx of liquidation orders therefore intensifies the market shock and reinforces the existing trend and volatility.

From the standpoint of the micro-transmission path, the positive feedback loop of the liquidation cascade forms a self-reinforcing chain: "initial decline → liquidation of high-leverage positions → price-insensitive market sell orders consume bid-side depth → accelerated price decline → deeper liquidations triggered → procyclical retreat of market makers → liquidity vacuum." In this loop, the collective retreat of market

makers plays a key accelerating role, pushing the order book from "thin depth" into a "liquidity vacuum" and thereby amplifying a normal price correction into a systemic liquidity collapse.

The flash crash of October 2025 provides empirical validation of this transmission mechanism. According to the post-mortem report by FTI Consulting (2025), after the structural long position that a large fund had built near $86,000 was triggered for liquidation, the bid-ask spread of the BTC/USDT perpetual futures widened within minutes from less than 10 basis points to the thousand-basis-point range recorded on individual platforms at the peak of the cascade (spread snapshots vary enormously across exchanges and across moments in time; the thousand-basis-point level here is an extreme reading on a thin-book platform at the peak of the collapse, which differs in measure and moment from the 26.43 basis points recorded on a mainstream platform at 21:15 UTC cited earlier), with cumulative forced liquidations reaching $9.89 billion over about 14 hours [2][1]. The complete micro-transmission mechanism of the liquidation cascade on the order book (in particular, how market makers form a defensive depth cliff) is analyzed further in the four-fingerprints framework in Section 8.5.1.

The failure of the existing risk-buffer mechanisms to interrupt the cascade during this crisis deserves scrutiny. Mainstream cryptocurrency exchanges typically deploy three lines of defense: an insurance fund to absorb underwater losses, an auto-deleveraging mechanism that hedges and closes profitable-side positions when the insurance fund is insufficient, and position limits and price-protection mechanisms that constrain extreme behavior. In the October 2025 event, the insurance funds of several exchanges were substantially depleted during the peak of the cascade, and some exchanges triggered their auto-deleveraging programs, but the design parameters of these mechanisms (the size of the insurance fund relative to potential liquidation exposure, the trigger thresholds for auto-deleveraging, and the width of the price-protection band) had never been stress-tested against a synchronized liquidation event of this scale. The existence of the safety net gave market participants a sense of institutional security, but the gap between the safety net's actual carrying capacity and the extreme liquidation pressure is precisely the institutional reason the cascade could not be interrupted.

This transmission mechanism bears a surface resemblance to — but a fundamental mechanistic difference from — the "hot potato effect" described by Kirilenko et al. (2017) in their microstructural analysis of the U.S. equity flash crash of May 2010 [14]. In the 2010 U.S. equity flash crash, the "hot potato" referred to the rapid passing of toxic inventory among high-frequency traders — that is, a position repeatedly changing hands among multiple intermediaries, with each transfer accompanied by a further deterioration in price. In the liquidation cascade of crypto perpetual futures, by contrast, the driving force is not the lateral transfer of positions but their one-directional elimination: the forced market orders generated by the liquidation engine are entirely involuntary, absolutely price-insensitive, one-directional selling. Their distinctive destructive power lies precisely in this complete price insensitivity: they do not "wait" for a reasonable price but execute immediately at any available price, punching directly through all available depth in the order book.

The destructive power of the liquidation cascade spreads further through cross-market

contagion paths. Under a unified margin system, the liquidation of a BTC position in an account consumes all the available margin in that account, forcing the trader to simultaneously reduce positions in ETH and other altcoins to free up margin, thereby transmitting the pressure from the BTC market to the entire crypto derivatives market. In addition, liquidation pressure on centralized exchanges spills over to decentralized exchanges through arbitrageurs' cross-platform activity: when the price of BTC perpetual futures on a CEX falls significantly below the DEX quote because of liquidation selling pressure, arbitrageurs execute sell orders on the DEX to capture the spread, replicating the CEX liquidity crisis in the on-chain market. This multilayered contagion network makes the reach of the liquidation cascade extend far beyond the boundary of any single trading pair or single platform.

Figure 8-6 aligns the spread (Panel A), depth (Panel B), and liquidation volume (Panel C) of the October 2025 flash crash along the same time axis.

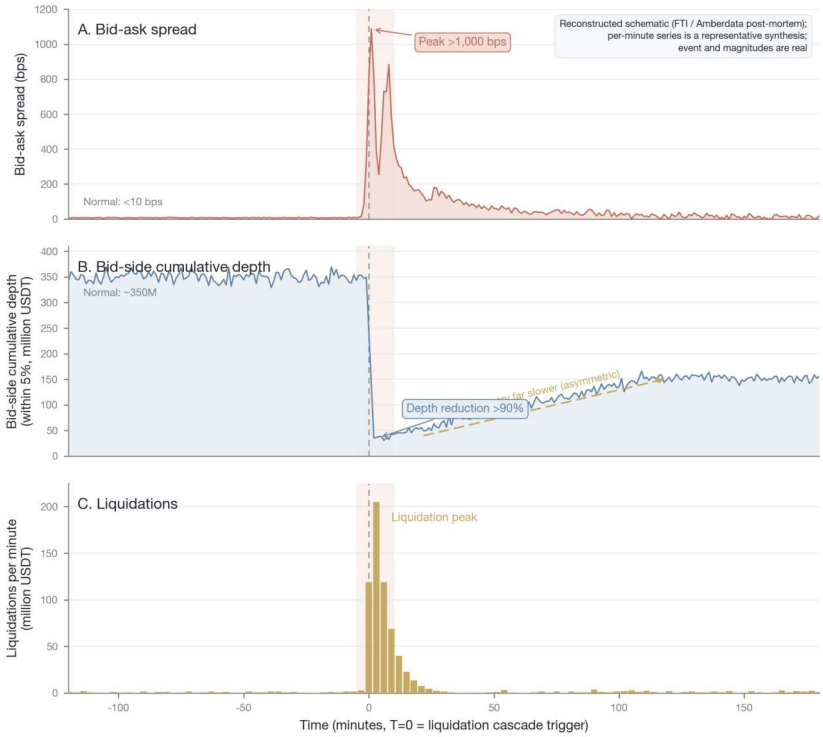

Figure 8-6. The microstructure of the October 2025 flash crash in three panels (a stylized three-panel view of the October 2025 flash crash: the spread peak of >1,000 basis points, bid-side depth of about $350M contracting by >90%, and the liquidation peak of about $200M are representative synthetic values; the event is real, but the minute-by-minute waveform is a post-mortem reconstruction rather than raw empirical measurement; the spread peak is on a thin-book-platform basis, distinct from the 26.43 basis points recorded on a mainstream platform at 21:15 UTC in the main text; following Amberdata 2025 [1] and FTI Consulting 2025 [2])

The temporal alignment of the three panels reveals a key empirical finding: the widening of the spread (Panel A) and the evaporation of depth (Panel B) were almost perfectly

synchronized, indicating that the collective retreat of market makers and the influx of liquidation selling pressure were concurrent rather than sequential processes. The depth recovery in Panel B, in turn, exhibits the asymmetry of "rapid collapse, slow repair" (collapse in minutes, recovery over hours or more), which is analyzed further in Section 8.6.

8.3.2 The cyclical influence of the funding rate

The reason perpetual futures can remain "perpetual" without their price drifting far from spot lies, at its core, in the distinctive funding rate mechanism. This mechanism anchors the perpetual futures price to the spot index through a periodic exchange of fees between longs and shorts. Carried out every 8 hours (or every hour on some high-frequency platforms), however, this compulsory settlement introduces a distinctive cyclical imbalance into the order book's microstructure.

When the funding rate is positive and high (which is relatively common in the crypto market's systematic long bias), longs must pay a fee to shorts. For cost-sensitive traders and arbitrage funds, their collective avoidance behavior — briefly closing positions before the settlement moment (such as UTC 00:00, 08:00, and 16:00) and re-establishing them afterward — has a cyclical structural effect on the order book.

In an empirical study of cryptocurrency perpetual futures, Ruan and Streltsov (2022) found that the spot bid-ask spread and trading activity exhibit a U-shaped pattern within the 8-hour funding rate cycle: in the period approaching funding settlement, informed trading and adverse selection rise (more markedly when the absolute value of the funding rate is large), prompting market makers to widen their quoted spreads [15]. This cyclical variation in liquidity, driven by an institutional mechanism, constitutes the empirical basis for the "depth tide" fingerprint in Section 8.5.2.

8.3.3 Order book fragility under high leverage

Leverage is the core attraction of derivatives markets, but from a microstructural perspective it brings both capital efficiency and systemic risk. To understand the fragility of the perpetual futures order book, one must first understand the highly nonlinear mathematical relationship between the leverage multiple and the "liquidation distance" (the percentage margin by which the current price is separated from the price that triggers forced liquidation).

In the most simplified model, the liquidation distance can be approximated as 1/leverage. The actual liquidation-trigger mechanism, however, is far more complex than this simplified formula. First, the existence of the maintenance-margin ratio further shortens the liquidation distance: for an isolated-margin long (entry price P_0, leverage L, maintenance-margin ratio m, ignoring fees and funding), the exact liquidation distance is $\dfrac{1/L - m}{1 - m}$, whereas liquidation distance $\approx 1/L - m$ is only a first-order approximation under small m (for the short direction the denominator should become $1 + m$). Taking Binance as an example, the maintenance-margin ratio corresponding to the highest leverage tier for BTCUSDT is about 0.4%; by this approximation, the actual liquidation distance at 100x leverage is not 1% but about 0.6% (the exact

expression gives $(0.01 - 0.004)/0.996 \approx 0.60\%$, consistent with the approximation). Note that the formula above does not include opening/closing fees and accumulated funding, both of which would further shorten the actual liquidation distance. Second, liquidation behavior differs fundamentally between isolated-margin and cross-margin modes: under isolated margin, the liquidation distance is determined strictly by the margin of the individual position, whereas under cross margin all available account balance can be used to maintain the position, so the liquidation distance depends on the account-level aggregate risk exposure. In addition, most mainstream exchanges have introduced a tiered margin-ratio system, in which large positions require a higher maintenance-margin ratio than small ones, as well as partial-liquidation mechanisms (reducing position size before full liquidation in an attempt to restore margin adequacy) and auto-deleveraging mechanisms. These institutional-level nuances have a material effect on the actual timing of liquidation triggers and on the transmission speed of the cascade.

This inverse relationship means that as the leverage multiple increases, the margin for error contracts exponentially. For a moderate investor using 2x leverage, the market would need to move about 50% adversely to trigger liquidation, which usually requires an extreme macro black-swan event; at 10x leverage, the liquidation distance shrinks to about 10%, which falls within the range of normal monthly or even weekly volatility in the crypto market.

When the leverage multiple is pushed up to 50x, 100x, or even 125x, however, the situation changes qualitatively. The liquidation distance corresponding to 100x leverage is a mere 1%; at 50x leverage it is only 2%. We define the region where the liquidation distance is less than 2% as the "extreme-risk zone." In a market such as cryptocurrency — where Bitcoin's average daily volatility can reach 3% to 5% (based on the median range of the absolute value of daily BTC/USD returns from 2023 to 2025), and altcoin volatility is higher still — a price movement of 1% to 2% falls within the normal range of the market's everyday volatility.

In the euphoric phase of a bull market, large numbers of retail traders and aggressive capital pour in, using extremely high leverage to build long positions. This produces a microtopological structure with a high degree of systemic risk: the liquidation price lines of a vast number of traders overlap heavily and cluster within a narrow band just 1% to 2% away from the current market price.

This position-distribution feature caused by high leverage is structurally embedded in the fragility of the order book. In such an environment, no macro bad news and no deterioration in fundamentals are needed; the normal fluctuation of order book liquidity, or the ordinary market impact caused by a medium-sized market order, is enough to move the price down by 1%. This tiny 1% drop instantly touches the first dense liquidation cluster, detonating the liquidation-cascade chain reaction described in Section 8.3.1.

Therefore, the extreme fragility that the perpetual futures order book exhibits when facing liquidation pressure is not a technical defect of the matching engine, nor an accidental market failure, but an inevitable product of the institutional design of high leverage, and it directly constrains the order book's resilience under extreme stress.

If 100x leverage means almost certain liquidation under normal volatility, why do so many traders still choose it? The prospect theory of Kahneman and Tversky (1979) offers an explanatory framework [16]: humans exhibit a systematic distortion of probability weighting when evaluating low-probability events, tending to assign excessive subjective weight to low-probability, high-payoff events. The potential payoff under 100x leverage (a 1% price movement leveraging a 100% return on principal) is experienced psychologically as a kind of "lottery ticket," and its extremely asymmetric profit-and-loss structure precisely caters to this bias in the probability-weighting function.

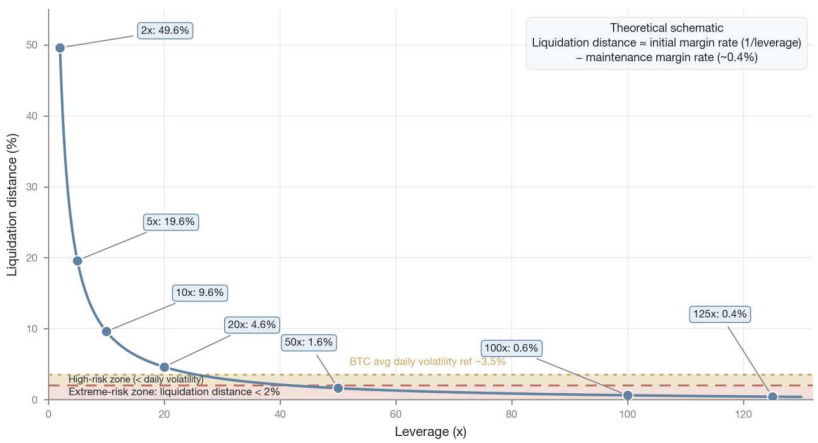

Figure 8-7. The nonlinear relationship between the leverage multiple and the liquidation distance

Note: This figure is a theoretical illustration. The curve is drawn according to "liquidation distance ≈ initial margin ratio (1/leverage) − maintenance-margin ratio (about 0.4%)," consistent with the exact expression $(0.01-0.004)/0.996 \approx 0.60\%$ in this section, and all labeled points are theoretical calculations, not empirical data. The hyperbola shows that once the leverage multiple exceeds 20x, the liquidation distance enters a steeply declining segment, in which the liquidation distance reduced by each additional unit of leverage is disproportionately amplified. The "extreme-risk zone" in the figure (liquidation distance $< 2\%$) and the BTC average-daily-volatility reference line (about 3.5%, taken from the 3%–5% range in the main text) together delimit an operational dividing line: high-leverage positions falling within this zone can be liquidated under everyday price movements, which mathematically explains why liquidation events cluster and erupt in the high-leverage range. The behavioral explanation for the high-leverage preference follows Kahneman and Tversky (1979) [16]; "1979" is the publication year of prospect theory, not a data point.

8.3.4 The divergence signal between mark price and traded price

In traditional spot markets, the price is singular: the price of the most recent matched trade is the current market price. To prevent market manipulation and unfair liquidations caused by anomalous wicks, however, perpetual futures introduce a dual-track price system: the last traded price and the mark price. These two prices play distinct

yet intertwined roles in the order book microstructure.

The last traded price, abbreviated LTP, is the final result of the actual matching of buyers' and sellers' funds on the order book; it reflects the instantaneous supply-demand balance on that specific exchange at the current microsecond. It is directly affected by that exchange's local liquidity depth, the impact of large orders, and market-maker behavior.

The mark price, by contrast, is a synthetic indicator, typically computed from a price index of several leading spot exchanges (such as Binance, Coinbase, and Kraken) plus a funding basis that decays over time. Its core function is to calculate users' unrealized profit and loss and to serve as the sole benchmark price for triggering forced liquidations. The mark price was designed from the outset to filter out short-term anomalous fluctuations on any single exchange's local order book.

The specific construction of the mark price — the weighted or median synthesis of the spot prices of multiple constituent exchanges, the removal of outlier constituents that deviate from the median beyond a threshold, and the exponential-moving-average smoothing of the basis between the perpetual price and the index price, together with the differences across exchanges in algorithm and sampling window — belongs to the domain of price-benchmark governance, which Chapter 14 develops systematically. For the purposes of this chapter, it suffices to grasp the essential point: this multi-source synthesis and smoothing is exactly what lets the mark price screen out short-term anomalies on any single exchange's local book.

Well designed as it is, the mark price mechanism still faces operational risk. The Mango Markets incident of October 2022 provides a cautionary case: the attacker manipulated the oracle quote by artificially pushing up the token price on a constituent exchange with extremely low liquidity, thereby raising the mark price, and on that basis borrowed and withdrew more than $110 million in assets (>$110M, on the CFTC/DOJ/SEC basis) [17]. In addition, under extreme market conditions, the price feeds of constituent exchanges may be delayed by API failures or network congestion, causing the mark price to fail to reflect the true state of the market in time and thereby creating the risk of improper or delayed liquidation.

Under a normal liquidity environment, cross-exchange arbitrageurs quickly eliminate any small spread between the LTP and the mark price, keeping the two closely aligned. Makarov and Schoar (2020) show that cross-exchange price deviations in crypto markets are typically small in normal times but widen significantly during periods of market stress, and that frictions in capital flows are the main reason price deviations persist [18].

A distinction is needed: three layers of price deviation exist in perpetual futures markets. The first layer is the deviation between the traded price and the mark price within the same exchange, which reflects the degree of supply-demand imbalance on that exchange's local order book. The second layer is the deviation of the price of the same contract across different exchanges — the cross-exchange arbitrage opportunity studied by Makarov and Schoar (2020) [18]. The third layer is the basis deviation between the perpetual futures price and the spot price, which is the target the funding rate mechanism seeks to correct. All three layers of deviation are at low levels in a

normal market but widen synchronously and reinforce one another during a crisis.

When the market encounters extreme volatility, however, or when a particular exchange's local liquidity faces exhaustion, these two prices diverge significantly.

This divergence is itself a highly valuable microstructural signal. When the LTP falls significantly below (or rises significantly above) the mark price, and the magnitude of the deviation exceeds the normal arbitrage-cost threshold, it clearly indicates that this exchange's local order book is bearing enormous one-directional selling pressure (or buying pressure) and that market makers and arbitrageurs have stopped providing liquidity because the risk is too high or their capital is exhausted. The local liquidity reservoir has dried up and can no longer effectively maintain the anchor between the price and the global macro fair value.

The degree of divergence between the LTP and the mark price can therefore be regarded as a real-time gauge of the pressure borne by the order book. When constructing an advanced trading algorithm or risk-control system, this deviation indicator should be used as a key supplementary signal to the state dashboard (as described in Section 8.1.4). It also demonstrates, conversely, the importance of using the mark price for liquidation: if, at the instant a liquidity drought causes the LTP to plunge, the system were to use the LTP to trigger liquidations, countless positions that were originally safe would be liquidated unjustly, setting off an even more devastating death spiral. The mark price mechanism is a necessary institutional safeguard for high-leverage derivatives markets.

8.3.5 Open interest as a harbinger of latent order flow

Synthesizing the analysis above, we must extend our view from the instantaneous snapshot of the order book to a macro indicator that measures the market's overall stock of leverage — namely open interest, abbreviated OI. OI represents the total value or total quantity of all derivatives contracts that have been matched and executed but not yet closed and settled at a specific moment.

Within the framework of microstructural analysis, open interest is not merely a static size figure; at the analytical level, its essence is a macro reservoir that foreshadows latent future order flow. The logic can be stated briefly as follows: derivatives trading is a zero-sum game, and every contract currently in an open state (whether long or short) will, at some future moment, be closed out through a trade in the opposite direction. The 10 BTC a trader buys to open a long today will ultimately be closed by an opposing trade — whether the holder actively sells or the liquidation engine or auto-deleveraging mechanism closes the position. In a low-leverage traditional market, these future closing order flows are typically dispersed, rational, and price-sensitive. In the high-leverage environment of perpetual futures, however, the situation is entirely different. As noted earlier, a considerable proportion of the vast OI is composed of high-leverage capital. This means that this portion of latent future order flow is highly likely, when the market encounters headwinds, not to appear as gentle limit orders but to be converted into forced market orders executed automatically by the liquidation engine, potentially far larger than normal in scale. The absolute size of OI, the growth slope of OI, the market's long-short position ratio, and the density of leverage distribution across different price ranges inferred from on-chain data therefore constitute the core

set of indicators for assessing the potential fragility of the current order book under future stress.

An order book that on the surface has low volatility and symmetric, ample bid-ask depth is misleading in its appearance of "health" if lurking behind it are open interest at a historical high, an extremely skewed long-short ratio (for example, a markedly elevated share of retail long positions), and a large accumulation of high-leverage positions clustered just below the current price. Once a tiny price fluctuation triggers the first round of liquidations, the latent closing pressure embedded in the vast OI rapidly converts into a large-scale one-directional forced-liquidation order flow.

In quantitative analysis, the OI-to-market-cap ratio is widely regarded as a core indicator of the degree of leverage accumulation for a specific asset. When this ratio spikes into the historically high zone, it becomes a highly salient early warning: leverage within the system has reached a historical extreme, and any tiny disturbance may trigger a violent deleveraging process. The introduction of this indicator elevates static order book analysis to the level of dynamic systemic-risk assessment, and it takes on diagnostic value that directly determines the efficacy of the analysis when the superposed effect of the four fingerprints is discussed later.

OI as a measure of leverage accumulation, however, has several inherent limitations. First, the statistical measure of OI includes a large volume of hedged positions (for example, in a delta-neutral strategy both the long and short legs are counted in OI, yet their net directional risk is zero). Second, different exchanges differ in how they compute OI (whether by number of contracts or by dollar value, whether expired-but-unsettled positions are included, and so on), so a simple aggregation across exchanges may result in double counting. A rise in the OI-to-market-cap ratio therefore does not necessarily indicate the accumulation of directional leverage. The net long-short ratio (that is, net long-short ratio = (long OI−short OI)/total OI, the share of the difference between long OI and short OI in total OI) and the estimated leverage ratios computed by third-party data platforms, as complementary indicators, can more precisely reflect the actual degree of directional-risk accumulation in the market.

8.4 Topological features of the order book

The order book is not merely a matching engine but a complex information machine. Cont, Stoikov, and Talreja (2010), through statistical modeling of the limit order book, demonstrated that the order book's shape features (rather than merely the absolute value of depth) have significant predictive power for short-term price movements [19]. The order book therefore possesses not only a "size" that reflects market capacity (that is, depth) but also a "shape" that reflects the market microstructure (that is, topological features). The shape of the order book — including its symmetry, slope, and convexity/concavity — carries rich information about the balance of directional forces and the composition of participants. Combined with the signal channels described earlier, these topological features constitute a mapping from micro-morphology to macro market states.

8.4.1 Symmetry and asymmetry

In analyzing the order book's topological structure, symmetry is one of the most intuitive and important features — the core dimension for quantifying the balance of buying and selling forces. In a fully "healthy" market in a random-walk state, the depth distribution on the two sides of the order book is typically approximately symmetric. This symmetry indicates that market makers and liquidity providers assess the risk of a price move in either direction as balanced, and that the forces of buyers and sellers are roughly equal.

When the market develops a directional preference or expectation, however, the symmetry of the order book breaks. The emergence of asymmetry is a clear signal that a significant change is occurring in the market microstructure. For example, when bid-side depth significantly exceeds ask-side depth, it usually means that buying power is dominant and that the market may face upward pressure. From the market maker's standpoint, however, this asymmetry may carry a different message: buyers may be exhibiting an overly aggressive tendency, while concentrated sell orders not yet revealed may exist at higher price levels above. Conversely, if bid-side depth thins while ask-side depth remains thick, this often indicates that selling power is dominant, or that market makers have become more cautious on the bid side.

In perpetual futures markets, asymmetry carries a special meaning that spot markets lack. Because of high leverage and the forced-liquidation mechanism, order book asymmetry often carries key information about liquidation risk. If bid-side depth suddenly thins sharply at a specific price level below the current price, this very likely means that market makers foresee a large cluster of long-liquidation trigger prices near that level. To avoid becoming the counterparty to toxic order flow in a liquidation cascade, market makers selectively withdraw bid orders in that region. In perpetual futures, therefore, asymmetry is not merely a reflection of directional pressure but an early-warning signal of the market's endogenous fragility.

8.4.2 Slope and convexity/concavity

Beyond symmetry, the slope and the convexity/concavity of the order book are two further key dimensions for describing its topological features. Slope is defined as the rate at which resting depth decays as distance from the mid price increases. It reflects the distribution of liquidity along the price axis and directly determines the market's capacity to absorb the impact of large orders.

A gentle slope means that liquidity is evenly distributed across a relatively wide price range. In this configuration, even a relatively large market order produces only relatively mild price slippage, because the subsequent depth can quickly take over and absorb the impact. Conversely, a steep slope indicates that liquidity is highly concentrated near the mid price. Once the price moves beyond this narrow high-liquidity band, the market rapidly enters a thin liquidity vacuum. In an order book with a steep slope, the market's impact-absorption capacity is significantly reduced, and even a tiny order imbalance can trigger a violent price jump.

Convexity/concavity, in turn, is the rate of change of the slope; it reveals the second-

derivative feature of order book depth. A normal order book typically exhibits a "convex" shape — that is, depth decays at a decreasing rate as the price deviates from the mid price, with the decline in depth becoming gentler the farther out one goes. When the order book exhibits a "concave" feature, however — that is, depth drops sharply at a specific price level and then recovers only slowly in a farther price range — this usually means that some "structural obstacle" exists in the market microstructure.

In the context of perpetual futures, this structural obstacle that gives the order book a concave shape is, in the vast majority of cases, the dense liquidation-price zone. Market makers' strategic retreat carves a distinct "pit" into the depth curve. Anomalous changes in convexity/concavity — especially the emergence of a concave feature — are therefore an important topological indicator for identifying the accumulation of liquidation risk and assessing the market's extreme fragility.

8.4.3 Order book morphology

By combining topological features such as symmetry, slope, and convexity/concavity, we can classify the complex shapes of the order book into five typical morphologies. These five morphologies form a continuous spectrum reflecting the market's different phases, from extreme calm to extreme panic.

At one end of the spectrum is the "thick book" morphology, the typical representation of the market in its healthiest state: order book depth is ample, the two sides are highly symmetric, the slope is gentle and exhibits normal convexity, the market has an extremely strong impact-absorption capacity, volatility is at a low level, and market makers' willingness to supply liquidity is abundant.

When market activity declines, the order book often evolves into the "thin book" morphology, in which overall depth is limited but symmetry is still fairly well preserved. It typically appears during low-activity periods such as weekends, holidays, or the late night of a particular time zone; although depth is shallow, the absence of pronounced one-directional pressure keeps the market in a relatively balanced state.

Further deterioration presents as the "skewed book" morphology: when the market develops directional pressure or when market makers engage in one-sided risk avoidance, the order book exhibits pronounced asymmetry — deep on one side, shallow on the other. This is common in trending markets or when the price gradually approaches an important support or resistance level.

More extreme still is the "cliff book" morphology unique to perpetual futures markets: below (or above) a specific price level, depth drops abruptly, forming a distinct "cliff." This is direct microstructural evidence of the existence of a dense liquidation zone, marking that leverage accumulation has reached a statistically high level and that market makers are engaged in a defensive withdrawal of liquidity.

At the other end of the spectrum is the "vacuum book" morphology, the hallmark of severe liquidity exhaustion: bid- or ask-side depth has fallen to nearly zero, and market makers have withdrawn entirely from the order book. It typically appears at the peak moment of an extreme crisis event, such as when a liquidation cascade is in full swing, at which point the market has lost any meaningful pricing capacity.

Figure 8-8 arranges the five morphologies along a continuous spectrum from maximum resilience to complete fragility. This arrangement reveals a structural regularity: the progression from "thick book" to "vacuum book" is not a random jump but an ordered degradation — depth contracts, symmetry breaks, and the slope shifts from gentle to steep until it ruptures — with each phase containing the precursor signals of deterioration into the next.

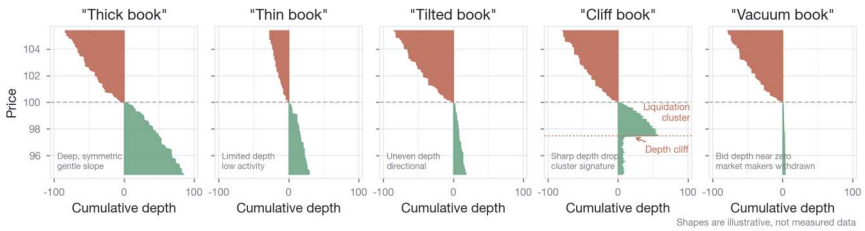

Figure 8-8. A visualization of the five order book morphologies (conceptual illustration of the five order book morphologies; synthetic depth profiles, not empirical data)

From left to right, the figure shows the ordered degradation of the order book from "thick book" to "vacuum book"; the cliff book and vacuum book are morphologies unique to perpetual futures under extreme stress and almost never appear in traditional spot markets. Table 8-3 further summarizes, in a feature matrix, the differences among the morphologies along three dimensions — topological features, market implications, and typical occurrence scenarios — providing traders and risk managers with a rapid classification and diagnostic framework based on topological features.

Morphology	Topological features	Market implications	Typical occurrence scenario
"Thick book"	Ample depth, symmetric on both sides, gentle slope	Market healthy, strong impact-absorption capacity	Calm periods, low volatility, ample market-maker confidence
"Thin book"	Limited depth, but still symmetric	Low market activity, no pronounced directional pressure	Weekends, holidays, or liquidity-trough periods
"Skewed book"	Deep on one side, shallow on the other, pronounced asymmetry	Presence of directional pressure or one-sided market-maker risk avoidance	Trending markets, or when the price approaches an important support/resistance level
"Cliff book"	Depth drops abruptly near a certain price level, exhibiting concavity	Unique to perpetual futures: dense liquidation zone, defensive market-maker retreat	Leverage-accumulation periods, with the OI-to-market-cap ratio markedly elevated
"Vacuum book"	Depth on one side (usually the bid side) is nearly zero	Liquidity collapse, complete market-maker retreat, liquidation cascade underway	The peak moment of an extreme crisis event (such as a flash crash)

8.4.4 The mapping between morphology and market state

The evolution of order book morphology is not random; it maps strictly onto the deterioration of the macro market state. The transition from "healthy" to "collapsed" exhibits complex dynamics in which continuous deterioration and nonlinear jumps coexist. During the evolution from "healthy" to "tense" to "fragile," the changes in the order book's topological structure are indeed traceable and approximately continuous: the gradual widening of the spread, the progressive contraction of one-sided depth, and the steady climb of the cancellation rate all constitute traceable precursor warning signals. The transition from "fragile" to "collapsed," however, may exhibit a phase-transition-like nonlinear jump. Sornette's (2003) research on critical phenomena in financial markets shows that systemic collapse often manifests as "quasi-continuous" micro-deterioration that, upon reaching a critical threshold, suddenly triggers a violent qualitative change at the macro level [20]. The empirical observation that "70% of the damage was concentrated within 40 minutes" in the October 2025 event is precisely a textbook feature of a critical transition: the system had already accumulated sufficient fragility at the micro level, but the macro-level collapse, once triggered, erupted in a discontinuous manner, with no gradual transitional phase available for intervention in between.

The starting point of this continuous deterioration is the transition from healthy to tense, manifested as the evolution from "thick book" to "skewed book." When the market receives an initial shock or a directional expectation begins to form, the spread starts to widen, one-sided depth begins to contract, the order book evolves from a symmetric "thick book" into an asymmetric "skewed book," and the market-maker cancellation rate begins to rise, indicating that their sensitivity to risk is increasing. As leverage accumulates further and the price moves in an adverse direction, the market slides from tense into fragile: market makers foresee liquidation risk and begin to actively withdraw liquidity near the dense liquidation zone, and the "cliff book" morphology appears on the order book. This is the key marker that the market has entered a highly fragile state, indicating that even a tiny shock could trigger a chain reaction. Once the price breaks through the residual depth above the "cliff" and touches the liquidation trigger line, the market plunges from fragile into the collapse phase: a large volume of forced market orders floods in, market makers instantly cancel all remaining quotes to control their own risk exposure, bid-side depth is entirely consumed, the order book evolves into a "vacuum book," and the positive feedback loop of the liquidation cascade unfolds in full. When all the liquidation momentum has been released, the market enters the long process from collapse to recovery: the price stabilizes at the bottom, market makers re-enter the market with smaller order sizes and wider quote intervals, and the order book gradually recovers to a "thin book" morphology with limited depth. Only with the passage of time and the gradual rebuilding of confidence can depth slowly return to the "thick book" state. It should be noted that the speed of this recovery is often far slower than the speed of the collapse, reflecting the asymmetry of perpetual futures market resilience.

Figure 8-9 uses a state-transition diagram to map the characteristic microstructural signal corresponding to each phase transition (each transition signal is labeled in the figure). Particular attention should be paid to the pronounced asymmetry of the recovery path: the return from collapse to health is far longer than the deterioration path and must pass through a gradual rebuilding of "vacuum book → thin book → thick book," reflecting the time cost of market makers' capital redeployment, risk-model recalibration, and gradual restoration of confidence after an extreme event.

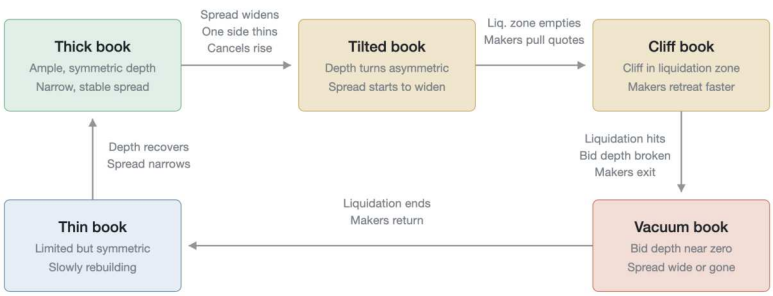

Figure 8-9. The transition path between order book morphology and market state (conceptual illustration of the morphology-to-market-state mapping path, not empirical data)

In theory, an analyst who continuously monitors the evolution of the order book's topological structure can identify the early indicators of rising market fragility before a collapse occurs. This morphology-based diagnostic capability constitutes the core foundation for the discussion of volatility clustering and the construction of a liquidity early-warning system in later chapters.

8.5 The four fingerprints of the perpetual futures order book

The underlying financial rules of perpetual futures (in particular high leverage, forced liquidation, the funding rate mechanism, and the around-the-clock, uninterrupted trading environment) significantly alter their market microstructure. These distinctive institutional features produce observable structural characteristics on the order book, which we call the "four fingerprints." These microstructural patterns simply do not exist in traditional spot markets or in futures markets with an expiry date. The four fingerprints constitute a microstructural diagnostic framework designed specifically for perpetual futures.

8.5.1 The depth cliff

In perpetual futures markets, because of the widespread use of high leverage, traders' liquidation trigger prices often cluster heavily within certain specific price ranges, forming what is called a "dense liquidation-price zone." When the price approaches these

zones, a distinct topological feature appears on the order book: the depth cliff. Specifically, bid-side (or ask-side) depth near that price level becomes abnormally thin, and the depth curve exhibits a cliff-like vertical drop.

The cause of the depth cliff is market makers' defensive order cancellation: high-frequency market makers can identify the location of dense liquidation zones with considerable precision and foresee that, once the price touches them, the liquidation engine will throw out the toxic liquidation orders described in Section 8.3.1 (involuntary, entirely price-insensitive, far larger than normal orders). Unwilling to serve as the counterparty here, they sharply reduce their resting orders in that region in advance, or push their quotes to deeper and wider levels, artificially creating a liquidity vacuum. This complete causal chain of "identify the dense liquidation zone → defensive cancellation → liquidity vacuum" was developed in Section 8.2.4.

Figure 8-10 visually shows the formation mechanism of the depth cliff and its spatial overlay with liquidation-price density.

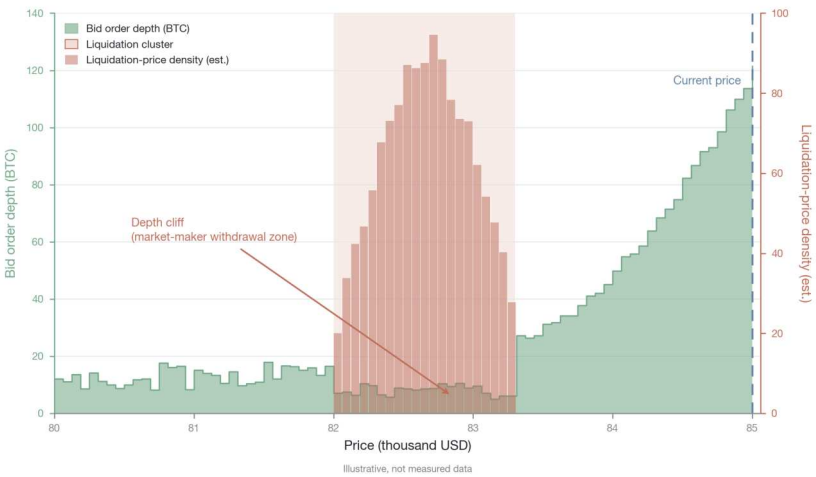

Figure 8-10. The depth cliff at the dense liquidation-price zone (conceptual illustration of the depth cliff; both bid-side depth and liquidation-price density are illustrative, not empirical data)

The existence of the depth cliff gives the dense liquidation zone a dangerous game-theoretic property: it becomes a positive-feedback region with a self-fulfilling tendency. Once the price falls into the cliff region, the lack of sufficient bid support means that even minimal ordinary selling pressure is enough to consume the remaining thin depth and push the price directly to the liquidation trigger line. The triggered liquidation orders then execute continuously in the low-liquidity range that lacks counterparty quotes, causing a violent price plunge that in turn triggers deeper liquidations. This is precisely the core transmission mechanism of the liquidation cascade at the level of the micro order book. In an on-chain transparent environment, this mechanism may even be maliciously exploited and evolve into a strategic liquidity attack.

8.5.2 The depth tide

Perpetual futures anchor the contract price to the spot index price through the funding rate mechanism. This mechanism requires longs and shorts to exchange funds at specific settlement moments (typically every 8 hours, or every hour on some high-frequency platforms). This cyclical institutional arrangement gives rise to the second fingerprint on the order book: the depth tide.

The depth tide manifests as cyclical, predictable fluctuations in the order book's depth, spread, and bid-ask asymmetry around the funding-settlement moment. According to the empirical study by Ruan and Streltsov (2022), this tidal phenomenon is especially pronounced when the expected funding rate is positive (that is, longs must pay shorts) and high [15].

In the several hours approaching settlement, the market experiences an "ebb tide" period. To avoid paying a high funding rate, cost-sensitive long traders choose to close positions briefly before settlement. This significantly increases selling pressure, and the order book develops a pronounced sell-side skew. Funding-rate arbitrageurs, meanwhile, establish short positions to collect the rate, further intensifying sell-side pressure. Faced with this one-directional, structural order-flow imbalance, market makers — to control inventory risk — actively widen the bid-ask spread and reduce resting depth.

After the settlement moment passes, the market enters a "flood tide" period. Longs that had avoided the rate re-establish their positions, arbitrageurs may close and exit, and directional pressure quickly recedes. Market makers accordingly narrow the spread and restore resting orders, and the order book's depth and symmetry return to normal levels.

The morphology and intensity of the depth tide depend heavily on the design of the funding-rate settlement frequency. The traditional 8-hour settlement cycle (such as Binance's UTC 00:00/08:00/16:00) produces the clearest tidal pattern, because the rate accumulates a large enough payable amount over the longer accumulation period that the directional order flow around settlement is sufficient to leave a discernible structural feature on the order book. As exchanges compete to introduce higher-frequency settlement mechanisms (Binance has implemented 4-hour settlement for some trading pairs, and Hyperliquid uses hourly settlement), however, the payable amount at each settlement shrinks correspondingly, and the amplitude of the tide weakens with it. If the settlement frequency were raised further to a near-real-time variable-rate system, the directional impact of a single settlement might fall below the level of market noise, at which point the diagnostic value of the depth-tide fingerprint would be significantly diminished. In addition, in an extreme funding-rate environment (an annualized rate exceeding 100%), the normal tidal pattern may fail entirely: the scale of directional position closing before settlement may exceed market makers' normal absorption capacity, causing the tide to shift from a regular ebb-and-flow into a one-directional liquidity shock.

Figure 8-11 simulates and displays this cyclical tidal process based on the characteristics of empirical data.

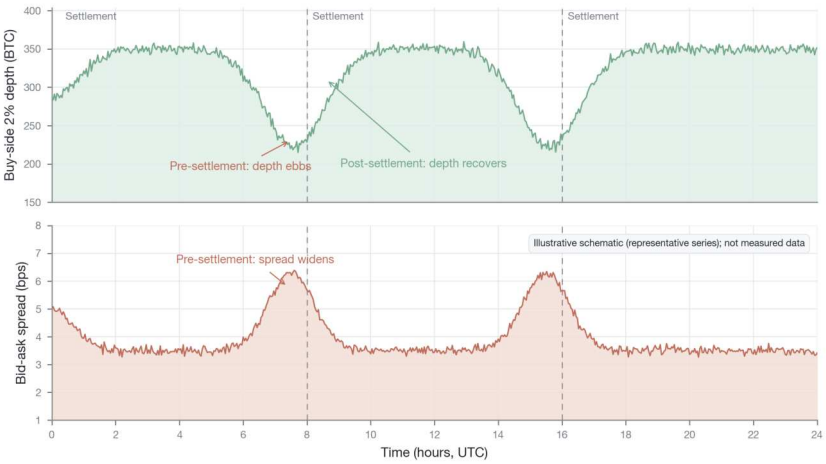

Figure 8-11. The depth tide around funding-rate settlement

Note: This figure is a theoretical illustration drawn from the characteristic parameters of the empirical data in Ruan and Streltsov (2022) [15] (a synthetic illustration of the depth tide, not empirical data). The depth tide is a microstructural feature unique to perpetual futures. It shows that even in the absence of an external macro information shock, internal institutional friction alone is enough to cause a cyclical contraction of market liquidity. For an ordinary trader, executing a large order during the ebb-tide period entails significantly higher implicit transaction costs (slippage).

8.5.3 The liquidity circadian rhythm

The cryptocurrency perpetual futures market is the world's first trillion-dollar financial market to achieve genuine around-the-clock, uninterrupted operation. The continuity of trading hours, however, does not equate to uniformity in the distribution of liquidity. On the contrary, the order book exhibits a third fingerprint highly correlated with the time zones of the world's major financial centers: the liquidity circadian rhythm.

Structurally, this rhythm exhibits a pronounced alternation of peaks and troughs. The absolute peak of liquidity typically appears during the few hours in which the European and American trading sessions overlap (approximately UTC 13:00–17:00). At this time, the world's most important institutional investors, high-frequency market makers, and active traders are online simultaneously, order book depth reaches its maximum, the spread compresses to an extremely narrow level, and the market's resilience in absorbing shocks is strongest.

By contrast, the trough of liquidity appears during the "transition period" between the close of the American market and the full activation of the Asian market (approximately UTC 00:00–05:00), as well as during traditional weekend periods. In these trough periods, the algorithms of many Western institutional market makers may enter a low-risk operating mode or reduce their quoting frequency, causing order book depth to fall significantly below peak-period levels and accompanied by a widening of the spread.

Figure 8-12, by superimposing the activity of different time zones, clearly delineates

this 24/7 liquidity rhythm.

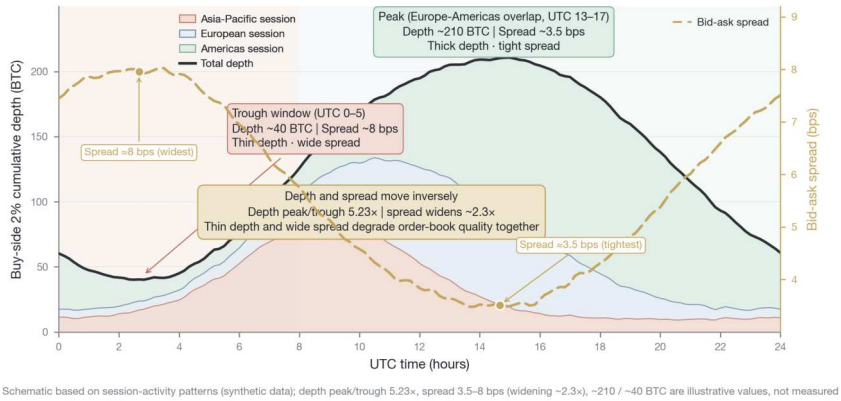

Figure 8-12. The 24/7 liquidity circadian rhythm (a stylized illustration of the 24/7 liquidity circadian rhythm: the peak of about 210 BTC, the trough of about 40 BTC, and the peak-to-trough ratio of 5.23x are synthetic representative values, not empirical data)

The existence of this rhythm reveals a serious endogenous risk of the perpetual futures market. In traditional financial markets, the market-close mechanism functionally serves to interrupt the transmission of negative feedback. The perpetual futures market lacks this interruption mechanism; in its place are cyclical liquidity-trough periods. The problem is that a trough not only fails to cushion shocks but actually becomes a window in which they amplify more easily. If a sudden piece of bad news is encountered during a liquidity-trough period, or a liquidation cascade is triggered, its destructive power is amplified exponentially, because there is simply not enough depth at that time to absorb the selling pressure.

8.5.4 The asymmetric response of the spread

In traditional low-leverage spot markets, the bid-ask spread's response to market volatility is typically approximately symmetric. That is, whether volatility is caused by a price rise or a price fall, market makers synchronously widen the spread and reduce depth on both the bid and ask sides to compensate for the increased adverse-selection risk. In the high-leverage environment of perpetual futures, however, the order book exhibits a fourth fingerprint: the asymmetric volatility response of the spread.

Specifically, during a volatility spike triggered by a sharp price decline, the widening of the order book's bid-side spread is significantly greater than the widening of the ask-side spread during volatility triggered by a sharp price rise. This asymmetry is deeply rooted in the crypto market's systematic long bias and in the asymmetry of the liquidation mechanism.

When the price falls, a large volume of high-leverage long positions faces liquidation. As noted earlier, this produces a massive volume of price-insensitive forced sell orders. Foreseeing this impending large-scale toxic selling pressure, market makers rapidly cancel their bid quotes, causing bid-side depth to plunge to near zero and the bid-side

spread to widen nonlinearly.

By comparison, although a price rise also triggers short liquidations and generates forced buy orders, in the vast majority of periods the scale of longs in the crypto market far exceeds that of shorts. The forced-buy impact during a rise is therefore typically smaller in magnitude than the forced-sell impact during a fall. The magnitude and speed of market makers' retreat on the ask side are correspondingly smaller, and the widening of the ask-side spread is relatively mild.

Figure 8-13, through a scatter plot and a fitted curve, visually shows this asymmetric response pattern.

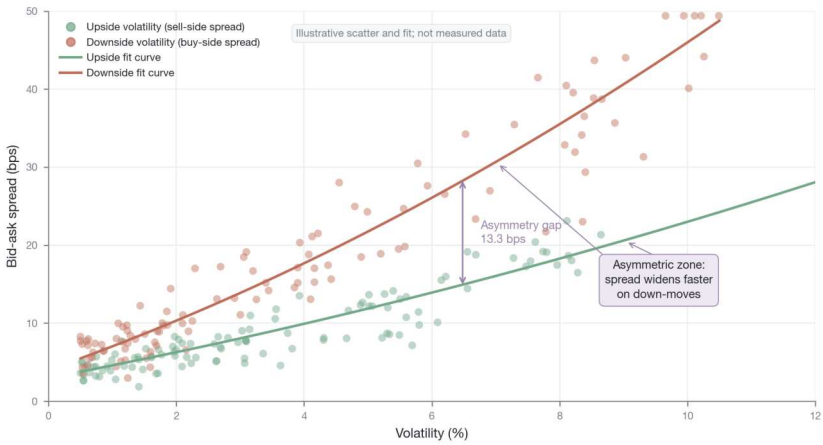

Figure 8-13. The asymmetric volatility response of the spread (a synthetic scatter illustration of the asymmetric volatility response of the spread: the 13.3 basis points is a representative asymmetry gap, not empirical data)

The scatter in the figure reveals this structural skew: the fitted slope of the bid-side spread in the negative-return (decline) range is significantly greater than that of the ask-side spread in the positive-return (rise) range, meaning that under the same magnitude of volatility shock, a decline systematically damages bid-side liquidity more than a rise damages ask-side liquidity. This is precisely the microstructural root of the perpetual futures adage that "declines tend to be faster than rises" — the forced liquidation selling pressure, the rapid retreat of market makers, and the sharp drop in depth occur simultaneously and reinforce one another, forming a high-intensity positive feedback loop.

8.5.5 The superposition effect of the four fingerprints

The four fingerprints described above (the depth cliff, the depth tide, the liquidity rhythm, and the asymmetric response) do not exist in isolation. In specific market environments, they undergo a high-risk resonance and superposition, producing a market-shock magnitude far exceeding that of any single factor. Understanding this superposition effect is key to building an advanced market-risk early-warning system.

In the most dangerous superposition scenario, the market has undergone a prolonged

one-directional rise and has accumulated a large volume of high-leverage long positions, and the funding rate remains positive and high (Fingerprint 2: longs are unwilling to close positions, and leverage is locked in). At this point, a dense liquidation-trigger zone has already formed just below the current price (Fingerprint 1: a depth cliff is emerging). If this happens to coincide with a liquidity-trough period on a weekend or in the early Asian morning (Fingerprint 3: depth is at its weakest overall), then once a tiny piece of negative news causes the price to dip slightly, it can easily break through the already-thin bid-side depth. After touching the liquidation line, the enormous selling pressure from long liquidations causes market makers to retreat sharply on one side (Fingerprint 4: the bid-side spread asymmetry widens to an extreme). In that instant, all four fingerprints point simultaneously to "liquidity collapse," and the probability of a flash crash rises sharply.

To monitor this superposition risk systematically, we can construct a "comprehensive perpetual futures order book risk dashboard" (Figure 8-14). This dashboard tracks the state indicators of the four fingerprints in real time, and when multiple indicators simultaneously break through their warning — or even danger — thresholds, it issues the highest-level systemic-risk alert.

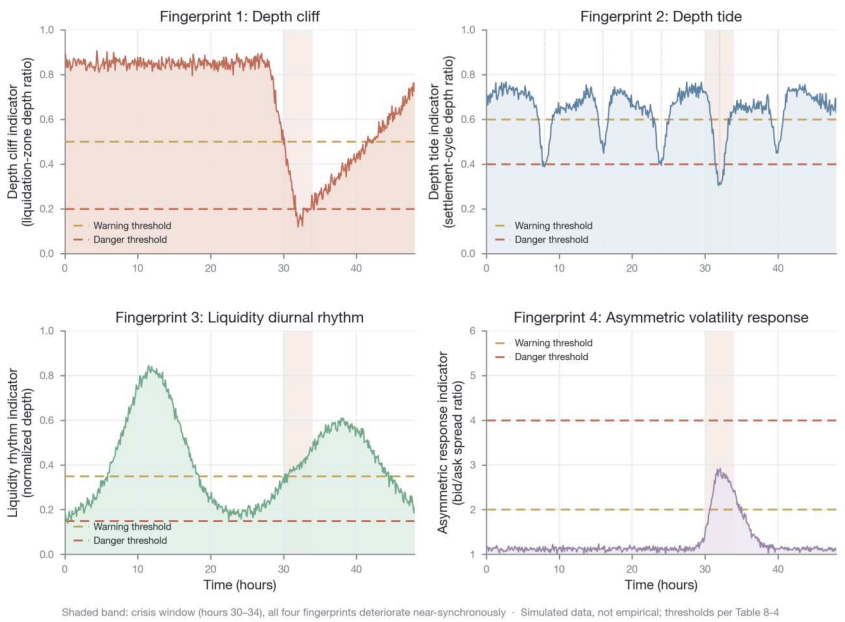

Figure 8-14. The comprehensive risk dashboard of the four fingerprints

Note: This figure is drawn from simulated data based on the characteristic parameters of historical events (the thresholds of the four fingerprints are the author's ratings, not empirical data). During the crisis period (the shaded region), the indicators of the four fingerprint dimensions deteriorate almost synchronously within an extremely short time window. This synchronized deterioration pattern is the core criterion for distinguishing a systemic-risk event from normal volatility. The diagnostic value of the dashboard lies in capturing the synchronized-deterioration signal across multiple dimensions, rather than monitoring the absolute level of any single indicator.

Table 8-4 lists the parameters of this comprehensive diagnostic matrix. The thresholds for each fingerprint dimension are calibrated on the basis of backtesting analysis of multiple historical extreme events, including the October 2025 flash crash (the thresholds are calibrated through historical backtesting; specifically, the distribution of each indicator across multiple extreme events is analyzed statistically, and the corresponding quantiles are selected as the grading boundaries).

Fingerprint dimension	Core observation indicator	Normal-state benchmark	Warning threshold (entering the tense period)	Danger threshold (approaching the collapse point)
Fingerprint 1: depth cliff	Bid-side depth in the dense liquidation zone / average depth in the normal range	$> 80\%$	$< 50\%$	$< 20\%$ (market makers have clearly retreated)
Fingerprint 2: depth tide	Depth 1 hour before settlement / average depth within the cycle	~ 90%	$< 60\%$	$< 40\%$ (accompanied by an extremely high funding rate)
Fingerprint 3: liquidity rhythm	Total depth in the current period / 24-hour peak depth	Naturally fluctuates by period (typically $> 50\%$)	$< 35\%$	$< 15\%$ (period of extreme liquidity exhaustion)
Fingerprint 4: asymmetric response	Bid-side spread widening rate during a decline / ask-side spread widening rate during a rise	~ 1.0–1.2 (slight long bias)	> 2.0	> 4.0 (one-sided liquidity is being drained)

Table 8-4. The comprehensive diagnostic matrix of the four fingerprints (Data source: compiled by the author)

The threshold settings in the diagnostic matrix above face several applicability limitations, and users should regard them as a methodological framework rather than fixed point estimates. First, the validity of the thresholds depends on a specific volatility regime: an indicator reading flagged as "dangerous" in a low-volatility environment may fall within the normal fluctuation range under a high-volatility regime, and vice versa. Fixed thresholds therefore run the risk of being invalidated by a switch in volatility regime; a more robust approach is to use conditional thresholds — that is, to replace absolute levels with the distributional quantiles of the indicator within a rolling window, so that the thresholds adapt to the market state. Second, the thresholds for Fingerprint 4 (the asymmetric spread response) — normal at about 1.0–1.2, warning at $>$ 2.0, danger at > 4.0 — are at present inferred mainly from the mechanistic narrative of the "systematic long bias" and still lack independent quantitative empirical anchoring; they should be regarded as illustrative. Moreover, all of the above thresholds are calibrated on BTC historical data as a whole, and their extension to altcoins and long-tail assets requires recalibration: the normal-state liquidity level, volatility structure, and participant composition of these assets differ systematically from those of BTC, and

applying the BTC thresholds directly may produce a large number of false positives or false negatives. The core value of this matrix lies in providing a multidimensional joint-monitoring diagnostic methodology, not a set of static numbers that can be applied mechanically.

In sum, the four fingerprints of the perpetual futures order book are both the microscopic projection of its distinctive institutional design and microstructural diagnostic tools in their own right. By integrating the signals of these four dimensions, we can move beyond surface-level price fluctuations and systematically identify how liquidity evolves from ample to fragile to collapsed.

8.6 Order book resilience

Operationalizing "resilience" from a vague qualitative concept into a measurable micro indicator is a key step in understanding the dynamic properties of the order book. The preceding sections analyzed the static structure of the order book (depth, slope, morphology) and the four fingerprints of perpetual futures, but all of these analyses are cross-sectional descriptions of the order book state "at a single moment." Introducing the time dimension, we will argue that the resilience of the perpetual futures order book is systematically weaker than that of the spot market — not a technical defect but an intrinsic cost that necessarily accompanies the institutional combination of "high leverage + liquidation mechanism + no expiry date + 24/7 trading." The positive-feedback mechanism of the liquidation cascade makes shocks not only larger in scale but also self-amplifying, thereby significantly lengthening the recovery time. The measurement of resilience provides a key micro foundation for the market-quality assessment in Chapter 25. In the October 2025 flash crash, the market experienced the extreme asymmetry of "collapse in about 2 hours, recovery over more than 24 hours," which is a real-world portrayal of the resilience characteristics of perpetual futures [2].

8.6.1 The operational definition and measurement of resilience

In the market microstructure literature, liquidity is typically decomposed into three dimensions: tightness (the size of the spread), depth (the order size the market can absorb without causing a significant price move), and resilience (the speed of recovery to a normal state after a shock). The first two dimensions are static descriptions of the order book at a single moment, whereas resilience characterizes the order book's dynamic adjustment capacity. In his seminal paper, Large (2007) explicitly proposed that an electronic limit order book possesses resilience when it can rapidly restore its normal shape after a large trade [21]. This definition transforms resilience from a vague intuition into an operational concept that can be empirically tested with time-series data.

We operationally define order book resilience as follows:

> the time required for the order book's spread and depth to recover to their pre-shock levels after it is subjected to a standardized shock.

The specific measurement method comprises the following steps. First, select a "standardized shock" as the starting point of the measurement. A standardized shock refers to a market order that consumes a certain proportion (for example, 50% or more) of the depth near the current best bid and ask, or an observable price jump driven by an exogenous event. Record the instant the shock occurs, t_0, at which the spread widens from its pre-shock steady-state level S_0 to S_1, while cumulative depth falls from D_0 to D_1. Subsequently, track the recovery process of these two core state variables. Record the time required for the spread to recover to the pre-and-post-shock mean $0.5 \times (S_0 + S_1)$, denoted τ_{spread}; record the time required for depth to recover to $0.5 \times (D_0 + D_1)$, denoted τ_{depth} [22]. The resilience indicator is a function of these two time variables. The smaller the value of τ, the faster the market recovers from the liquidity vacuum, and the stronger the resilience of the order book.

A more precise operational definition of "recovery" itself is needed. The framework above uses the midpoint of the pre-and-post-shock mean (that is, a 50% recovery rate relative to the pre-shock level) as the recovery threshold, but different analytical purposes may require different recovery criteria: the τ values corresponding to a 75% recovery rate and a 90% recovery rate may differ by several fold. In addition, the recovery speed differs significantly across price tiers: depth near the best bid and ask typically recovers fastest, because market makers prioritize re-posting at the most profitable best-price levels, whereas the deeper regions of the order book far from the mid price take longer to recover, because the return to providing liquidity at these levels is lower and the adverse-selection risk is higher [9]. A single τ value may therefore mask the significant heterogeneity in recovery speed across price tiers.

Empirical research shows that in traditional markets the different dimensions of the order book deteriorate simultaneously after a shock but recover at significantly different speeds. Wuyts (2008) documented this pattern of synchronous deterioration and uneven recovery [22], and Lo and Hall (2015) further confirmed that the spread typically recovers faster than depth [23]. This finding has an intuitive economic interpretation: after a shock, market makers tend to first provide a small amount of liquidity at the best price to narrow the spread (a "tentative" return that carries little risk), and then gradually replenish the depth at each price tier in response to market feedback (a "committed" return that requires greater capital investment and stronger confidence).

This asymmetric recovery pattern of "spread recovers first, depth recovers later" is further amplified in perpetual futures markets. As shown in Figure 8-15, in a typical shock event the spread and depth of the spot market can both recover to close to pre-shock levels within a relatively short time (on the order of minutes). The perpetual futures market, by contrast, not only experiences a larger initial shock (because of the amplification effect of the liquidation cascade) but also follows a more tortuous recovery path, in which a liquidation-triggered "secondary shock" may appear after the initial shock, repeatedly interrupting the recovery process. More critically, perpetual futures depth often cannot fully recover to its pre-shock level but instead stabilizes at a lower "new baseline," reflecting market makers' permanent reassessment of risk exposure after an extreme event.

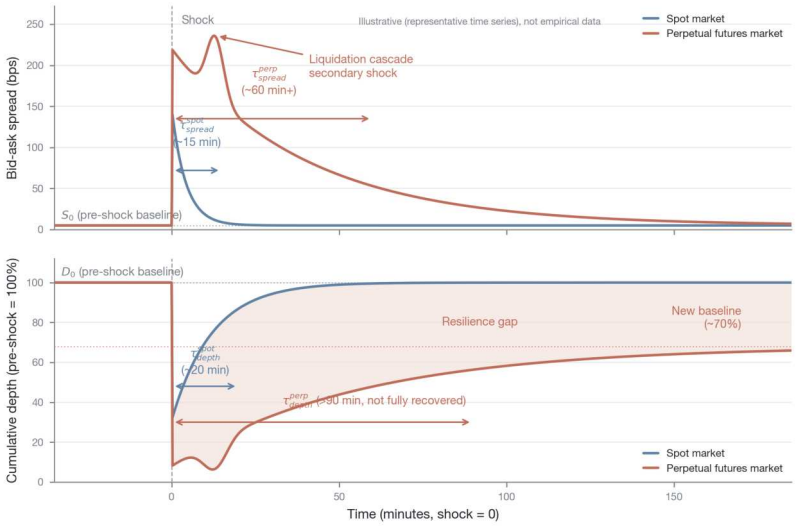

Figure 8-15. The resilience measurement of the shock-recovery time series (a conceptual time-series illustration of order book shock-recovery resilience; the τ, the ~70% new baseline, and similar values are conceptual illustrative values, not empirical data)

The upper and lower panels of the figure track, respectively, the post-shock recovery paths of the spread and of depth. In the spot market (dashed line), both the spread and depth return to close to pre-shock levels within minutes; in perpetual futures (solid line), the initial shock is not only larger ($S_1 - S_0$ and $D_0 - D_1$ are both significantly greater than in spot) but also, in the initial recovery phase, a liquidation cascade produces a "secondary shock" (marked in red in the upper panel as "liquidation-cascade secondary shock"), so that the recovery curve is sawtooth-shaped rather than a smooth monotonic path. More critical is the recovery endpoint: spot depth returns to close to D_0, whereas perpetual depth stabilizes at a significantly lower "new baseline" D_0', with the gap $\Delta D = D_0 - D_0'$ quantifying market makers' permanent reassessment of risk exposure.

8.6.2 The structural disadvantage in resilience

By comparing the recovery paths of perpetual futures and the spot market, one finds that the resilience of perpetual futures is systematically weaker than that of spot. This disadvantage does not stem from a deficiency in technical performance but is caused by three structural reasons derived from its core institutional features.

The foremost structural reason is the positive-feedback mechanism of liquidation. In a spot market, the shock produced by a large sell order is typically a one-time, exogenous event. Once the seller has completed the sale, the selling pressure ends. After absorbing the shock, if market makers assess that no new fundamental information is driving events, they quickly adjust their quotes, and price and depth tend to recover naturally. In perpetual futures markets, however, the situation is entirely different. A large sell order not only produces the initial price shock but is also highly likely to trigger the forced liquidation of leveraged long positions. The liquidation engine throws these positions into the market as market orders, producing a new round of selling pressure. This new selling pressure pushes the price down further, thereby triggering deeper liquida-

tions. The shock is no longer an isolated one-time event but a self-amplifying positive feedback loop. Market makers are keenly aware of the destructive power of this positive feedback loop. After a shock, therefore, a rational market maker will not immediately provide liquidity but must wait until "all liquidations that can be triggered have been completed" and confirm that the selling pressure has been thoroughly exhausted before beginning to slowly restore quotes and depth [2]. This rational behavior of "waiting for the liquidations to end" is precisely what lengthens the duration of the market's low-resilience state.

The flash crash of October 10, 2025, provides extreme empirical evidence of this mechanism. FTI Consulting's post-mortem report noted that on that day the depth near the best bid of BTC perpetual futures contracted by more than 90%, and the bid-ask spread widened from the normal single-digit basis points to double-digit percentages [2]. Two different depth measures must be distinguished: the ">90%" contraction described under "stress depth" in Section 8.2 characterizes the instantaneous stress-depth collapse at the 21:15 UTC cascade peak, whereas the following persistent decline characterizes the residual depth level that had not recovered weeks after the crisis; the two differ in measure and in moment. As for the persistent residual, CoinDesk Research's follow-up tracking data show that the order book depth of BTC within the 1% price range (two-sided) fell from about $20 million before the shock to about $14 million, a decline of nearly one-third, and had still not recovered to pre-shock levels five weeks after the event [3]. Amberdata's analysis in February 2026 went further, noting that BTC's order book depth within the 10-basis-point range plunged about 63%, from a peak of $38 million in September 2025 to $14 million (this 10-basis-point window differs in measure from the 1% window above, and its baseline moment is also the September 2025 peak rather than the eve of the crash, so the two sets of figures cannot be compared directly), and that "the market never fully recovered" [24]. Together, these data indicate that the collapse took only about 2 hours, whereas the recovery (if it can be called a "recovery") remained incomplete months later.

Attributing the persistent depression of depth entirely to "resilience failure," however, may be an oversimplification. Market makers' reduction of quote size and depth after the crisis was partly a rational repricing based on higher volatility expectations: after an extreme event, market makers systematically revise their estimates of future volatility upward, and a wider spread and thinner depth are their optimal response in a higher-risk environment, rather than pure loss of confidence or inadequacy of capacity [12]. In addition, the actual losses suffered during the crisis also consumed market makers' available capital, limiting their capacity to restore their market-making scale. The post-crisis "new baseline" of depth therefore contains both a structural resilience defect (that is, the system lacks a mechanism at the institutional level to promote rapid recovery) and market makers' reasonable behavioral adjustment based on a new information set. Distinguishing these two components is of significant analytical value for assessing whether the market is truly "damaged" or merely "repriced."

At the same time, the lowering of market makers' retreat threshold further weakens resilience. As discussed in Section 8.2.2, perpetual futures abolish the expiry date, causing market makers to bear open-ended inventory risk and depriving them of the definite risk-termination point and natural exit of the traditional futures "hold to delivery."

This open-ended risk exposure significantly lowers market makers' retreat threshold when market uncertainty rises: at the earliest sign of an anomaly, they are more inclined to cancel orders immediately to protect capital rather than "wait a little longer," which weakens their willingness to "stay in the market and provide resilience" and causes the order book to enter a "vacuum" state faster after a shock. CoinDesk Research described this phenomenon as "a prudential contraction of market-making commitment" and regarded it as a "structural shift" rather than a temporary panic reaction [3].

Building on this, the absence of a "reset window" caused by the 24/7 operating model constitutes another important factor. Traditional financial markets have fixed trading hours, and the closed period provides the market with a natural "resilience-recovery window": market makers can reassess their risk exposure, adjust pricing models, replenish margin, and re-enter the next day in a fresher state and with more ample capital. This window also provides three often-overlooked functions — time to digest information (rationally assessing new information during non-trading hours and avoiding overreaction under immediate emotion), cross-time-zone coordination (participants in different time zones fully pricing in the same event during their respective active periods), and a definite point for clearing and settlement (providing an institutional deadline for margin calls and risk-position adjustments). The around-the-clock operation of perpetual futures means all three functions are simultaneously absent, and market makers must make "stay or leave" decisions in real time under a continuous flow of information and pressure, so that the system's continuous fatigue further weakens its recovery capacity after an extreme event. Combined with the "liquidity circadian rhythm" analyzed in Section 8.5.3, if a shock happens to coincide with a liquidity-trough period (such as between the American close and the Asian open), the absence of market-making force worsens resilience further. The October 2025 event occurred at 20:50 UTC, at the tail end of the American trading session, when the activity of European and American market makers was declining and Asia-Pacific had not yet fully started — not the absolute trough of the 24-hour cycle, but already on the downward slope of the transition from peak to trough [2]. This coincidence of the liquidity level with the moment of crisis may have had a strategic component, and it also amplified the system's vulnerability to shocks during a relatively weak period.

Figure 8-16, in the form of a causal diagram, provides a systematic visualization of the three structural reasons above and the specific paths by which they transmit to order book resilience.

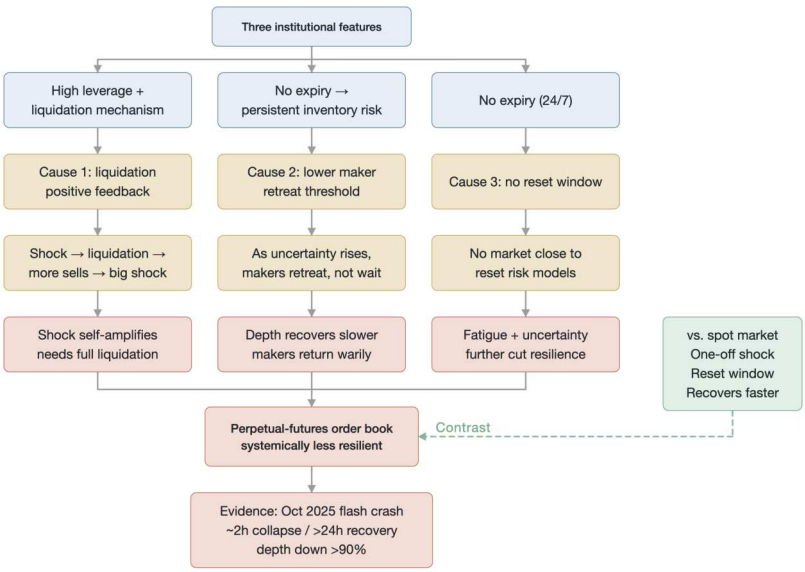

Figure 8-16. The causal mechanism of the resilience disadvantage of perpetual futures (an illustration of the three-cause causal mechanism; at the bottom, "October 2025 flash crash depth contraction >90%" is hard data, and "collapse in about 2 hours / recovery over more than 24 hours" is a representative time scale; following CoinDesk, November 15, 2025 [3])

The causal diagram reveals the synergy of three paths: the liquidation positive feedback produces immediate, self-amplifying destructive power during the shock; the low retreat threshold weakens the order book's defensive depth even before the shock; and the absence of a 24/7 reset window eliminates the institutional opportunity for recovery after the shock. The simultaneous presence of all three means that the perpetual market is already in a resilience-weakened state before the shock, suffers self-amplifying destruction during the shock, and lacks a recovery mechanism after the shock. This triple superposition, which spot markets do not possess, is precisely the structural root of why perpetual resilience is systematically inferior to that of spot (this tendency is inferred mainly from the institutional causal chain above and is corroborated by a small number of events such as October 2025; its cross-event generality still awaits testing against more extreme events).

8.6.3 A comparison of resilience across architectures

Beyond the difference in asset type (perpetual futures vs. spot), the market structure in which the matching engine resides also strongly affects the order book's resilience. Under different technical architectures, the measurement of resilience exhibits a trade-off between "verifiability" and "recovery speed."

On centralized exchanges, the order book and matching engine run on private servers, and market makers, using extremely low network latency and zero-gas-cost quote updates, can complete quote cancellations and resets at the millisecond level. On the surface, CEX resilience therefore "looks" strongest: the spread after a shock can often narrow within an extremely short time, and depth too seems to recover quickly.

This resilience, however, is unverifiable. An external observer cannot know for certain whether this rapidly recovered depth contains genuine trading intent or is merely "ghost quotes" posted to obtain market-maker rebates or maintain market rankings. The problems of "flickering liquidity" and "conditional depth" analyzed in Section 8.2 are especially prominent in the assessment of CEX resilience. A CEX order book that rapidly "recovers" its nominal depth after a shock may still have extremely weak stress depth.

By comparison, a central limit order book on an application chain is subject to the physical constraint of block time. For example, on an application chain with a block time of about 200 milliseconds to 1 second, there is a hard upper limit on the frequency of market-maker quote updates, which makes its surface recovery speed inferior to that of a CEX. But every order submission, modification, and cancellation on an on-chain CLOB is recorded in a distributed ledger, and its recovery process is fully transparent and auditable: every unit of depth that is rebuilt locks in real margin, rather than a "ghost" that can be canceled instantly at zero cost (this "capital authenticity" mechanism and its contrast with CEX ghost liquidity are detailed in Section 8.9.2). The resilience of an on-chain CLOB, therefore, though inferior to that of a CEX in speed, may be more reliable in "quality."

As for DEXs deployed on general-purpose public chains (such as the Ethereum mainnet), because the block-confirmation time is long (about 12 seconds) and they face intense gas competition, their order book resilience is the weakest and their recovery speed the slowest. When updating quotes, market makers face high on-chain costs and enormous adverse-selection risk (in the several seconds of waiting for block confirmation, the market price may already have moved substantially), making depth recovery after a shock exceedingly difficult. This architecture, however, offers the highest degree of transparency and censorship resistance.

This difference reveals a core insight: in assessing market resilience, a trader must choose between "surface-level rapid recovery" and "verifiable genuine recovery." This is precisely the concrete manifestation, at the level of order book microstructure, of the "impossible triangle" in Chapter 5 and the "risk visibility-manageability proposition" in Chapter 6. A high-frequency trader who pursues execution speed may place greater value on the surface resilience of a CEX, whereas an institutional investor concerned with counterparty risk and market fairness may place greater trust in the verifiable resilience of an on-chain CLOB.

8.6.4 Resilience and market quality

Resilience is not merely a technical micro indicator but a core dimension of the five-dimensional market-quality model to be established in Chapter 25. It directly determines traders' behavioral patterns and cost expectations in a given market and has a significant effect on the overall efficiency and stability of the market.

In a market with strong resilience, traders can more boldly use market orders to execute their trading strategies, because they know that even if a large order punches through the current depth and produces a price shock, market makers will quickly fill the liquidity gap and the market price will soon recover to fair value. This expectation

makes transaction costs highly certain, and traders can estimate fairly accurately the total cost of executing a trade (including the spread cost and the market-impact cost), enabling more effective portfolio management and risk control.

Conversely, in a market with weak resilience, traders must adopt a more conservative execution strategy. They need to split a large order into multiple small orders, or use algorithms such as time-weighted average price and volume-weighted average price to disperse the execution impact. Because in such a market "the shock may not recover and may even self-amplify," the positive-feedback mechanism of the liquidation cascade means that a large trade may trigger a price move far exceeding expectations. Transaction costs in this environment are full of uncertainty, and the trader faces not only the known spread cost but also an unpredictable tail-impact risk.

At the macro level, the strength of resilience also affects the market's price discovery efficiency. In a market with strong resilience, the price can quickly return to the fundamentals-driven fair value after a shock, and a temporary supply-demand imbalance does not produce a lasting distortion of the price. In a market with weak resilience, however, a shock may cause the price to deviate from fair value for a long time, or even trigger, through a liquidation cascade, a price collapse unrelated to fundamentals, severely damaging the accuracy of price discovery. The effective operation of the price discovery mechanism to be analyzed in Chapter 13 depends largely on the order book having sufficient resilience to absorb and digest information shocks.

The perpetual futures market's weaker resilience means it faces greater tail risk under extreme events. This is not a system "defect" that can be solved by patching code or adjusting parameters but an intrinsic cost that necessarily accompanies the institutional combination of "high leverage + no expiry date + 24/7 trading." These features are interrelated: high leverage provides traders with capital efficiency but also plants the seeds of a liquidation cascade; the absence of an expiry date eliminates rollover costs but also deprives market makers of a risk-termination point; and 24/7 trading provides around-the-clock market access but also eliminates the buffer window for resilience recovery. The theoretical discussion of "the cost of abolishing the expiry date" in Chapter 2 finds here, through the micro indicator of resilience, a complete and quantifiable expression. Understanding this point has important practical significance for traders in formulating risk-management strategies, for regulators in assessing market stability, and for protocol designers in optimizing liquidation mechanisms.

8.7 The evolution of matching-engine architecture

The preceding analysis shows that the resilience of the order book is structurally constrained by institutional features such as the liquidation mechanism, market-maker behavior, and market continuity. These microstructural manifestations (such as the width of the spread, the thickness of depth, and the strength of resilience), however, are also constrained to a considerable degree by the underlying technical architecture that carries the order book. A matching engine running on a sub-millisecond centralized server and one running on a public chain with second-level block confirmation will produce entirely different microstructural characteristics even when facing exactly the

same order flow. The deployment location and implementation of the matching engine have undergone a clear evolutionary path from fully centralized to application-specific. This path reflects not only the iteration of technology but also decentralized exchanges' ongoing trade-offs across three dimensions: performance (efficiency), decentralization (fairness and security), and sovereignty (protocol autonomy). Understanding this evolutionary thread is a prerequisite for grasping the institutional significance of matching-mechanism design in Section 8.8, and it also lays the groundwork for understanding how Hyperliquid, in Chapter 9, stakes out its distinctive position on this spectrum.

8.7.1 Centralized exchanges

In the early stages of the development of both traditional finance and cryptocurrency, the centralized exchange was the only viable solution for providing high-performance trading. Under this architecture, the maintenance of the order book and the operation of the matching engine are placed entirely within the private server cluster controlled by the exchange. Users deposit their assets into the exchange's custodial wallet, and all order submission, modification, matching, and cancellation are completed within the exchange's internal system.

The core advantage of this design lies in its high performance. Because all operations are conducted in memory and are not subject to the constraints of a blockchain consensus mechanism, a CEX can achieve sub-millisecond (<1 ms) matching latency, with throughput reaching hundreds of thousands of orders per second or even higher. For example, Binance has stated that the regular processing capacity of its futures matching engine can reach 100,000 orders per second, with average latency of about 5 milliseconds [25]. Note that these figures are the official values published for Binance's production environment and reflect performance under normal load. This low-latency, high-throughput environment provides a suitable trading environment for high-frequency traders and market makers, enabling them to update quotes at high frequency and thereby maintain, on the surface, narrower spreads and seemingly ample depth. For the perpetual futures market, which pursues execution speed, the CEX has long been regarded as the only venue capable of meeting the needs of professional traders.

This performance, however, comes with several structural risks. The most prominent is the counterparty risk brought by extreme centralization: users' assets are held in custody by the exchange, and once the exchange faces internal misappropriation, a hacking attack, or bankruptcy (such as the FTX incident of 2022), users' funds face the risk of total loss. This risk is especially acute in the perpetual futures market, because high-leverage trading requires users to deposit large amounts of margin at the exchange. At the same time, the unverifiability of the matching process constitutes a major hidden danger: external participants cannot verify the authenticity of order book depth, nor can they know for certain whether the exchange is using its informational advantage to manipulate internally, such as front-running user orders, wash trading to inflate volume, or improper operations during liquidation. In addition, the centralized architecture introduces censorship risk: a centralized entity can unilaterally freeze user accounts, reject specific transactions, or shut down specific markets under regulatory pressure, and users lack an effective remedy against this.

8.7.2 General-purpose-chain DEXs

To eliminate the centralization risk of the CEX, the blockchain community initially attempted to deploy the order book and matching engine directly on a general-purpose public chain (such as the Ethereum mainnet). The design goal of this approach has a clear decentralization orientation: all orders and the matching process are executed transparently on-chain, users' assets are self-custodied by smart contracts, and anyone can verify the fairness of the matching. This fully on-chain decentralized approach, however, immediately ran into a severe performance bottleneck.

A general-purpose public chain was designed to handle various types of smart-contract transactions, not optimized specifically for high-frequency trading. Ethereum's limited throughput (about 15 TPS before the Merge, improved somewhat afterward but still far from sufficient) and long block-confirmation time (about 13 seconds during the PoW period) cannot meet the performance requirements of real-time order book matching. In this environment, market makers must pay high gas fees each time they update a quote, and in the several seconds of waiting for block confirmation they face significant adverse-selection risk: the market price may have moved substantially before the quote is confirmed, making the market maker's resting order a stale quote easily exploited by arbitrageurs. In addition, because all pending transactions queue in the public mempool waiting to be packed, this architecture is vulnerable to maximal extractable value (MEV) attacks such as front-running and sandwich attacks, further worsening conditions for market makers.

Facing the performance dilemma, many DEXs adopted the compromise of a hybrid architecture. A typical case is dYdX v3, which used StarkEx as its Layer 2 settlement layer. In this model, the maintenance of the order book and the matching engine still run on off-chain centralized servers controlled by the project team; orders submitted by users are first sent to these servers for matching, while the trade results are periodically batched and submitted to the Ethereum mainnet through zero-knowledge proofs for on-chain settlement and verification. This architecture achieves smart-contract self-custody of user assets (users' funds are locked in a smart contract on Ethereum, and even if the off-chain servers go down, users can withdraw funds through an on-chain mechanism), thereby eliminating part of the counterparty risk. But its core matching component is still centralized and opaque, and the project team's servers remain a single point of failure and a potential manipulation node. The hybrid architecture makes a pragmatic compromise between performance and decentralization, but it still cannot fully resolve the contradiction of the "impossible triangle."

8.7.3 The application-chain architecture

As DeFi infrastructure matured, and especially as modular blockchain development frameworks such as the Cosmos SDK became widespread, a new paradigm began to dominate the development of high-performance DEXs: the application-chain architecture. An application chain is an independent blockchain tailor-made for a single application, whose consensus mechanism, network parameters, and state-machine logic can all be deeply optimized for that application's needs. dYdX's migration from Ethereum L2 to the independent dYdX Chain (v4) built on the Cosmos SDK marked the full

establishment of this trend.

The core motivation of the application-chain architecture is to ease the trade-off between performance and decentralization. In the dYdX v4 architecture, the order book is no longer hosted by a single centralized server but is jointly maintained and synchronized in the memory of the network's decentralized validators (about 50 to 60 active validators). When a user submits an order, that order is rapidly propagated to all validator nodes through a peer-to-peer network. Matching is performed by the proposer of each block based on the order book in its memory, and the trade results are then packed into a block and verified and confirmed by all validators through the CometBFT consensus mechanism. The dYdX v4 architecture therefore exhibits the hybrid characteristics of an off-chain order book and on-chain settlement: order matching is completed in the validators' off-chain memory, and only the final trade results and state changes need to pass through consensus confirmation. This design substantially improves performance while preserving decentralization. It does, however, introduce a specific trade-off: validators can observe pending orders before a block is produced, leaving potential room for validator-level MEV extraction (such as front-running based on order information).

Beyond dYdX v4, emerging platforms such as Hyperliquid have further expanded the performance frontier of the application-chain architecture. Hyperliquid uses its self-developed HyperBFT consensus mechanism (inspired by the academic HotStuff BFT protocol), which breaks the sequential constraint of traditional consensus through pipelining to achieve (for geographically co-located clients) a median end-to-end order latency of about 0.2 seconds (200 milliseconds) and a 99th percentile below 0.9 seconds; benchmark tests of its HyperCore component show it can process up to 200,000 orders per second, but this figure comes from a benchmark-test environment rather than production load and is not directly comparable to Binance's production-environment data. The actual throughput and latency data under extreme stress scenarios (such as the liquidation peak during the October 2025 flash crash) have not been publicly disclosed by either platform. Lighter.xyz takes another technical route — a zkRollup architecture based on Ethereum — achieving near-instant transaction confirmation (millisecond-level) through a single sequencer, while using zero-knowledge proofs to submit transaction batches to the Ethereum mainnet to inherit its security. This approach offers extremely high performance at the sequencer level, but its degree of decentralization depends on the design of the sequencer (currently mostly a centralized sequencer, with plans to gradually decentralize in the future).

The degree of decentralization of Hyperliquid, however, needs to be assessed with caution. As of this writing, Hyperliquid's validator set is largely dominated by nodes operated by Hyperliquid Labs, validator admission is not fully permissionless, and sequencing power is substantively concentrated in the core team. The JELLY incident of March 2025 highlighted this centralized operational reality: when the perpetual futures of the JELLY token exhibited suspected manipulation that threatened the solvency of HLP, the Hyperliquid team intervened directly in the market, voting to delist the JELLY contract and forcibly settling all positions at a price favorable to HLP. This intervention technically protected the platform's financial stability but also exposed the tension between its "decentralized exchange" positioning and its actual capacity for cen-

tralized intervention. From a regulatory perspective, this centralized control capacity may expose Hyperliquid to legal-characterization risks similar to those of a centralized exchange with respect to the Howey test and exchange-registration obligations.

The rise of the application-chain architecture has demonstrated that providing a high-performance order book meeting the needs of professional traders, without sacrificing the principle of decentralization, is now technically feasible. This technological advance has had multiple effects on the microstructure of the perpetual futures market: the on-chain-verifiable matching process eliminates the "black box" problem of the CEX, the self-custody asset model eliminates counterparty risk, and performance metrics approaching those of a CEX make professional market makers willing to deploy strategies on these platforms, thereby improving the depth and resilience of the order book.

Figure 8-17 uses an architecture-comparison diagram to visualize the three-stage evolution of the matching engine from the centralized exchange, through the general-purpose-chain hybrid DEX, to the application-chain DEX, highlighting the core differences of each stage in the hosting location of the order book, the settlement mechanism, and the asset-custody model.

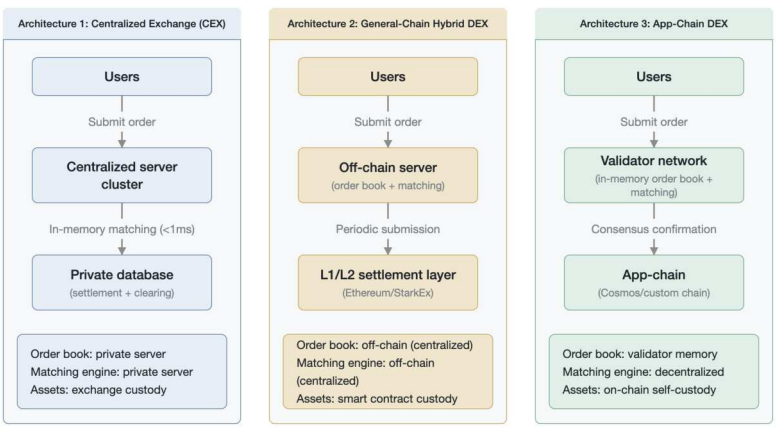

Figure 8-17. A comparison of the three matching-engine architectures (conceptual comparative illustration of the three matching architectures, not empirical data)

From left to right, the figure presents the core decentralization increments of the three architectures: from the decentralization of asset custody (the hybrid DEX migrates user assets to on-chain smart-contract self-custody, but the order book and matching are still off-chain, with only settlement on-chain) to the decentralization of the matching process itself (the application-chain DEX has validators jointly maintain the order book, matching is confirmed through consensus, and assets are fully self-custodied on-chain). The trust basis of the order book market gradually shifts from reliance on the operator's reputation to a verifiability guarantee grounded in cryptographic proof and distributed consensus.

8.7.4 A multidimensional comparison of the three architectures

To present the differences among these three architectures more clearly, we compare them across several key dimensions — matching location, settlement layer, performance metrics, custody model, transparency, MEV risk, and protocol sovereignty (see Table 8-5).

Dimension	CEX (e.g., Binance)	General-purpose-chain hybrid DEX (e.g., dYdX v3)	Application-chain DEX (e.g., dYdX v4, Hyperliquid)
Matching location	Centralized server (private)	Centralized server (private)	Decentralized (validator network)
Order book location	Centralized server (private)	Centralized server (private)	Validator memory (off-chain synchronization) / on-chain state
Settlement layer	Private database	Ethereum L2 (e.g., StarkEx)	Independent application chain (e.g., Cosmos, Hyperliquid L1)
Throughput	Extremely high (~100k+ TPS)	High (limited by L2 performance)	Very high (>10k TPS, Hyperliquid reaching 200k)
Latency	Extremely low (<1 ms)	Low (~10–100 ms)	Relatively low (~100 ms – 1 s)
Custody model	Exchange custody (centralized)	Smart-contract self-custody	On-chain self-custody
Transparency	Opaque (black box)	Partially transparent (settlement results on-chain)	Highly transparent (fully on-chain verifiable)
MEV/manipulation risk	High internal-manipulation risk	Moderate (depends on the fairness of the L2 sequencer)	Relatively low (jointly supervised by decentralized validators)
Protocol sovereignty	Full sovereignty (controlled by a corporate entity)	No sovereignty (depends on the governance of the underlying L1/L2)	Full sovereignty (protocol/DAO autonomy)

Table 8-5. A comparison of the core dimensions of the three matching-engine architectures (Data source: compiled by the author from the public documentation of each platform)

The "application-chain DEX" category in the table covers multiple implementation paths with significant internal architectural differences: dYdX v4 is built on the Cosmos SDK and relies on CometBFT consensus, Hyperliquid runs on its own Layer 1 and uses its self-developed HyperBFT consensus, and Lighter.xyz uses an Ethereum zkRollup architecture and relies on a single sequencer. These three paths differ fundamentally in security assumptions (independent consensus vs. inheriting Ethereum's security), degree of decentralization (dozens of validators vs. a single sequencer), and MEV-protection mechanisms. Grouping them into the same category facilitates macro comparison, but the reader should attend to the specific architectural details of each platform.

Table 8-5 shows clearly that the three architectures form a progressive spectrum between performance and decentralization. The CEX occupies the performance extreme but faces the most limitations in decentralization, transparency, and the security of user assets. The general-purpose-chain hybrid DEX achieves a breakthrough in asset self-custody, but its core matching component remains a centralized core weakness. The application-chain DEX achieves significant progress in both performance and decentralization; although it still lags the CEX on the pure latency metric (about 200 milliseconds vs. <1 millisecond), this gap is narrowing rapidly and is already entirely acceptable for the vast majority of non-high-frequency trading strategies.

As shown in Figure 8-18, in the logarithmic two-dimensional space of throughput and latency, the application-chain DEX (green) is migrating rapidly from the upper-left corner (low throughput, high latency) toward the lower-right corner where the CEX resides (high throughput, low latency), gradually approaching its performance frontier. This convergence will reshape competition: as the performance gap narrows, the relative advantage of the CEX will lie more in compliance licenses, fiat on-ramps and off-ramps, liquidity network effects, and brand recognition, while the unverifiability of its matching and its custody risk will face greater scrutiny as transparency becomes a focus of competition.

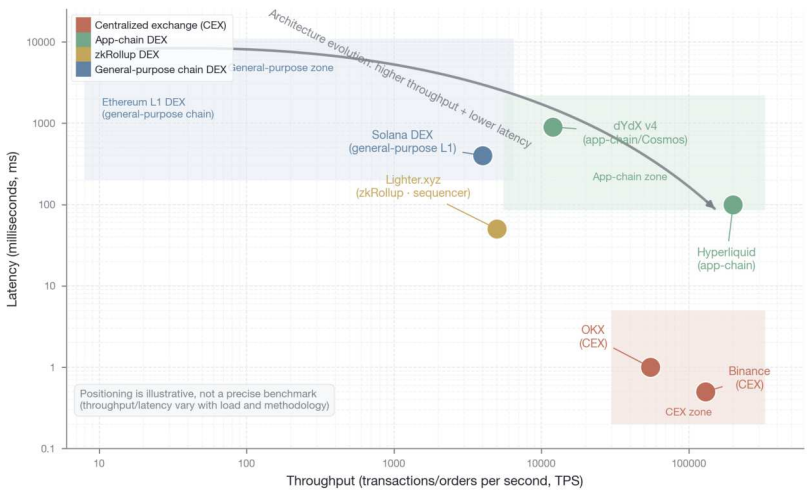

Figure 8-18. The positioning of matching engines in the throughput-latency space (conceptual illustration of two-dimensional throughput-latency positioning; the coordinates of each platform are representative orders of magnitude based on official documentation, not measured against a unified benchmark; Hyperliquid's about 200k is a benchmark-test value, not production load)

This architectural evolution is not merely technical progress; it is the infrastructural precondition for the evolution of the market microstructure. The architecture of the matching engine determines how fast market makers can update quotes (affecting resilience), whether order book depth can be externally verified (affecting the degree of the depth illusion), and whether MEV attackers can use information asymmetry to front-run (affecting the proportion of toxic order flow). Building on this, Section 8.8 further analyzes how the design of the matching mechanism itself (from continuous

auction to batch auction) optimizes market fairness and efficiency through institutional innovation, within the constraints of a given technical architecture.

8.8 Continuous auction and batch auction

Having explored the on-chain evolution of the automated market maker and the central limit order book, we need to examine closely a core assumption of the order book model itself: continuous-time matching. Traditional financial markets and early decentralized exchanges mostly adopt a continuous-auction mechanism by default — that is, orders are matched immediately upon arrival against existing orders in the order book according to the principles of price priority and time priority. As high-frequency trading rose and the characteristics of blockchain infrastructure became apparent, however, the structural defects of this continuous-time matching gradually became evident. This section analyzes how the frequent batch auction and its variants optimize the market microstructure through the discretization of time.

8.8.1 The speed race and latency arbitrage

In the continuous limit order book model, the matching engine follows a strict serial processing logic. When new public information emerges in the market (for example, the price of an asset changes on another exchange), market makers and high-frequency arbitrageurs receive this signal simultaneously. A rational market maker needs to immediately cancel its old quote and submit an updated one to avoid being filled at a stale price, whereas a high-frequency arbitrageur (or scalper) attempts to trade with the market maker at the stale price before the market maker cancels, thereby capturing a risk-free profit [26].

This competition gradually turns into a speed race centered on latency advantage. In traditional financial markets, this race takes the form of enormous hardware investment in microwave communication networks, direct fiber connections, and exchange colocation, with participants competing on infrastructure for an advantage of a few microseconds or even nanoseconds. In their widely cited paper "The High-Frequency Trading Arms Race: Frequent Batch Auctions as a Market Design Response," Budish, Cramton, and Shim (2015) noted that the continuous limit order book drives price correlations toward zero at micro time scales, thereby generating obvious mechanical arbitrage opportunities [27]. They emphasized that market competition has not eliminated the scale or frequency of these arbitrage opportunities but has merely raised the speed threshold required to capture them.

In the blockchain environment, because of network latency, the discreteness of block time, and miners'/validators' control over transaction ordering, this speed race evolves into a contest over MEV. When the on-chain price deviates from an external oracle or centralized-exchange price, searchers ensure that their arbitrage transactions are ordered ahead of the market maker's cancellation transaction by paying a high priority fee or directly bribing the block builder. This behavior, known on-chain as latency arbitrage or front-running, is essentially identical to high-frequency arbitrage in traditional markets: both exploit the loophole of the time-priority principle in the CLOB.

The time-priority principle imposes a significant social cost. Under the continuous-auction mechanism, a market maker must bear the risk of having its stale quotes selectively attacked by a faster arbitrageur. This risk does not stem from any inaccuracy in the market maker's pricing model but is caused purely by the physical limitation of the system's serial processing of orders in continuous time. The profit the arbitrageur extracts constitutes a direct loss to the market maker, and this loss is ultimately passed on to all ordinary traders through the market mechanism.

8.8.2 The formation of toxic order flow and adverse selection

When arbitrageurs use their speed advantage to trade against market makers' stale quotes, this order flow is called "toxic order flow." The essence of toxic order flow is the adverse selection caused by information asymmetry. In their classic microstructure theory, Glosten and Milgrom (1985) noted that a market maker facing informed traders who may possess private information or a speed advantage will necessarily suffer adverse-selection losses [26].

In perpetual futures markets, the transmission mechanism of toxic order flow is especially pronounced. When the market is highly volatile, there is not only front-running by high-frequency arbitrageurs but also a large volume of triggered liquidation orders. These liquidation orders often sell or buy at market regardless of cost, forming an extreme toxic order flow. To measure the toxicity of this order flow in real time, Easley, López de Prado, and O'Hara (2011) proposed the VPIN indicator [28]. When the VPIN indicator rises, it means that the toxicity of the order flow is increasing and that the adverse-selection risk faced by market makers rises significantly.

Facing highly toxic order flow, a rational market maker has only two choices: either widen the bid-ask spread to compensate for the expected adverse-selection loss, or reduce resting depth at the best bid and ask to lower risk exposure.

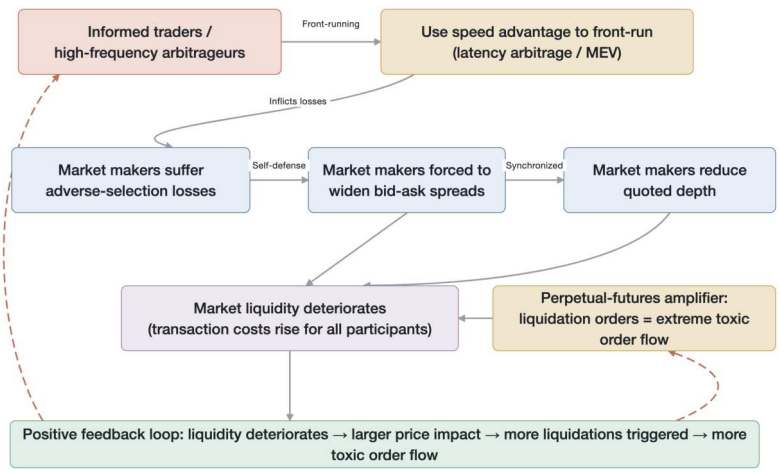

Figure 8-19. The transmission mechanism of toxic order flow (illustration of the transmission mechanism of toxic order flow, not empirical data; theoretical basis: Glosten & Milgrom 1985 [26], Easley,

López de Prado & O'Hara 2011 [28])

As shown in Figure 8-19, the adverse selection triggered by toxic order flow forces market makers to widen spreads and reduce depth, leading to a deterioration of overall liquidity, so that ordinary traders (natural order flow) bear higher spreads and slippage; in the extreme, the drying up of liquidity amplifies price shocks and triggers more liquidations, forming a positive feedback loop that intensifies market instability. Solving the problem of toxic order flow is therefore not only a matter of market-maker profitability but is key to maintaining market health and protecting the interests of ordinary traders.

8.8.3 The frequent batch auction

To fundamentally solve the problems of latency arbitrage and adverse selection brought by the continuous-auction mechanism, academics and industry proposed an alternative market microstructure: the frequent batch auction (FBA). The core idea of the FBA is to abandon the continuous-time assumption, discretize time into extremely short intervals (for example, 100 milliseconds or one block time), and clear orders through a uniform-price two-sided auction at the end of each time window [27].

Under the FBA mechanism, all orders arriving within a time window are treated as arriving simultaneously. The system aggregates all buy orders (constructing the demand curve) and sell orders (constructing the supply curve) and searches for a single clearing price that maximizes the trading volume. All buy orders with a price higher than (or equal to) the clearing price, and all sell orders with a price lower than (or equal to) the clearing price, are executed at this uniform clearing price.

The FBA eliminates the micro-scale speed advantage through time discretization. Within the same auction cycle, an order submitted 1 millisecond — or even tens of milliseconds — later enjoys exactly the same execution priority as an order submitted earlier, as long as it arrives before the window closes. This mechanism pulls the competition among participants back from the "speed dimension" to the "price dimension." Market makers no longer need to invest heavily for a few milliseconds of cancellation speed, and arbitrageurs can no longer profit risk-free by relying on a speed advantage alone to exploit market makers' stale quotes.

Gong, Liu, and Kate (2025) conducted an empirical analysis of BTC-USD and ETH-USD trading data on the decentralized exchange dYdX [29]. Their study uses the realized spread as the measure of transaction cost. The results show that, compared with the CLOB model, the FBA can reduce overall transaction costs by about 21% to 37% (BTC-USD by about 24%–37% and ETH-USD by about 21%–34%, depending on the auction frequency of 5, 10, or 15 seconds). This improvement mainly benefits market makers: because the elimination of latency arbitrage lowers the adverse-selection risk they face, they are able to offer narrower quoted spreads. Note that the above data are based on a sample under normal market conditions, and the batch interval introduced by the FBA itself produces an opportunity cost of execution delay: in a high-volatility environment, a trader may miss favorable price movements while waiting for the next auction window, and whether this delay cost partly offsets the spread improvement was not included in the study's analysis. In addition, whether this conclusion applies to less liquid long-tail assets awaits further verification. Their study notes that when public

information in the market (such as price-oracle updates) is more frequent than private information, the FBA has a clear welfare advantage over the CLOB.

Figure 8-20. The transaction-cost-reduction effect of the FBA (the only empirical figure in this chapter: relative transaction cost is baselined at CLOB = 100%; the FBA lowers BTC-USD by 37% to 63% and ETH-USD by 21% to 79%; the 37% and 21% are the two endpoints of the 21%–37% range, depending on the auction frequency of 5, 10, or 15 seconds; in the main text the overall reduction is 21%–37%, BTC about 24%–37%, and ETH about 21%–34%; data source: Gong, Liu & Kate 2025 [29], based on BTC-USD and ETH-USD trading data from the dYdX exchange, January 2023 – October 2024)

As shown in Figure 8-20, by eliminating latency arbitrage the FBA substantially lowers market makers' adverse-selection risk, making them willing to offer narrower spreads and deeper liquidity; its uniform-price clearing also provides price improvement for market orders — buyers may be filled below their expected ceiling, and sellers above their expected floor.

8.8.4 The dual-flow batch auction

Although the FBA succeeds in eliminating the speed advantage, it remains an "all-to-all" market structure. In a traditional FBA, market makers may still be matched against one another. To optimize the market structure further, institutions such as Jump Crypto proposed the dual-flow batch auction (DFBA) mechanism [30].

The core innovation of the DFBA is to explicitly distinguish order flow into two categories — makers (liquidity providers) and takers (liquidity consumers / natural order flow) — and to strictly prohibit makers from being matched against one another. In the DFBA, each auction cycle actually contains two independent auction processes: the buy-side auction matches makers' sell orders against takers' buy orders, and the sell-side auction matches makers' buy orders against takers' sell orders.

This design brings several key advantages. It eliminates adverse-selection competition among market makers. In a continuous auction or an ordinary FBA, when an external price changes, a market maker must guard not only against arbitrageurs but also

against other, faster-reacting market makers. By prohibiting maker-to-maker matching, the DFBA allows market makers to quote their best prices with confidence, without worrying about being "sniped" by peers.

At the same time, the DFBA strongly encourages market makers to display genuine liquidity depth. Because the clearing price is a uniform price determined by the supply and demand curves, and fills at the clearing price are typically allocated pro rata, market makers have a strong incentive to provide as large a size as possible at the best price in order to capture more taker order flow.

A key implementation challenge of the DFBA mechanism lies in the classification standard for makers and takers. In a continuous auction, this distinction is clear: whoever rests passively on the order book waiting to be filled is a maker, and whoever actively issues a taking instruction is a taker. In a batch-auction environment, however, all orders participate in clearing "simultaneously" when the window closes, and the boundary between maker and taker becomes blurred. The classification method used in Jump Crypto's proposal is based on the ex ante declaration of order type and submission intent [30], but this may give rise to circumvention behavior, in which participants disguise what is essentially active trading as passive resting in order to enjoy maker treatment. As of this writing, no mainstream exchange has fully deployed the DFBA mechanism in a production environment, and the robustness of its classification standard remains at the stage of theoretical discussion.

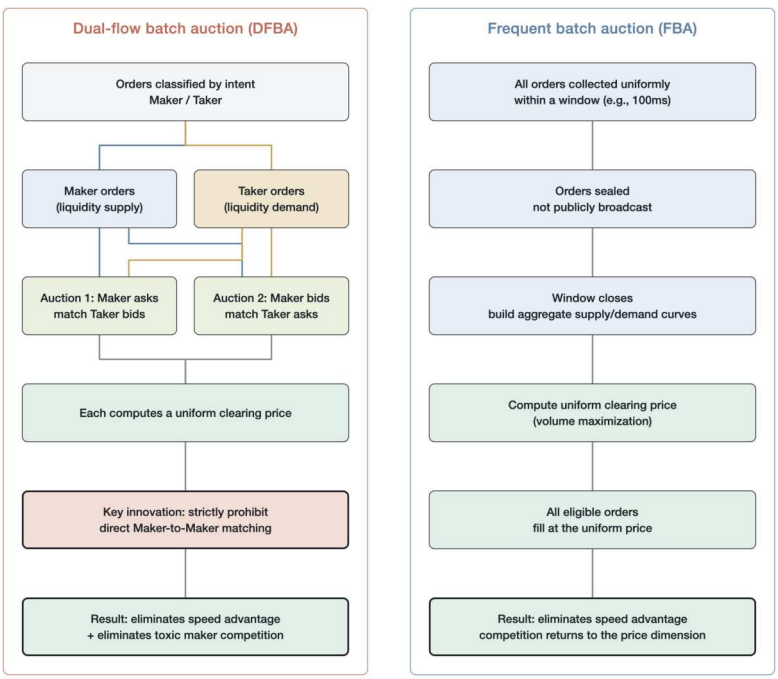

Figure 8-21. A process comparison of the FBA and the DFBA (illustration of the process comparison between the FBA and the DFBA, not empirical data; following Jump Crypto 2025 [30])

As shown in Figure 8-21, while inheriting the FBA's advantage of eliminating the speed advantage, the DFBA lowers the adverse-selection risk market makers face through structured order isolation. This improved environment ultimately translates into narrower spreads and deeper market depth, thereby benefiting the natural order flow the market is meant to serve.

8.8.5 Injective's FBA practice

A representative case of putting the FBA mechanism into practice on a blockchain is the Injective protocol. Injective is an application chain optimized specifically for decentralized finance, and it is the first blockchain network to embed the frequent batch auction mechanism directly into the Layer 1 consensus layer [31].

Implementing the FBA on a traditional smart-contract platform faces many challenges, especially the problem of order privacy protection. If orders are publicly broadcast during the auction window, they can easily trigger front-running or sandwich attacks by MEV bots. Injective effectively solves this problem by combining the Tendermint consensus mechanism with a sealed-bid design.

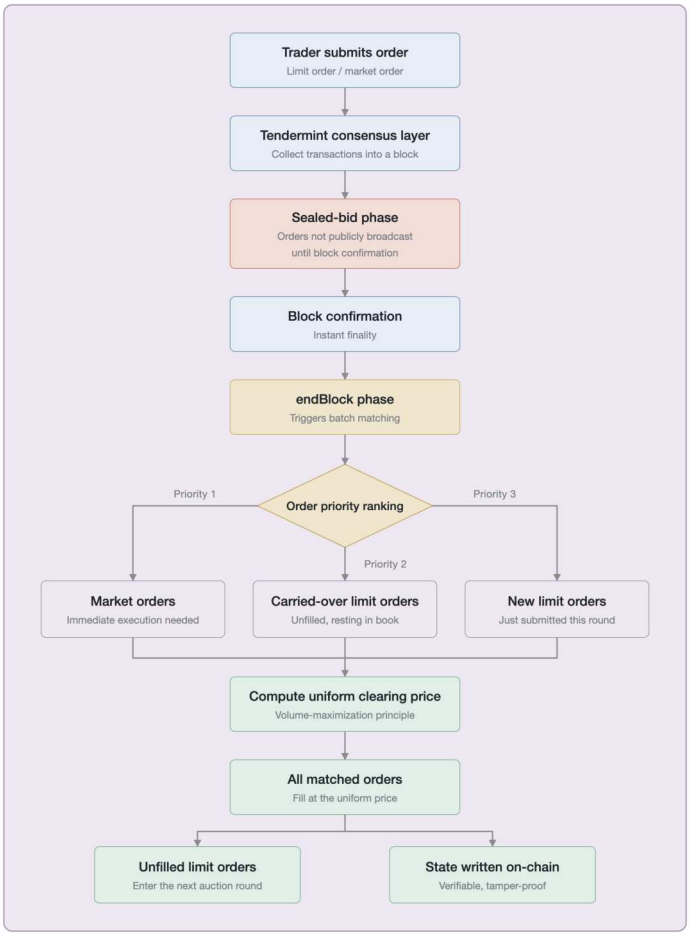

Figure 8-22. Injective's on-chain FBA execution flow (illustration of Injective's on-chain FBA execution flow, not empirical data; following Injective Protocol 2024 [31])

Injective's FBA execution flow (as shown in Figure 8-22) is deeply bound to the block life cycle. In the phase in which a block collects transactions, all submitted orders are in a sealed state and do not expose their specific price and quantity information in the public mempool. Only after the block is confirmed (which, thanks to Tendermint's instant finality, typically takes only an extremely short time) are the orders decrypted.

In the final phase of the block life cycle, the system triggers the batch matching engine. The matching logic follows a strict priority order: market orders have the highest priority to ensure the need for immediate execution, followed by unfilled limit orders from the previous round, with the lowest priority assigned to newly submitted limit orders in the current round. After determining the pool of orders participating in the matching, the engine computes the uniform clearing price that maximizes the trading volume and settles all eligible orders at this price.

Injective's practice demonstrates the feasibility and superiority of the FBA in an on-chain environment. By synchronizing time discretization with block generation and supplementing it with cryptographic means to protect order privacy, Injective has successfully built an order book market on-chain that can effectively resist latency arbitrage and harmful MEV. As of this writing, however, the liquidity and volume data for Injective's perpetual futures market remain relatively limited, making it difficult to empirically compare the FBA's real effect on this platform against theoretical expectations. Whether the theoretical advantages of the FBA hold equally in a low-liquidity environment (that is, whether uniform-price clearing can still achieve meaningful price improvement when there are few participants and possibly only a handful of orders within a batch-auction window) still requires more practical data for verification. This provides not only a predictable trading environment for market makers but also lays a microstructural foundation for the decentralized perpetual futures market to advance toward institutional-grade liquidity.

8.9 The information ecosystem of on-chain and off-chain order books

Having explored the matching mechanism of the order book, we must turn our attention to the data the order book itself carries. The order book is not only where trading happens but also the market's most important source of microstructural information. From centralized exchanges to decentralized exchanges, the migration of the order book involves both a transformation of infrastructure and a structural change in the information ecosystem. This section compares the fundamental differences between on-chain and off-chain order books in transparency, verifiability, and the barrier to data acquisition, and explores how these differences give rise to an entirely new on-chain data-analysis ecosystem.

8.9.1 The characteristics of the CEX order book

On centralized exchanges, the order book is highly opaque and unverifiable. Traders receive order book snapshots and incremental updates through the APIs (such as WebSocket) the exchange provides, but this data is generated entirely by the exchange's centralized servers. Users cannot independently verify whether a resting order at a specific price level truly exists, nor can they confirm whether the exchange is conducting wash trading or spoofing internally to manufacture false liquidity depth.

What this unverifiability buys is high performance. Because there is no need to reach consensus in a distributed network, a CEX's matching engine can achieve submillisecond latency. More importantly, canceling or updating a quote on a CEX is typically free (or extremely low-cost). This zero-cost quote-update mechanism lets high-frequency market makers revise their quotes dozens of times per second in response to tiny market fluctuations.

This information ecosystem, based on centralized trust and zero-cost updates, however, causes the CEX order book to be flooded with a large volume of "ghost liquidity." When the market fluctuates violently, these seemingly substantial resting orders are often canceled in an instant, causing liquidity to vanish suddenly precisely when it is most needed.

8.9.2 The characteristics of the on-chain CLOB

Entirely unlike the CEX, a central limit order book built fully on a blockchain (such as Hyperliquid or Injective) offers a fully transparent and verifiable information ecosystem. In an on-chain CLOB, every resting order, cancellation, and trade record is packed into a block as a transaction and broadcast to the entire network through the consensus mechanism. Anyone can run a full node, replay all transaction states from the genesis block, and thereby reconstruct locally an order book precisely consistent with the on-chain state.

This verifiability changes the trust basis of order book depth, but its meaning needs to be defined precisely. An on-chain resting order, at the legal and operational level, is still a revocable offer, just like an order on a traditional order book: a market maker can submit a cancellation transaction in the next block to cancel a prior quote. The POPCAT incident analyzed in Section 8.2.5 has already clearly demonstrated this: the $20 million order wall the manipulator posted on-chain was ultimately withdrawn in full. An on-chain resting order therefore does not possess "execution irrevocability." What the on-chain order book genuinely improves is the degree to which "capital authenticity" is verifiable: every resting order must lock in real on-chain margin, and both submitting and canceling orders require paying gas fees, which significantly raises the capital cost of spoofing at the economic level. On a centralized exchange, posting and canceling a false order of $100 million is nearly costless, but in an on-chain environment the manipulator must at least actually lock in the corresponding margin assets, substantially raising the economic barrier to spoofing.

At the same time, the full transparency of the on-chain order book is a double-edged sword. The distribution of liquidation prices, the location of large positions, and the

price ranges with weak liquidity — this information is visible equally to all market participants, including potential attackers. As the POPCAT incident demonstrated, an attacker can use on-chain-visible position-distribution information to locate a manipulation target precisely and design a targeted liquidity-attack strategy. This "information symmetry" aids price discovery efficiency in a normal market, but in an adversarial environment it also provides malicious actors with a complete "map of the attack surface."

This verifiability, however, comes at the cost of speed and flexibility. The update frequency of an on-chain order book is limited by the block time of the underlying blockchain. Even on a high-performance application chain or Layer 2 network, this time is typically between a few hundred milliseconds and a few seconds. In addition, every on-chain state update (including cancellations) requires paying a gas fee. This time constraint and cost friction force on-chain market makers to abandon high-frequency quote-update strategies in favor of wider spreads and more stable resting-order strategies. As a result, although the depth of an on-chain order book may not be as "thick" as that of a CEX, the liquidity it provides is more genuine and more durable.

8.9.3 The democratization of data access

In traditional finance and CEX markets, obtaining high-quality order book data is an expensive privilege. Exchanges typically divide data into different tiers (such as Level 1, Level 2, and Level 3) and charge high subscription fees for Level 3 data, which provides full depth and tick-by-tick trade records. In addition, to obtain the lowest-latency data feed, institutions must also pay expensive colocation fees. This data-commercialization model creates a stratification of information access, placing ordinary retail traders at a structural disadvantage.

On the surface, the public and transparent nature of the blockchain seems to "democratize" this reading capability. On-chain, order book data becomes a public good. No centralized entity can restrict access to this data, and there is no need to pay expensive API subscription fees. Anyone willing can obtain the lowest-level smart-contract state through an RPC node and parse out the most complete Level 3 order book data.

This gives rise to an interesting "transparency paradox," however: although the data is public, the barrier to extracting valuable information from it is extremely high. To reconstruct and analyze an active on-chain order book in real time requires building a high-availability node cluster, writing complex smart-contract event-parsing logic, and handling a massive data stream. For an ordinary DeFi user facing a vast volume of hexadecimal raw data, the barrier to interpreting the data is actually higher than when using a CEX's standardized API. The "reading" capability has therefore been democratized in theory, but in engineering practice it remains in the hands of a small number of professional teams with powerful infrastructure capabilities.

8.9.4 The on-chain data-analysis ecosystem

It is precisely on the basis of this "transparency paradox" that the decentralized perpetual futures market has given rise to an entirely new on-chain data-analysis ecosystem.

Since the underlying order book data is public and tamper-proof, third-party developers can build a rich variety of visualization tools and real-time monitoring platforms on top of it, filling the information gap between ordinary users and professional market makers.

In this new ecosystem, we see many innovative data products. For example, through joint analysis of on-chain open interest and order book depth, data platforms can plot high-precision "liquidation heatmaps." These heatmaps can intuitively show users the price ranges in which large volumes of high-leverage positions are clustered, and the chain reaction that may be triggered when these positions are liquidated.

In addition, targeting the "whale behavior" unique to the on-chain order book, analysis tools can track in real time the resting and cancellation actions of specific addresses, identifying potential "order-propping" or "order-suppressing" behavior. Because the transaction history of an on-chain address is fully public, users can even assess whether the address behind these large orders has sufficient financial strength, thereby judging the true intent of these orders.

Feature dimension	Centralized exchange order book	Fully on-chain order book
Data-generating entity	Exchange's centralized servers	Decentralized consensus network
Transparency and verifiability	Black box, unverifiable, risk of false trades	Fully transparent, cryptographically verifiable, every trade recorded
Data-acquisition cost	High (Level 3 data and colocation require payment)	Free (data is a public good, obtained via RPC)
Engineering-parsing barrier	Relatively low (standardized API directly outputs structured data)	Extremely high (requires parsing underlying contract events and the state tree)
Quote-update friction	Extremely low (sub-millisecond latency, typically no cancellation fee)	Relatively high (limited by block time, requires paying gas fees)
Liquidity characteristics	Large depth, but containing a large volume of easily cancelable "ghost liquidity"	Relatively smaller depth, but strongly committed and more genuine liquidity

Table 8-6. A comparison of the core differences between the CEX and on-chain order books at the level of the information ecosystem (Data source: compiled by the author)

Table 8-6 summarizes the core differences between the CEX and on-chain order books at the level of the information ecosystem. Overall, the on-chain order book shifts trust from "reliance on a centralized entity" to "verification of cryptography and code." Although this shift brings engineering challenges, it compresses the space for a centralized operator to conduct unverifiable black-box operations (such as internal wash trading, zero-cost spoofing, and improper operations during liquidation), and it lays the data foundation for building a fairer, more transparent decentralized derivatives market. As the POPCAT incident in Section 8.2.5 shows, however, the on-chain transparent environment does not eliminate market manipulation itself but merely changes the cost structure and traceability of manipulation. As infrastructure continues to improve and third-party analysis tools mature, the information ecosystem of the on-chain order book

is expected to continue developing toward greater openness and efficiency.

8.10 Chapter summary

Taking the order book as its central object, this chapter has constructed an analytical framework for understanding the operating logic of the perpetual futures market from the standpoint of microstructure. The starting point of this framework is the redefinition of the order book as an information machine: the five signal channels of spread, depth, slope, flow, and dynamics continuously gather the private information and risk preferences of market participants and transform them into observable state variables. By cross-validating the joint changes in these five channels (rather than observing any single indicator in isolation), one can diagnose the market state systematically, mapping the continuous deterioration from "healthy" to "collapsed" into identifiable structural features that can be flagged early.

The depth illusion is the core risk concept this chapter reveals. A systematic gap exists between the visible nominal depth on the order book and the trading size the market can genuinely bear under stress, and this gap is amplified in the perpetual futures market by three mechanisms: high-frequency market makers' flickering quotes cause a large volume of visible depth to exist only within a millisecond-scale time window; market makers' liquidity commitment is implicitly premised on "normal market conditions" and triggers a collective retreat once volatility rises; and the strategically constructed false depth demonstrated by the Hyperliquid POPCAT incident shows that visible depth can even be actively constructed as a tool of manipulation. Empirical data from the October 2025 flash crash show that the reduction between nominal depth and stress depth exceeded 90%, providing quantitative validation of this concept.

Building on this, the chapter has proposed the four microstructural fingerprints of the perpetual futures order book: the depth cliff, the depth tide, the liquidity circadian rhythm, and the asymmetric volatility response of the spread. None of these four patterns exists in traditional spot markets or in futures markets with an expiry date; they arise, respectively, from perpetual futures' unique institutional features of the liquidation mechanism, the funding rate, 24/7 trading, and the systematic long bias. When the four fingerprints resonate and superimpose in a specific market environment (for example, when a high-funding-rate period coincides with a liquidity-trough period and a dense liquidation zone approaches the current price), the systemic risk the market faces far exceeds the level any single fingerprint could foreshadow.

The resilience analysis further reveals the structural fragility of the perpetual futures market along the time dimension. The positive-feedback mechanism of the liquidation cascade gives shocks a self-amplifying character, market makers face open-ended inventory risk because of the absence of an expiry date and therefore have a lower retreat threshold, and 24/7 uninterrupted trading eliminates the resilience-recovery window that the closed period provides in traditional markets. These three factors together produce the asymmetric resilience characteristic of "collapse measured in minutes, recovery measured in weeks," with the fact that depth had still not recovered to pre-shock levels months after the October 2025 event serving as direct evidence.

Finally, the chapter has traced the evolutionary path of the technical architecture that carries the order book from the centralized exchange to the application chain, as well as the institutional innovation of the matching mechanism from continuous auction to batch auction. The application-chain architecture achieves the verifiability of the matching process through a decentralized validator network, eliminating the CEX's counterparty risk and the possibility of manipulation; the frequent batch auction and the dual-flow batch auction, through time discretization and order-flow separation, reduce at the mechanism level the harm that latency arbitrage and toxic order flow inflict on market makers, thereby lowering traders' implicit costs. These advances at the technical and institutional levels are reshaping the microstructural foundation of the perpetual futures market, and their implementation and effects on specific platforms will be analyzed in detail in Chapter 9, using Hyperliquid as a case study.

Hyperliquid's Microstructure Innovations

Chapter 7 defined the order as a complex vehicle that carries intent, risk, and information, and it systematically analyzed the signal strength and maximal extractable value (MEV) exposure of different order types. Building on this, Chapter 8 dissected the structural dynamics of the order book, revealing microstructural fragilities such as depth illusion and liquidation cascades, and traced the evolution of matching mechanisms from continuous auction to batch auction. Together, the analytical framework established by these two chapters points to a core question that remains unanswered: when a large number of buy and sell orders arrive within the same time window, whose order should be executed first? This ordering problem is decisive for the profits and losses of market participants, shapes the structure of the market ecosystem, and even defines market fairness. The central tension of market microstructure is that a market must simultaneously provide traders with ample liquidity and efficiently aggregate information into prices, and the ordering mechanism is precisely what mediates this tension. In a traditional centralized exchange (CEX), this core mechanism resides within an opaque, closed architecture. The matching engine processes orders at microsecond or even nanosecond speeds, and its internal ordering logic, latency compensation, and potential differential treatment are entirely opaque to the outside world. This opacity gives rise to the costly speed race analyzed in Section 8.8.1. Aquilina, Budish, and O'Neill (2022) found that the social cost of this speed race across the world's major exchanges amounts to billions of dollars annually [1]. Participants lay dedicated fiber-optic lines, build microwave towers, and colocate their servers in exchange data centers, all to gain a microsecond-level physical head start.

The advent of blockchain, and in particular the rise of general-purpose smart contract platforms such as Ethereum, transferred the power to order transactions from private exchange operators to networks of validators. A distinction is warranted here: *decentralization* in this context operates on two different levels — the protocol-level decentralization of rule definition (the ordering rules are encoded in open-source software rather than privately controlled by a single entity) and the operational decentralization of rule enforcement (the size of the validator set, the distribution of stake, and the governance structure). This *open but semantically agnostic* ordering paradigm created transparency, but it also gave rise to the problem of MEV. In a public mempool, all pending transactions are fully visible, allowing MEV searchers to bribe block producers to arbitrarily reorder, insert, or censor transactions, and thereby to execute predatory

strategies such as sandwich attacks and front-running. In this environment, market makers face not only the adverse selection risk of traditional markets but also continuous value extraction from the MEV supply chain, leaving them exposed to greater risk than in the CEX environment.

It is against this backdrop that the emergence of Hyperliquid offers an important case study. It is not merely a decentralized exchange (DEX) but an open and observable microstructure experiment: all of its rules, trades, and order book states are recorded on-chain and can be audited and verified by anyone, in marked contrast to the *black box* of a CEX. Addressing the limitations of the first two paradigms, Hyperliquid's designers proposed an entirely new solution — semantic ordering: identifying the economic meaning of a transaction at the consensus-protocol level and ordering transactions differentially on that basis, placing liquidity-protecting actions ahead of liquidity-consuming ones (its definition and implementation are detailed in Section 9.1).

This chapter analyzes Hyperliquid's microstructure system layer by layer: the two mechanism innovations of semantic ordering and cancellation priority, and how the discrete-time property — an inevitable consequence of on-chain matching — provides their structural foundation. It examines how these elements operate in concert and how they trade off among liquidity, efficiency, fairness, transparency, and robustness, while also probing their boundary conditions and failure modes. Among these, the JELLY incident provides a critical stress test that exposes systemic fragilities lying beyond microstructural protection. Understanding these underlying ordering and matching mechanisms is also the key foundation for analyzing the higher-level liquidity incentive structures built on top of them, such as the HLP Vault.

9.1 The semantic ordering mechanism

How transaction ordering fundamentally determines the ultimate profits and losses of market participants is a core question in understanding market microstructure. The closed time-priority of the CEX, the open bribe-priority of the general-purpose DEX, and the semantic priority of Hyperliquid — these three paradigms lead to sharply different outcomes in the distribution of value. As the first layer and guiding design principle of Hyperliquid's mechanism innovations, semantic ordering interprets the economic meaning of transactions directly at the consensus-protocol level and, on that basis, makes explicit priority choices that embody a value judgment.

Semantic ordering refers to a mechanism in which the consensus protocol determines a transaction's execution priority within a block according to its economic intent, rather than by a bare timestamp or the fee paid. This marks a paradigm shift: from semantically agnostic processing that treats all transactions *identically* to semantically aware processing that treats different transactions *differently*.

9.1.1 The limitations of traditional paradigms

In a traditional CEX, the matching engine is a highly optimized piece of software whose primary design goals are throughput and low latency. To achieve high performance, the engine must be kept as simple as possible, treating every incoming instruction —

whether a new order, a cancellation, or an amendment — as a data packet devoid of economic meaning. Minimizing per-order semantic processing has long been regarded as advantageous for matching speed. The engine's ordering logic follows a strict price-time priority principle: at the same price, the timestamp at which an order reaches the server determines its priority. This ordering process takes place in a fully closed, opaque *black box*; outside participants can neither observe nor audit its internal workings, which in principle leaves room for the exchange to treat clients differentially. This *semantically agnostic plus closed ordering* paradigm made the *speed race* the primary dimension of market competition — the source of the billions of dollars in social cost noted at the start of this chapter [1]. In a continuous-time black-box game, speed directly determines profitability.

The emergence of general-purpose blockchains such as Ethereum transformed the closed ordering regime of the CEX. On an on-chain DEX, transactions are broadcast to a public mempool, and the validators responsible for assembling blocks determine the final ordering. This *semantically agnostic plus open ordering* paradigm achieved procedural transparency but also introduced the problem of MEV. Anyone can observe the pending transactions in the mempool, and this transparency creates significant opportunities for MEV extraction. Typical MEV strategies include sandwich attacks, front-running, and back-running. Daian et al. (2020) first systematically described this phenomenon and warned that it could threaten the consensus stability of blockchains [2]. Under this paradigm, block producers effectively act as allocators of ordering rights, and the highest-bidding MEV searcher obtains a priority position in the transaction ordering. Value is transferred from ordinary users and liquidity providers to a complex supply chain composed of searchers, builders, and proposers. For market makers, this environment is harsher than the CEX: they face not only traditional adverse selection risk but also additional value extraction from the MEV supply chain.

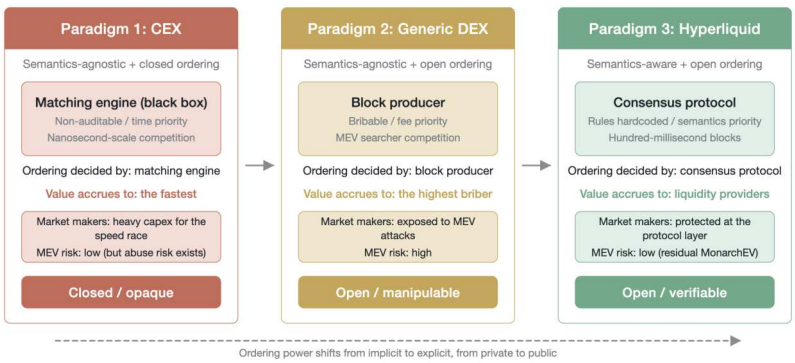

Figure 9-1. Comparison of the three ordering paradigms (conceptual architecture, not empirical data; the MEV and *bribable* mechanisms follow Daian et al. 2020 [2], and the social cost of the CEX speed race follows Aquilina et al. 2022 [1]; the multi-level ordinal ranking of *semantic priority* is an analytical characterization, whereas what the documentation records is *cancellations and post-only orders ahead of GTC/IOC*)

As shown in Figure 9-1, the three paradigms evolve progressively — ordering rights move from an unauditable matching engine, to a bribable block producer, and finally

to public information hardcoded in the consensus protocol. The core trend is that ordering power moves from implicit to explicit and from private to public.

9.1.2 Definition and implementation

Hyperliquid's designers recognized that the core problem of the first two paradigms is rooted in semantic agnosticism. Whether the closed black box of the CEX or the open auction of the general-purpose DEX, both treat all transactions as homogeneous data packets, entirely disregarding the fundamental economic differences among transaction types. A market maker's cancellation instruction and an arbitrageur's aggressive order are economically very different in meaning, yet under both paradigms they are treated as entirely equivalent.

Hyperliquid's solution embeds this capacity for distinction directly into the blockchain's consensus protocol. When its layer-1 (L1) blockchain protocol processes the transactions within a block, it does not order them by time or fee but first performs a semantic classification. Each transaction is parsed for its type tag — the order types defined in Chapter 7, such as Cancel, post-only, GTC, and IOC — and is then explicitly sorted into two priority categories [3], as shown in Table 9-1.

Priority	Transaction type	Economic meaning
System (highest)	Mark price updates, funding rate settlement	System maintenance: ensuring the correctness of price anchoring and contract settlement.
High	`Cancel`, `Amend/Replace`, `Post-only`	Liquidity protection or provision: a market maker withdraws a potentially loss-making quote, modifies the parameters of an existing order, or passively submits a limit order that only rests on the book and does not take.
Standard	Liquidation engine forced-closure orders	Solvency maintenance: forced liquidations triggered by the liquidation engine when margin is insufficient.
Low	`GTC`, `IOC`, triggered conditional orders	Liquidity consumption: a taker actively accepts the current quote to execute, consuming liquidity on the order book.

Table 9-1. Hyperliquid transaction priority classification (Data source: compiled by the author)

The priority tiering in Table 9-1 reflects a fine-grained design trade-off. Placing liquidation engine orders at *standard* priority rather than *high* priority carries important implications: if liquidation orders were given too low a priority, solvency protection would be delayed and systemic risk would rise; if too high, an attacker might deliberately trigger liquidations to obtain high-priority execution, creating a new attack vector. Standard priority allows market makers to withdraw their quotes before liquidation orders execute; this protects market makers but may also degrade the quality of

liquidation execution, a trade-off examined concretely in the JELLY incident in Section 9.4.3. An Amend/Replace order is semantically equivalent to the atomic operation of a Cancel plus a new order; it inherits high priority because its core intent is still to adjust an existing supply of liquidity rather than to consume liquidity. Hyperliquid's official documentation and its January 2024 technical blog post [4] explicitly record a protocol-level rule that orders transactions by semantic type: cancellations and post-only orders execute ahead of GTC/IOC taker orders. (The documentation describes within-block ordering as three classes: (1) actions that do not send a GTC/IOC order to the book, (2) cancellations, and (3) actions that send a GTC/IOC order.) The listing above, which places system-maintenance transactions and the liquidation engine in separate *System* and *Standard* tiers, is an interpretive reconstruction made in this chapter for analytical convenience; the documentation does not explicitly frame mark price and funding rate updates and liquidation as ordered priority tiers. The claims below that *liquidation sits at standard priority and that market makers can cancel before a liquidation fills* actually rest on the documented mechanism that *cancellations precede all fillable orders, and a liquidation fill is a fillable order*, rather than on the four-tier ordinal ranking itself, which the documentation does not confirm.

When a block is processed, transactions execute in strict sequence according to the priority tiers above. These rules are encoded in the open-source software run by all validator nodes, and changing them requires the majority consensus of the validator set rather than the unilateral decision of any single entity. However, as Section 9.4.7 will analyze, the size of the validator set and the distribution of stake determine the actual strength of this safeguard. In economic terms, this *semantically aware plus open ordering* paradigm amounts to an explicit value judgment made at the consensus level: actions that protect and provide liquidity take priority over actions that consume it. Table 9-2 provides a systematic comparison of the three ordering paradigms.

Dimension	CEX (semantically agnostic + closed)	General-purpose DEX (semantically agnostic + open)	Hyperliquid (semantically aware + open)
Who decides ordering	Matching engine (unauditable)	Block producer (bribable)	Consensus protocol (rules hardcoded)
Value allocation logic	Accrues to the fastest	Accrues to the highest briber	Favors liquidity providers
Market maker's position	Must incur costs to join the speed race	Disadvantaged (exposed to MEV attacks)	Protected at the protocol level
MEV risk	Low (but risk of exchange abuse of power)	High	Low (only residual MonarchEV)

Table 9-2. Systematic comparison of the three ordering paradigms (Data source: compiled by the author)

A key pattern emerges from the comparison in Table 9-2: in the CEX value accrues to the fastest, in the general-purpose DEX to the highest briber, and in Hyperliquid it is systematically directed toward liquidity providers. The three paradigms also handle MEV risk in sharply different ways: the CEX internalizes it as the exchange's private

informational advantage, the general-purpose DEX externalizes it as open rent-seeking competition, and Hyperliquid compresses it to a structural residual through semantic rules.

To make the differences among these three paradigms concrete, the following analysis traces how ordering determines trading outcomes by comparing the results of an identical set of trading instructions under the three ordering regimes. In a hypothetical scenario, the price of ETH on Binance drops suddenly from \$2,000 to \$1,980 at t = 0. At this moment, on a given trading platform, three participants issue instructions almost simultaneously (Table 9-3). The three instructions reach the platform within an extremely short time window (< 200 ms), and the different ordering rules determine the final distribution of profits and losses.

Participant	Role	Action	Intent
Alice	Market maker	Cancel — withdraw the \$1,995 bid (10 ETH)	Avoid being filled at a stale price and protect herself against adverse selection
Bob	Arbitrageur	IOC sell order — sell 10 ETH at \$1,995	Exploit the price lag by selling high on this platform and buying back on Binance at \$1,980 for a profit
Carol	Ordinary trader	GTC limit buy order — post a bid for 5 ETH at \$1,970	Believing ETH will keep falling, hopes to acquire it at a lower price

Table 9-3. The three core participants and their actions (across the CEX, general-purpose DEX, and Hyperliquid paradigms) (Data source: compiled by the author)

Under the traditional CEX's speed-priority paradigm, Bob holds the latency advantage: his IOC sell order reaches the matching engine before Alice's Cancel instruction and executes 10 ETH at \$1,995. Bob immediately hedges by buying back on Binance at \$1,980, earning a profit of \$150. Alice's cancellation arrives too late; her \$1,995 bid is passively filled at a stale price, buying 10 ETH worth only \$1,980, for a loss of \$150. Bob's profit comes entirely from a physical latency advantage. Under the general-purpose DEX's bribe-priority paradigm, both Bob's IOC sell order and Alice's Cancel are broadcast to the public mempool. An MEV searcher, Dave, spots the opportunity and pays a bribe to the block builder to place his own sell order ahead of Alice's Cancel. Dave sells 10 ETH at \$1,995 into Alice's stale bid, and Alice's cancellation fails because her order has already been filled. Dave profits (net of the bribe), while Alice again loses \$150. Under Hyperliquid's rule-priority paradigm, the three instructions arrive within the same block window. The consensus protocol automatically groups them by category: Alice's Cancel is high priority, while Bob's IOC and Carol's GTC are low priority. The execution order is as follows: Alice's Cancel is executed first, her \$1,995 bid is successfully withdrawn, and she suffers no loss. Bob's IOC sell order cannot execute because the counterparty no longer exists. An MEV searcher's aggressive order would likewise be ranked behind Alice's Cancel, so a sandwich attack is structurally infeasible.

Table 9-4 summarizes the profit-and-loss outcomes for each participant under the three paradigms.

Participant	CEX	General-purpose DEX	Hyperliquid
Alice (market maker)	−$150	−$150	$0
Bob (arbitrageur)	+$150	$0	$0
Carol (ordinary trader)	$0 (not filled)	$0 (not filled)	$0 (not filled)
Dave (MEV searcher)	Not present	+$100 (assumed)	Cannot act
Builder/exchange	Implicit gain	+$50 (assumed)	No additional gain

Table 9-4. Summary of profit-and-loss outcomes for each participant under the three paradigms (Dave exists only in the general-purpose DEX scenario) (Data source: compiled by the author)

This case reveals not merely a technical difference but a fundamental question about who value belongs to: when a price dislocation occurs, to whom should the economic value it generates accrue? The first two paradigms assign it to the fastest participant and to the one best at manipulating ordering, respectively (as in Table 9-2 and the discussion above), whereas the answer of the third paradigm is that this value is captured by no one — it is not transferred away from the liquidity provider (Alice) but remains in the market (in the Hyperliquid column, every party's profit and loss is $0). In other words, Hyperliquid protects liquidity providers from predation rather than redistributing value to market makers. Its design embeds a core assumption: the adverse selection risk borne by market makers constitutes the supply cost of liquidity as a public good, and the protocol should compensate for this structurally.

Crucially, the protection above holds only when Alice's Cancel instruction and Bob's IOC order fall within the same block. If Bob's aggressive order is included in block N while Alice's cancellation falls into block N+1 owing to network latency, then Alice's stale quote is still executed in block N, and the market maker's adverse selection loss is no different from the CEX scenario. The probability of this cross-block failure scenario depends on the network latency between the market maker and the validator nodes and on the timing relationship at the block boundary, which Section 9.3.7 analyzes in detail.

9.1.3 Effects on market makers

The deeper effect of semantic ordering on market makers is that it systematically alters the cost structure of the market-making business. A market maker's equilibrium spread must cover the various costs it faces. According to the classic model framework established by Glosten and Milgrom (1985), these costs consist mainly of adverse selection costs, inventory risk costs, and order processing costs [5]. In the CEX environment, one must add the high infrastructure cost of maintaining a speed advantage. In the general-purpose DEX environment, adverse selection costs are amplified by the presence of MEV.

By granting market makers' defensive instructions (such as cancellations) high priority, semantic ordering directly reduces the adverse selection risk they face. Under normal market conditions, a market maker can, with high probability, successfully cancel before

informed traders exploit its stale quote, thereby protecting itself from loss. However, this protection probability drops significantly during network congestion or near a block boundary, where a cancellation instruction may fall into the next block owing to transmission latency, leaving the market maker exposed to adverse selection in the current block. In its pricing model, a market maker should reserve a buffer for this tail risk rather than treat cancellation priority as unconditional protection. This protocol-level protection means market makers no longer need to invest heavily to compete in the speed race, which significantly lowers infrastructure costs. The decline in these two core costs allows market makers to remain profitable even while quoting narrower spreads. Drawing on the model framework of Glosten and Milgrom [5], Figure 9-2 conceptually presents the decomposition of a market maker's equilibrium spread across the three market environments. In the semantic ordering environment, the substantial reduction in adverse selection and infrastructure costs significantly compresses the total spread, ultimately benefiting all traders.

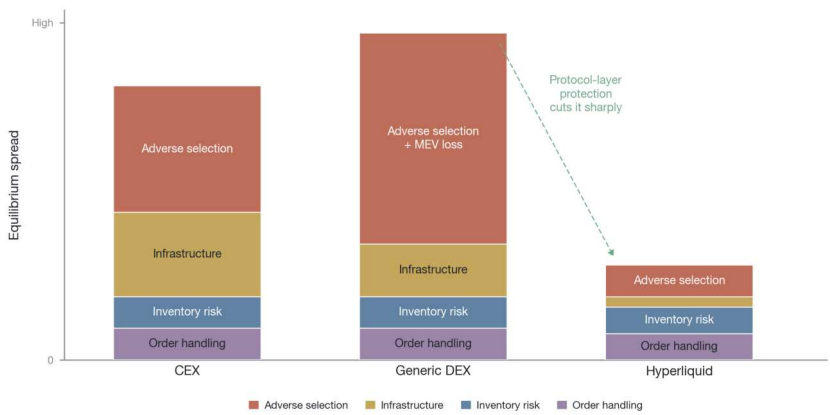

Figure 9-2. Decomposition of a market maker's equilibrium spread across three market environments (conceptual illustration; relative heights are assigned by the author and are not empirical data; the spread-decomposition framework follows Glosten and Milgrom 1985 [5], where [5] supports the adverse selection component, while the infrastructure cost is an extension added in this chapter and is not part of [5]; for the general-purpose DEX, the adverse selection segment is folded into the MEV loss)

As Figure 9-2 shows, the compression of the equilibrium spread in the semantic ordering environment comes mainly from two components: adverse selection costs fall sharply owing to protocol-level protection, and infrastructure costs approach zero as the speed race loses its purpose. Inventory risk and order processing costs differ little across the three environments and are only weakly linked to the ordering mechanism.

9.1.4 Effects on arbitrageurs

Semantic ordering does not eliminate MEV; rather, it structurally redefines and redistributes it. Traditional sandwich-attack and front-running MEV is largely suppressed because aggressive orders have lower priority than market makers' defensive orders. MEV does not vanish entirely, however, but persists in a more constrained form. Because the ordering of transactions within a single priority category is still determined

by the block proposer, the proposer retains a degree of ordering power. This ordering power held by the block proposer within the framework of the protocol's rules is termed *residual MEV* in this chapter; it also corresponds to the *Monarch* category in the {Monarch, Moloch, Mafia} extractable-value framework proposed by Sun (2022) [25] in the MEV literature — the value extracted by a single sequencer by virtue of its ordering monopoly (the term is not official Hyperliquid terminology, nor is it equivalent to *residual MEV* in the generic sense).

MonarchEV is far smaller in scale than traditional MEV and arises mainly in the following scenario: when two arbitrageurs submit identical arbitrage transactions within the same block, the block proposer can choose which executes first. This power can be *sold*, with an arbitrageur paying part of its profit to the block proposer as an *ordering fee*. But because such arbitrage opportunities are themselves greatly reduced by the protection afforded to market makers, the absolute scale of MonarchEV is very limited. It is closer in nature to a theoretical residual risk than to a serious problem in practice. This mechanism pushes high-frequency traders away from latency arbitrage that relies on micro-timing advantages and toward the discovery of cross-market price discrepancies based on information analysis, a behavior pattern closer to traditional cross-market arbitrage (Section 9.2.3 further analyzes the positive effect of this strategic shift on price discovery).

9.1.5 Theoretical foundations

The design of semantic ordering is supported by well-established theory in financial economics. As noted earlier, the model of Glosten and Milgrom (1985) shows that a market maker's spread is directly related to the adverse selection risk it faces [5]. By granting priority to cancellation operations, semantic ordering systematically lowers the probability of adverse selection faced by market makers, thereby allowing them to quote tighter spreads. Viewed through Harris's (2003) framework for analyzing market microstructure, semantic ordering is in essence a major innovation at the level of *trading rules* [6]. It elevates the protection of liquidity providers from a reliance on market makers' own investment (speed) or on ex post compensation in market design to an ex ante guarantee at the protocol level.

The deeper logic of this value judgment is that liquidity is a public good of the market from which all traders benefit, yet its providers (market makers) bear a disproportionate share of the risk. Without protection, market makers would widen their spreads to compensate for this risk, and wider spreads mean that all traders pay higher transaction costs. Protecting market makers at the protocol level is therefore not an unfair tilt but a mechanism design intended to improve the overall efficiency of the market. By lowering market makers' risk, it lowers the spread compensation they demand and ultimately reduces transaction costs for all traders.

However, the systematic suppression of informed traders by semantic ordering may also produce unintended efficiency consequences. The impossibility theorem of Grossman and Stiglitz (1980) holds that if informed trading is unprofitable, the incentive to acquire and process information weakens, and the efficiency with which market prices aggregate information declines accordingly [7]. When semantic ordering makes it difficult to

exploit an informational advantage against a market maker's stale quote, the incentive for arbitrageurs to acquire and transmit new information is also weakened. This is not a design flaw of semantic ordering but an inherent design trade-off: between improving liquidity supply and preserving price discovery incentives, semantic ordering clearly chooses the former. Each ordering paradigm is a design choice made under particular constraints, with its own trade-offs, and should not be placed within a simple linear narrative of *progress*.

Semantic ordering offers a new dimension for market design: it makes explicit the priority of different trading behaviors and hardcodes that priority into the consensus rules. Yet semantic ordering is not the only path to solving the MEV problem, and situating it within the broader range of mitigation approaches helps clarify its distinctive position.

9.1.6 A comparison of MEV mitigation approaches

Current mainstream MEV mitigation approaches can be grouped into several categories according to their technical path. Private-mempool approaches, exemplified by Flashbots Protect and MEV-Share, work by encrypting or privatizing the transaction-submission process to prevent searchers from observing the contents of unconfirmed transactions, thereby eliminating front-running and sandwich attacks that rely on information visibility [8]. Such approaches have been widely adopted in the Ethereum ecosystem, but their limitation is that they do not change the ordering rules themselves: once a transaction is decrypted, its ordering is still decided by the block builder, so MEV is redistributed rather than eliminated. Cryptography-based approaches, exemplified by the threshold-encrypted mempool, use cryptographic means to ensure that transaction contents remain invisible until ordering is fixed, technically eliminating content-based MEV extraction. However, such approaches introduce additional computational and communication latency and cannot treat different transaction types differentially; in their encrypted state, all transactions are treated as equivalent. Intent-based approaches, exemplified by CoW Protocol and UniswapX, abstract a user's trading need into an *intent*, and specialized solvers compete to find the optimal execution path [9]. This approach performs well in swap scenarios, but its applicability is limited to transaction types that can be expressed as outcome constraints and cannot cover the full order-book trading environment.

Hyperliquid's semantic ordering occupies a distinctive position among these mechanisms. Unlike the approaches above, semantic ordering explicitly classifies the economic meaning of transactions at the consensus-protocol level and, on that basis, makes priority decisions that embody a value judgment. This makes it a rare MEV mitigation mechanism among the mainstream approaches surveyed in this chapter that explicitly expresses, at the protocol level, a value orientation about *which market behaviors should be given priority protection*. However, this design requires an application-specific chain as its implementation vehicle and cannot be deployed on a general-purpose L1, because Hyperliquid's L1 blockchain is itself infrastructure custom-built to support semantic ordering. Table 9-5 provides a systematic comparison of these approaches.

Approach category	Representative	Protection mechanism	Scope of MEV reduction	Applicable setting	Limitation
Private mempool	Flashbots Protect	Hides transaction contents	Front-running, sandwich attacks	General-purpose L1	MEV redistributed, not eliminated
Threshold encryption	Shutter Network	Encryption until ordering is fixed	Content-based MEV	General-purpose L1	Added latency, no differential treatment
Intent solving	CoW Protocol	Off-chain competitive solving	Swap slippage	Swap scenarios	Not applicable to the order book
Semantic ordering	Hyperliquid	Type classification at the consensus layer	Front-running, adverse selection	Dedicated order-book chain	Requires an application-specific L1
Distributed ordering rights	dYdX v4	Ordering by validator consensus	Single-point ordering manipulation	Dedicated order-book chain	Semantic priority not explicitly encoded

Table 9-5. Comparison of MEV mitigation approaches (Data source: compiled by the author)

The comparison with dYdX v4 is especially instructive, because, like Hyperliquid, it is a decentralized order-book exchange on an application-specific chain. dYdX v4 mitigates single-point ordering manipulation by distributing ordering rights to validator consensus, but it does not classify different transaction types semantically at the protocol level, and all orders are treated equally when ordered. As a result, dYdX v4's market makers do not enjoy Hyperliquid-style protocol-level cancellation-priority protection, but they also avoid the suppression of informed-trader incentives that semantic ordering entails. The two paths strike different balances between liquidity protection and price discovery efficiency.

The value of surveying these solutions is that it reveals Hyperliquid's design choice to be not without alternatives but a particular philosophical and engineering trade-off made among several viable paths.

9.1.7 The interaction of semantic ordering with the transaction lifecycle

Semantic ordering does not act in isolation on the transaction-ordering stage; it interacts deeply with the other core subsystems of perpetual futures, and these interactions both amplify the protective effect of semantic ordering and, under certain conditions, introduce new dimensions of risk.

At the level of the margin system, the interaction between semantic ordering and liquidation cascades differs between isolated margin and cross margin. Under isolated margin, the liquidation of a single position does not affect other positions, and cascade risk is confined to a single trading pair; under cross margin, the liquidation of one position may render overall margin insufficient and trigger a chain of liquidations across trading pairs. Semantic ordering provides the same ordering protection in both modes, but under cross margin the transmission path of a liquidation cascade is more complex,

and its systemic risk lies beyond what the ordering layer can cover.

At the level of funding rate settlement, the periodic settlement of the funding rate is placed at the system's highest priority (Table 9-1), which means that settlement transactions cannot be front-run by market participants at the ordering level (although, as Section 9.4.3 shows, the external price inputs on which the funding rate and mark price depend can still be manipulated; the protection here is confined to on-chain execution ordering). This design safeguards the integrity of the funding rate mechanism as a price-anchoring tool for perpetual futures, and its detailed workings are analyzed in Chapter 10.

At the level of the liquidation engine, the design choice to place liquidation orders at standard priority produces subtle but important consequences. When a market maker's Cancel instruction and the liquidation engine's forced-closure order coexist within the same block, the Cancel, as high priority, executes before the liquidation order — that is, the market maker can withdraw its quote before the liquidation order seeks a fill. This protects market makers from being forced to absorb liquidated positions at extreme prices, but it may also leave liquidation orders facing thinner order-book depth at execution, degrading the quality of liquidation execution. The JELLY incident is precisely an extreme manifestation of this interaction: when many market makers exercised their cancellation priority before liquidation was triggered, an oversized liquidated position, unable to find sufficient depth on the order book, was transferred to the HLP Vault, as analyzed in depth in Section 9.4.3. These interactions show that the effects of semantic ordering cannot be assessed in isolation from the broader contract-settlement system in which it is embedded. The design details of the liquidation mechanism and the margin system are discussed in Chapter 11 and Chapter 10, respectively.

The effectiveness of this macro-level framework depends heavily on its most contested concrete implementation in practice: cancellation priority.

9.2 The cancellation priority mechanism

Cancellation priority is the most directly consequential concrete rule within the semantic ordering framework. The rule stipulates that, within a block's processing cycle, every instruction that seeks to cancel an existing order has an execution priority absolutely higher than that of every new instruction that seeks to fill those orders. This design gives market makers a right of last look enforced by the consensus protocol.

In traditional financial markets, last look is a market maker's final opportunity to accept or reject a client order in light of the latest market information. This power has been widely questioned for its opacity and potential conflicts of interest. Hyperliquid, however, fundamentally reworks this concept. Here, last look is not a market maker's private privilege but a public, universal rule hardcoded into the consensus protocol. All market participants are fully aware of the rule's existence and can adjust their strategies accordingly. This complete transparency means cancellation priority is no longer an unfair advantage but a known initial condition that reshapes the market game.

9.2.1 Hedging adverse selection

To understand the effect of cancellation priority, one must return to the core market-microstructure concept analyzed in Section 7.1.3: adverse selection. A market maker's core business is to quote continuously under uncertainty (its strategy framework is given in Section 7.7.1); its profit comes from the bid-ask spread, while its greatest risk comes from trading against better-informed *informed traders*. When external information causes the true value of an asset to change, informed traders can arbitrage against a market maker's stale, not-yet-updated quote, and the loss this imposes on the market maker is the adverse selection cost. The classic model of Glosten and Milgrom (1985) systematically shows that a market maker's quoted spread must be wide enough to cover the expected loss it incurs when trading against informed traders [5].

In the CEX and general-purpose DEX environments, market makers have limited means to combat adverse selection: they mainly rely on investing in faster technical systems to cancel first, or on widening their quoted spread to pass the risk cost on to all traders up front. The cancellation priority mechanism offers a third solution: at the protocol level, it compresses the probability of within-block adverse selection under normal market conditions to a residual level near zero (with risk remaining only in a narrow window near the block boundary). In essence, it establishes a layer of structural separation, enforced by the consensus protocol, between the aggressive orders of informed traders (such as arbitrageurs) and the defensive cancellation instructions of market makers.

Figure 9-3 compares the execution outcomes of the same set of trading instructions in the CEX and Hyperliquid scenarios.

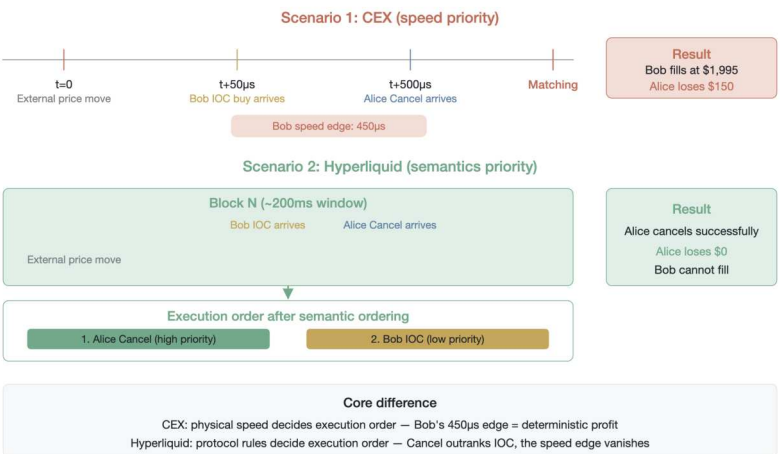

Figure 9-3. Comparison of execution timelines for the CEX and Hyperliquid (hypothetical worked example, not empirical data; $1,995, $150, 450 μs, and approximately 200 ms are all illustrative values; the mechanism by which the Cancel precedes the IOC is grounded in Section 9.1.2 and [5])

When the external market price changes, market maker Alice and arbitrageur Bob send instructions to the system at the same time. Even if Bob's instruction physically arrives first, as long as it falls within the same block as Alice's cancellation instruction,

the protocol's consensus rules force Alice's cancellation to be processed first. This means the protocol gives Alice a protection window of about 200–400 ms (one block time), allowing her to withdraw a stale quote before it is executed. This mechanism significantly lowers a market maker's adverse selection cost, enabling it to provide liquidity at narrower spreads over longer periods.

9.2.2 A comparison with the IEX speed bump

The design philosophy of cancellation priority is often compared with the speed bump of the IEX exchange. IEX's design, popularized by Michael Lewis in his book *Flash Boys* [10], imposes a physical delay of about 350 microseconds on all orders entering its matching engine by routing them through 38 miles of coiled fiber-optic cable, with the aim of eliminating the speed differential between high-frequency trading (HFT) firms and other market participants. Although the two share a similar goal — creating a fairer market environment — they differ fundamentally in philosophy and mechanism (Table 9-6).

Dimension	IEX speed bump	Hyperliquid cancellation priority
Mode of action	Physical layer: delays all orders indiscriminately.	Protocol layer: orders differentially according to the economic meaning of transactions.
Philosophy	Procedural fairness: attempts to have all participants reach the finish line *simultaneously*.	Outcome-oriented: prioritizes protecting the interests of liquidity providers.
Protective effect	Limited: can bridge only microsecond-level speed differences.	Provides strong protection within one block time (about 200–400 ms) (with a narrow gap at the block boundary).
Market impact	Fairly controversial; some studies argue it harms price discovery efficiency.	Explicitly redistributes value from predatory arbitrageurs to market makers.

Table 9-6. Cancellation priority versus the IEX speed bump (Data source: compiled by the author)

The speed bump is a form of *physical slowdown* that attempts to patch a flawed rule system through technical means. Cancellation priority, by contrast, is a *change of rules* that fundamentally alters the rules of the game. The behavioral difference between the two under liquidity-stress scenarios is especially critical: IEX's delay is symmetric, applying equally to all orders (including cancellations), so during a liquidity contraction the rate at which market makers withdraw slows in step with the rate at which takers consume, and the net change in liquidity is relatively gradual. Hyperliquid's mechanism, by contrast, is asymmetric: only cancellations receive priority acceleration, and in a liquidity-contraction scenario, where cancellations far outnumber new resting orders, net liquidity may drop sharply within a single block. This asymmetry strengthens liquidity supply in normal markets but may accelerate liquidity evaporation during periods of stress. The D-Limit order type that IEX later introduced also began to incorporate a semantically aware design philosophy, indirectly corroborating the need

to solve the ordering problem at the level of protocol rules.

9.2.3 Structural effects

The cancellation priority mechanism has profound structural effects on the market ecosystem, the most direct of which is a fundamental shift in the dimension along which market makers compete. In the CEX, a two-dimensional competition of *speed plus model* dominates, whereas in Hyperliquid the importance of speed is greatly diminished and the competitive focus shifts to *model quality* itself. This significantly lowers the barrier to entry for market making, enabling small quantitative teams that lack the capacity to invest in top-tier infrastructure to compete, thereby increasing the diversity of liquidity supply in the market. By comparing market makers' cost structures across the two environments, Figure 9-4 illustrates this structural shift from infrastructure investment to competition on model quality.

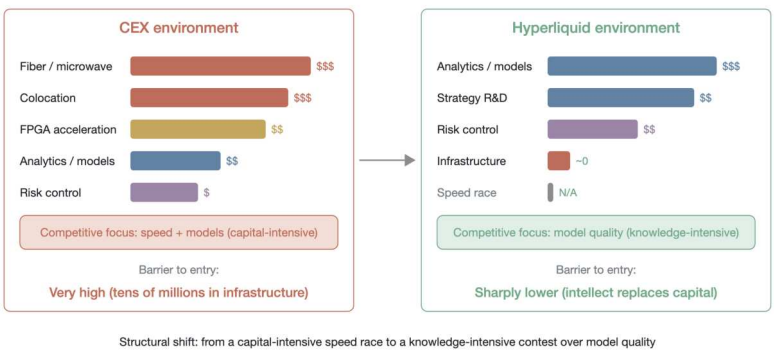

Figure 9-4. Comparison of market makers' cost structures across trading environments (conceptual illustration, not empirical data; $/$$/$$$, ~0, and N/A are qualitative cost tiers, not measured monetary values; maps to Sections 9.2.3 and 9.5.1)

Figure 9-4 reveals a structural shift: infrastructure investment falls from a dominant position in the CEX environment to a marginal level in the Hyperliquid environment, while model development and data analysis take its place as the core cost items. The direct consequence is that the capital barrier to entry for market making falls while its intellectual barrier to entry rises.

The mechanism also forces high-frequency takers to shift their strategies from latency arbitrage toward information-driven approaches. The traditional strategy of sniping stale quotes becomes unprofitable, forcing these traders toward strategies that rely more on information analysis and predictive capability — for example, predicting market makers' behavior patterns, or acting as a price-transmission intermediary across exchanges to promote price convergence, rather than arbitraging price lags.

At the level of spread structure, the effect of cancellation priority is equally significant. By lowering adverse selection and infrastructure costs, market makers can remain profitable even while quoting narrower spreads. Empirical data show that, during calm market periods, the spreads on Hyperliquid's major trading pairs are typically compa-

rable to, or even better than, those of top-tier CEXs (the measurement basis for this comparison and the static-versus-effective-depth qualifications are detailed in Section 9.5.4). However, the cost of these narrow spreads reveals a *liquidity paradox*. The research framework of Foucault, Kadan, and Kandel (2005) on the resilience of limit order markets helps in understanding this phenomenon [11]: cancellation priority lowers the option cost of a market maker's resting order, and under normal market conditions this incentive leads market makers to provide tighter spreads and deeper order books; but the same mechanism also means that, during periods of market stress, market makers can withdraw all of their liquidity with frictionless speed. The prospect theory of Kahneman and Tversky (1979) offers a behavioral explanation: when market volatility spikes, loss aversion drives market makers to exercise their cancellation right immediately rather than wait and assess [12]. Because the execution cost of cancellation (including its psychological cost) is reduced to near zero at the protocol level, panic withdrawal may occur faster and more completely on Hyperliquid than in the CEX environment. This constitutes a procyclical effect: the very mechanism that improves liquidity in normal times accelerates its evaporation in a crisis. Potential mitigations include introducing minimum market-making obligations or imposing a cancellation cooldown during extreme volatility, but these options are in tension with the core design philosophy of cancellation priority.

For ordinary traders, the net effect is positive. They enjoy lower transaction costs, and the risk of their market orders being sandwiched is significantly reduced. But they must also adapt to a new market characteristic: some of the liquidity displayed on the order book may be apparent liquidity — the *depth illusion* defined in Section 8.2 appears in a new form under the cancellation priority mechanism, in that when they attempt to execute a large order, this liquidity may vanish as market makers exercise their cancellation priority. For institutional traders who need to execute large orders, the complete transparency of the on-chain environment poses a structural challenge to execution quality. Traditional execution algorithms such as the time-weighted average price (TWAP), the volume-weighted average price (VWAP), and iceberg orders face a fundamental dilemma in a fully transparent on-chain environment: the size, timing interval, and direction of every child order are visible in real time, allowing competitors to infer the total size and execution strategy of the parent order. The optimal-execution framework of Almgren and Chriss (2001) shows that information leakage increases the permanent price-impact cost [13]: when market participants can anticipate the later portions of a large order, they adjust their quotes in advance, causing execution prices to deteriorate systematically. This transparency cost partly offsets the spread-level benefit that cancellation priority brings to institutional traders.

The effectiveness of the cancellation priority mechanism depends on a key structural foundation: the discrete-time window inherent to on-chain matching (about 200–400 ms). It is this window that forcibly reduces the resolution of the speed race from the nanosecond to the hundred-millisecond scale, making rules rather than speed the dominant factor in ordering. Its structural origin as an inevitable consequence of on-chain matching, and the mechanism-design space it opens up, are detailed in Section 9.3.

9.3 Discrete-time matching: an inherent property of on-chain matching

Semantic ordering and cancellation priority define the rules for *who should be processed first*, but these rules can take effect only if the matching engine can *collect* multiple transactions within a time window before ordering them together. Discrete-time matching provides this structural foundation. Discrete-time matching is not a mechanism invented by Hyperliquid but an inherent structural feature of any on-chain matching system: a blockchain reaches consensus and processes transactions in units of blocks, so once a matching engine is placed on-chain, it must process transactions in batches by block, switching from continuous time to a discrete-time window (about 200–400 ms). This structural feature is not itself complex, but Hyperliquid astutely recognized the mechanism-design space it creates and built semantic ordering and cancellation priority on top of it, fundamentally transforming the market's speed game.

9.3.1 Continuous- versus discrete-time games

To understand the economic consequences of discrete-time matching, one must first examine its opposite: the inherent problems of continuous-time matching. Budish, Cramton, and Shim (2015) argue that the continuous-time limit order book inherently gives rise to a speed race, because under this mechanism even a microsecond-level speed advantage can be converted into a deterministic profit [14]. This channels vast social resources into a *zero-sum* or *negative-sum* race to invest in infrastructure — building dedicated microwave towers, laying undersea fiber-optic cables — and ultimately concentrates the market ever more tightly among a few top-tier HFT firms.

> In traditional financial markets, the communication latency between the Chicago Mercantile Exchange (CME) and the New York Stock Exchange is a classic arena of the speed race. HFT firms invested hundreds of millions of dollars to build microwave-tower networks solely to shorten data-transmission latency along the Chicago–New York corridor from about 6.0 ms to about 3.8 ms (data from roughly 2014–2018; the latency of the most advanced microwave networks today may be lower). In a continuous-time *winner-take-all* game, this roughly 2.2 ms advantage can generate tens of millions or even hundreds of millions of dollars in profit each year, because the participant that reacts first to a price change captures almost all of the arbitrage opportunities. Hyperliquid's block time of about 200–400 ms is precisely where the economic essence of discrete-time matching lies: it transforms the winner-take-all game of continuous time into equal competition within a discrete-time window — as long as instructions fall within the same block, speed differences within the block no longer generate economic value at the protocol level (a quantitative worked example is given in Section 9.3.5).

Hyperliquid's L1 uses the HyperBFT consensus algorithm, a derivative implementation of the HotStuff family. Under normal network conditions, HyperBFT's block latency is about 200 ms; under high load (as during the JELLY incident), block time may extend to 400 ms or longer owing to mempool congestion and increased communication latency among validators. The 200–400 ms range of block times reflects precisely this load-dependent dynamic. Hyperliquid's matching mechanism operates in discrete time, with the block as its basic unit. The processing flow for each block (as shown in Figure

9-5 [3]) is uniform: collect transactions from the mempool, order them according to the semantic rules, match them one by one within the ordered sequence under a price-first, time-second principle, and finally update the order book state all at once and commit the block. This batch-processing model has significant microstructural consequences.

Figure 9-5. Hyperliquid's block-processing flow (mechanism illustration; the flow follows Hyperliquid documentation [3]; the *priority tiers: System/High/Standard* shown in the figure are an interpretive reconstruction in this chapter — what the documentation [3][4] explicitly records is only *cancellations and post-only orders ahead of GTC/IOC taker orders*, and placing mark price and funding rate updates and liquidation in separate ordered tiers is an interpretive reconstruction made in this chapter for analytical convenience rather than the documentation's own text; see the note to Table 9-1)

Figure 9-5 reveals an important design feature: semantic ordering takes place after transaction collection and before sequential matching — a three-stage flow of *classify, then order, then match* — which is the concrete way in which semantic ordering and discrete-time matching operate in concert.

9.3.2 The displacement of speed competition

The discrete-time matching mechanism displaces the dimension of the speed race. Within a block, the execution order of all transactions of the same type is determined by the order in which the block proposer receives them; but because the mempool typically buffers several blocks' worth of transactions, most transactions wait briefly in the pool before being packaged. This greatly dilutes the *who sends first* speed advantage within a block. Speed competition is not eliminated entirely, however, but is displaced to the level between blocks. If a participant's transaction can enter the mempool earlier than others', it is more likely to be packaged into an earlier block. The speed race therefore falls from the *microsecond-level* competition of the CEX to the hundred-millisecond-level competition of Hyperliquid.

This between-block speed competition is especially pronounced near the *block boundary*. As a block's packaging deadline approaches, a residual speed competition persists within a fuzzy interval of about 10–20 ms. Even so, compared with the 1–10 microsecond competition window of the CEX, Hyperliquid has reduced the intensity of speed competition by about three orders of magnitude.

9.3.3 A comparison with frequent batch auctions

Although Hyperliquid nominally still uses a price-time-priority central limit order book (CLOB) mechanism (its structure and rules are covered in Section 8.1.1), its discrete-time batch-processing property gives it some of the characteristics of the frequent batch auction (FBA) introduced in Section 8.8.3. The core idea of the FBA is to collect all orders within a time window and then execute all matchable orders at a single uniform clearing price, thereby eliminating the speed advantage entirely in theory [14]. Hyperliquid does not adopt a uniform clearing price but continues to use price-time-priority sequential matching within the block. Within a single priority category, transactions are arranged in the order in which the block proposer receives them from the mempool, effectively forming a first-in-first-out (FIFO) ordering. However, because the block proposer retains final control over the received ordering, this constitutes a concrete dimension of MonarchEV. This within-priority ordering rule gives rise to a key difference from the FBA.

> Suppose that within a block window the order book has sell orders at $2,002, $2,005, and $2,010, and that market buy orders from three buyers — Alice, Bob, and Carol — arrive simultaneously, with total demand less than or equal to the total supply at or below the $2,005 price level. Under the FBA mechanism, all buyers execute at the uniform clearing price of $2,005, and their arrival times are entirely irrelevant. Under the Hyperliquid mechanism, by contrast, the earliest-arriving buyer, Alice, first executes a portion at $2,002 and then the remainder at $2,005, obtaining a better average execution price. The later-arriving buyers, Bob and Carol, can execute only at $2,005. In this scenario, Alice's speed advantage — even if only at the millisecond level — brings her an economic benefit. Moreover, the block proposer can choose which of Bob and Carol executes first, which constitutes one source of residual MEV.

The differences in pricing mechanism, residual speed advantage, and MEV risk distribution revealed by this case can be compared systematically in Table 9-7.

Dimension	Hyperliquid block matching	Theoretical FBA
Pricing mechanism	Sequential matching within the block (price-time priority)	Uniform clearing price
Speed advantage	Greatly weakened but not fully eliminated	Fully eliminated in theory
MEV risk	Residual MonarchEV present (ordering power)	None in theory

Table 9-7. Key differences between the Hyperliquid and FBA mechanisms (Data source: compiled by the author)

Hyperliquid's design can be seen as a balance between the theoretical goal of the FBA and the practical constraints of the CLOB. It largely achieves the FBA's main goal (greatly weakening the speed race) while retaining the user experience of a traditional order book and a relatively simple implementation logic.

Behind this mechanistic difference lies a deeper divergence in design philosophy. Hyperliquid and the FBA share a common idea — both counter the speed race by discretizing time [14] — but they differ fundamentally in implementation path and philosophical

orientation. The core of the FBA is a uniform clearing price, so that all trades within the auction window execute at the same price, eliminating the incentive to front-run. Hyperliquid, by contrast, remains a price-time-priority order book: within a block, transactions execute sequentially by semantic priority and price level, and the price can move. Hyperliquid absorbs the core idea of the FBA but combines it with the traditional order-book mechanism and the innovative rule of semantic ordering. Hyperliquid differs structurally from the FBA along the dimensions of matching mechanism, price formation, ordering rules, and HFT-suppression strategy, and Table 9-8 provides a systematic comparison.

Dimension	FBA	Hyperliquid discrete-time matching
Matching mechanism	Batch auction, uniform clearing price	Sequential matching, batch processing
Price	Only one clearing price per batch	Price can vary continuously within a batch
Ordering rule	No ordering needed (or by price only)	Semantic ordering takes priority
Suppression of HFT	Eliminates front-running	Eliminates front-running but preserves room for other strategies

Table 9-8. Discrete-time matching versus the FBA (Data source: compiled by the author)

From a theoretical perspective, the core logic by which Budish et al. [14] argue for the FBA is that it breaks the *prisoner's dilemma* of the speed race. The discrete-time property inherent to on-chain matching achieves the same effect, and Hyperliquid adds to it a dimension the FBA lacks: semantic ordering. In the FBA, all participants are entirely equal within each auction window; in Hyperliquid, market makers' cancellation instructions are explicitly given higher priority. This is an important design difference: the FBA pursues *procedural equality*, whereas Hyperliquid pursues *outcome optimization*, explicitly placing the interests of liquidity providers above those of liquidity consumers. Hyperliquid can therefore be seen as a more explicit, deliberately weighted, and pragmatic implementation of the FBA idea in a blockchain-native environment.

9.3.4 Synergy with semantic ordering

The discrete-time property of on-chain matching and semantic ordering are mutually reinforcing complements, and their combination forms the foundation of Hyperliquid's microstructure. Discrete time creates a *batch window* that provides the basis for implementing semantic ordering. In continuous-time matching, orders are processed one by one in order of arrival, making it impossible to establish priority relationships among different order types. Conversely, semantic ordering solves an inherent problem of discrete time: within a batch window, absent explicit ordering rules, the block proposer would have complete freedom to order all transactions, which would lead to unconstrained MEV extraction. Through predefined priority rules, semantic ordering strictly limits the block proposer's discretion, compressing the MEV space to the single dimension of *ordering within the same category.*

Neither element can stand without the other. Without discrete time, semantic ordering cannot be implemented in continuous time; without semantic ordering, discrete time would degenerate into a pure block-space auction, leading to uncontrolled block-proposer MEV. Other decentralized exchanges share the structural feature of discrete time but have not converted it into a microstructural advantage. Hyperliquid's innovation lies in recognizing the mechanism-design space embedded in the discrete-time window inherent to on-chain matching and, on top of it, building semantic ordering and cancellation priority, thereby creating a self-consistent microstructure with few direct precedents in the known practice of either traditional finance or crypto finance.

Figure 9-6 presents the synergy between discrete-time matching and semantic ordering and its effect on the market ecosystem.

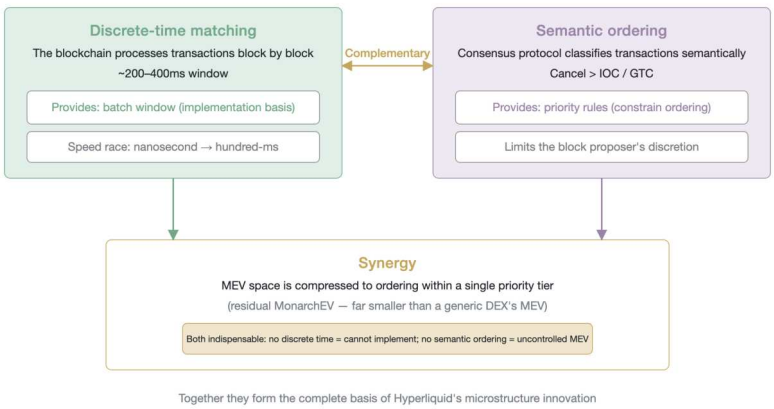

Figure 9-6. The synergy between discrete time and semantic ordering (conceptual illustration, not empirical data; MEV is compressed to ordering within a single priority category — that is, residual MonarchEV, a term drawn from the {Monarch, Moloch, Mafia} extractable-value framework of Sun 2022 [25] and not official Hyperliquid terminology)

Figure 9-6 shows that discrete time creates the batch window that makes semantic ordering implementable, while semantic ordering constrains the block proposer's discretion; the interaction of the two compresses the MEV space to the single dimension of ordering within a priority category, whose scale and harm are far smaller than the unconstrained MEV extraction seen on a general-purpose DEX.

9.3.5 The weakening of the speed race

In the CEX's continuous-time matching environment, a speed lead is measured in nanoseconds (billionths of a second), and HFT firms invest enormous sums to achieve it. In Hyperliquid's discrete-time matching environment, by contrast, the smallest unit of time is one block time (a few hundred milliseconds). This means that whether a trading instruction arrives with a latency of 1 microsecond or 100 ms, as long as it falls within the same block window it is treated as *equal* along the time dimension. What determines execution priority is no longer physical speed but the protocol's semantic rules.

This compression of time granularity from nanoseconds to milliseconds renders the traditional speed advantage of HFT almost entirely ineffective. Drawing on the theoretical framework of Budish et al. [14] and Hyperliquid's technical documentation [3], Figure 9-7 compares the effective competition time windows of different trading platforms.

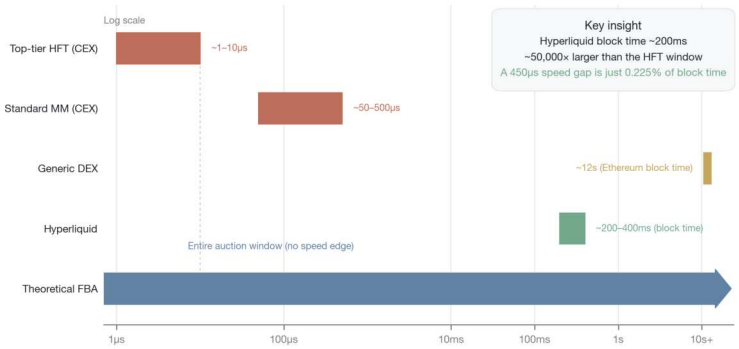

Figure 9-7. Comparison of effective competition time windows across trading platforms (representative parameters, not an external dataset; logarithmic time axis; Ethereum's block time of about 12 s and Hyperliquid's of about 200–400 ms follow Hyperliquid documentation [3] and refer to block production and confirmation rather than the roughly 70 ms single-block finality; the 1–10 μs for top-tier HFT and 50–500 μs for standard market making are industry orders of magnitude; the theoretical FBA spanning the entire window follows Budish et al. 2015 [14]; *about 50,000 times the roughly 4 μs window of top-tier HFT* is an arithmetic inference)

A simple model can quantify this effect. Suppose that on a CEX, HFT firm A has a latency of 50 microseconds and market maker B has a latency of 500 microseconds; A is 450 microseconds faster than B, a gap sufficient for A to capture B's stale quote first on every price change. But on Hyperliquid, where the block time is 200 ms (200,000 microseconds), the 450-microsecond latency difference between the two is only 0.225% of the block time. As long as the instructions fall within the same block, this difference is irrelevant. The *resolution* of the speed race is forcibly lowered from the nanosecond to the hundred-millisecond scale, substantially equalizing the competitive conditions among participants and shifting the competitive focus from infrastructure speed to model quality and information-analysis capability.

> On January 11, 2024, the U.S. Bureau of Labor Statistics released higher-than-expected consumer price index (CPI) data, setting off a chain reaction in the markets. At t = 0 the data are released; at t + 5 ms, algorithmic trading systems in the Chicago futures market react first and BTC futures prices fall; at t + 15 ms, top-tier HFT market makers on Binance begin adjusting their quotes; at t + 50 ms, spot prices on Binance have finished adjusting. Between t + 50 ms and t + 200 ms, market makers on Hyperliquid detect the price change on Binance and send Cancel instructions. At the same time, arbitrageurs also detect the spread and send IOC buy orders in an attempt to attack the stale quotes. The instructions of both fall within the same block. At t + 200 ms, the block is processed. Under the cancellation priority rule, the market makers' cancellation instructions execute before the arbitrageurs' buy orders. The market makers successfully withdraw their stale quotes and avoid loss, while the arbitrageurs' buy orders fail for lack

> of a counterparty. This case reveals a core characteristic of Hyperliquid's microstructure: its price discovery carries a structural lag of about 150–200 ms, giving it a price-following relationship to external markets. It is precisely this lag window that gives market makers ample time to send Cancel instructions, and the cancellation priority rule ensures that these instructions execute ahead of an attack, so that discrete time and cancellation priority form an effective synergy here. At the block boundary (for example, around t + 200 ms), a brief, temporary absence of liquidity may occur, because the market makers' old quotes have been withdrawn while their new quotes have not yet been confirmed on-chain.

9.3.6 Block time as a hyperparameter

The preceding analysis has treated the 200–400 ms block time as a given system parameter, but from a mechanism-design perspective, block time is an adjustable hyperparameter whose value directly determines the trade-off surface between the strength of market-maker protection and price discovery efficiency. When block time is short (for example, close to 50 ms), fewer transactions are collected within each block window, the reaction time available to market makers is compressed, the probability that a Cancel instruction lands in the same block as an aggressive order declines, adverse selection risk partly returns, market makers are forced to quote wider spreads to compensate, and the system's speed-competition characteristics begin to approach those of the CEX. When block time is long (for example, more than 2 seconds), market makers gain an ample protection window and adverse selection risk falls further, but the price-following lag widens in step. Within each block cycle, order-book quotes drift steadily away from external market prices, so market makers must widen their spreads in advance to cover this quote-staleness risk. The risk arises from within-block price drift, not from any need to hold positions longer, since market makers can still cancel and re-quote each block. The equilibrium spread therefore traces a U-shaped curve: when block time is too short, adverse selection costs push the spread up; when block time is too long, inventory risk and price staleness push the spread up; and in the middle region there is an optimal block time that minimizes the total spread.

Hyperliquid's current choice of a 200–400 ms block time can be located within this framework. Compared with other L1s, Ethereum's 12-second block time offers ample room to implement semantic ordering but too large a price-following lag; Solana's block time of about 400 ms is close to Hyperliquid's but does not introduce semantic ordering; and the subsecond block times of layer-2 (L2) chains such as Arbitrum likewise lack differential treatment of transaction types. Hyperliquid's distinctiveness lies in combining a relatively short block time with semantic ordering, seeking to operate near the low point of the U-shaped curve. The U-shaped curve above is a qualitative description, and its quantitative calibration faces significant challenges. The parameters of the FBA model of Budish et al. [14] are estimated from the volatility characteristics and participant structure of U.S. equity markets, and extending them directly to the crypto perpetual futures market would require recalibration to markedly different volatility distributions, leverage structures, and participant compositions. The optimal block time may differ significantly across trading pairs — for example, the difference in volatility characteristics between BTC perpetual futures and long-tail tokens implies

that their optimal points on the U-shaped curve may lie far apart — yet Hyperliquid currently applies a uniform block time to all trading pairs. As the underlying consensus technology advances, block time may shorten further, which would improve the price discovery lag but would also compress the protection window provided by cancellation priority; the dynamic balance between the two requires ongoing empirical calibration.

9.3.7 Boundary effects and MonarchEV

Discrete-time matching has inherent limitations, one distinctive risk being the block-boundary effect. Because transactions are processed in discrete blocks, transactions that happen to fall near the boundary between two blocks may have sharply different outcomes. As shown in Figure 9-8, market maker Alice sends a Cancel instruction 1 ms before block N's deadline tN; but if network latency delays that instruction so that it reaches the validator node 1 ms after tN, it is assigned to block N+1. During the processing of block N, Alice's stale quote is still active and may be filled by an arbitrageur within that block.

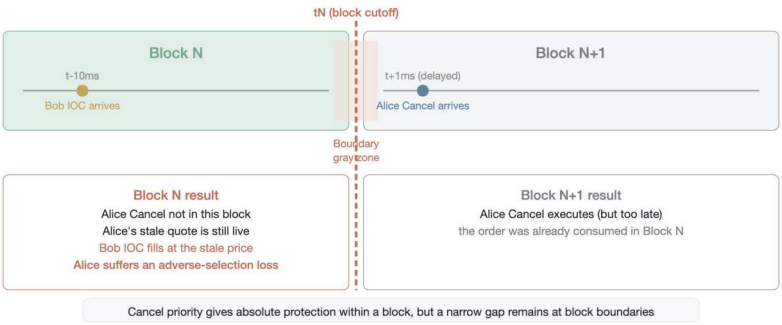

Figure 9-8. The block-boundary effect (hypothetical worked example, not empirical data; t − 10 ms and t + 1 ms are illustrative timestamps showing that cancellation priority provides near-absolute protection within a block but leaves a narrow gap at the block boundary; maps to Section 9.3.7)

This means that although cancellation priority provides near-absolute protection within a block (conditional on the cancellation being submitted and received by the proposer within the same block), a narrow protection gap remains at the block boundary, its width depending on fluctuations in network latency and typically ranging from a few milliseconds to a few tens of milliseconds. Market makers must therefore still attend to the network latency between themselves and the validator nodes, but the aim is to ensure that instructions reliably land in the intended block rather than to compete within a block — the competitive focus shifts from a *within-block speed race* to a *cross-block reliability race*, whose investment scale is far smaller than that of the traditional speed-infrastructure race.

Moreover, discrete-time matching does not eliminate MEV entirely. HyperBFT selects block proposers through a deterministic leader-rotation mechanism, which means that the identity of the next block's proposer is technically predictable. MEV searchers can exploit this predictability by submitting priority-ordering requests directly to the

validator about to produce a block. Within a block, the power to order transactions of the same priority (for example, two IOC orders) still rests with that block's proposer — the MonarchEV defined in Section 9.1.4. Although this MEV is far smaller in scale and harm than the MEV on a general-purpose DEX, it remains a concentration of power worth attending to within the Hyperliquid ecosystem.

The discrete-time property inherent to on-chain matching is the structural foundation of Hyperliquid's microstructure innovations. By switching time from continuous to discrete, the blockchain fundamentally changes the market's competitive paradigm: it not only greatly weakens the advantage of traditional HFT but also provides the necessary conditions for implementing the two mechanism innovations of semantic ordering and cancellation priority. The combination of the discrete-time property with these two mechanism innovations forms a complex synergistic system whose inherent trade-offs and risk boundaries equally merit examination.

9.4 Synergies and trade-offs

The power of the three-layer mechanism — semantic ordering, cancellation priority, and discrete-time matching — arises not from any layer operating in isolation but from the complex system they form in concert. The discrete-time property inherent to on-chain matching divides the continuous flow of time into discrete block windows, creating the necessary conditions for semantic ordering within a batch; semantic ordering, in turn, defines a non-economic, rule-based priority for the flow of transactions within that window, at the core of which is granting cancellation operations priority. Acting together, this layered structure significantly alters the market's microdynamics but also introduces new trade-offs and risk boundaries. This synergy ultimately drives a positive feedback loop aimed at strengthening the market's core function — liquidity: a self-reinforcing transmission chain running from market-maker protection to narrower spreads, greater trading volume, and the entry of more market makers, whose complete chain is laid out in Section 9.4.8 (Figure 9-9). In practice, however, this self-reinforcing loop faces multiple constraints, and its inherent trade-offs and risk boundaries merit examination one by one.

9.4.1 Transparency effects

One of Hyperliquid's core value propositions is its high degree of transparency, and the tension between *verifiability and strategy privacy* analyzed in Section 7.5 is concentrated here. All trade histories, order book snapshots, and even the protocol's ordering rules themselves are recorded on-chain and can be audited by anyone. This design eliminates the *black box* problem of centralized exchanges and establishes trust grounded in verifiable facts. However, this complete transparency also carries an asymmetric side effect: in eliminating one form of information asymmetry, it creates a new dimension of information competition, giving rise to a race in analytical capability.

Because all data are publicly available, quantitative analysis teams can use sophisticated algorithms to *reverse-engineer* the trading strategies of other market participants, market makers in particular. By analyzing a particular market maker's quoting behav-

ior, inventory management, and cancellation patterns under different market conditions, one can infer the key parameters of its model. These reverse-engineered strategy characteristics are called a *strategy fingerprint*. Having captured a rival's strategy fingerprint, a competitor can develop targeted countermeasures — for example, slightly improving on the rival's quote after it posts — and thereby systematically capture its order flow.

> A small quantitative market-making team, AlphaQuant, deployed an innovative market-making model on Hyperliquid and performed excellently at first. Months later, however, its profits fell sharply. Investigation revealed that a competitor had fully replicated its core algorithmic model by analyzing all of its public on-chain trade data. The competitor had captured AlphaQuant's *behavioral fingerprint* — for example, its cancellation thresholds and spread-adjustment patterns at particular volatility levels — and developed dedicated countermeasures on that basis. Because of Hyperliquid's transparency, AlphaQuant's strategic edge was rapidly eroded. In response, the team had to develop *strategy obfuscation* techniques, such as adding random noise to its quotes and randomizing cancellation delays, but this sacrificed a certain proportion of its market-making efficiency. Strategy obfuscation necessarily reduces signal precision in theory, because introducing noise also disturbs the market maker's own optimal quoting decisions; the exact magnitude of the efficiency loss, however, depends on the obfuscation parameters and market conditions, and public empirical measurements are still lacking. Although this analytical competition does not consume physical resources the way the CEX speed race does, it likewise raises the barrier to market making and poses a new challenge to small participants. This reveals an inherent contradiction: cancellation priority lowers the speed barrier to market making, but complete transparency raises the barrier of strategic complexity. The deeper risk is that on-chain transparency exposes not only individual strategies but also makes coordinated group behavior possible. The complete observability of market makers' positions and the HLP Vault's holdings, amplified by social media, can catalyze coordinated behavior against a particular participant; the JELLY attacker analyzed in Section 9.4.3 exploited precisely the public visibility of the HLP Vault's risk exposure to design its attack path.

9.4.2 The price discovery lag

Hyperliquid's mechanism design makes an explicit trade-off between *protecting liquidity* and *promoting price discovery*, choosing the former. Cancellation priority and discrete-time matching enable market makers to provide liquidity safely, but they also reduce market makers' incentive to quote proactively and push prices toward a new equilibrium level. Market makers increasingly favor a passive quoting strategy: quoting off the price of a mature external market such as Binance plus a fixed spread, and using cancellation priority to protect themselves when the external price moves, rather than actively predicting the direction of prices.

This pattern gives Hyperliquid's price discovery process a structural dependence: its price updates follow the price changes of external markets passively and with some lag (one block time). This inefficiency in price discovery is not a technical flaw but a cost paid to protect market makers in exchange for greater liquidity. Quantitatively, this lag is about one block time (200–400 ms) under normal market conditions [4]. During sharp market swings, because rising uncertainty may prompt market makers to withdraw from the market collectively, order-book depth can drop abruptly, and the

lag in price adjustment may widen to several block times. This structural dependence on external markets is the inherent fragility of its price-following posture. In systemic deleveraging events (such as the global liquidity crisis of March 2020 or the FTX collapse of 2022), Hyperliquid faces not merely a one-block-time price-following lag but a second-order risk: when several CEXs experience liquidity droughts simultaneously, the price reference source itself becomes unreliable. Hyperliquid's oracle price (the core input to the mark price) is a weighted median of external CEX spot prices, on top of which the mark price adds components such as an order-book exponential moving average (EMA); if these CEXs exhibit significant price deviations or trading halts under extreme stress, the anchoring function of the oracle price and mark price fails simultaneously, potentially triggering improper liquidations or erroneous funding rate settlement.

9.4.3 The JELLY incident: attack chain and mechanism analysis

Any rule system, however finely designed, can be exploited by participants in unexpected ways. Kirilenko et al.'s (2017) study of the 2010 *flash crash* shows that even the rules of a mature market can be exploited in unintended ways under extreme conditions [15]. The JELLY incident of March 26, 2025, stress-tested Hyperliquid's rule system; its attack path is closely related to the liquidation-cascade transmission mechanism analyzed in Section 8.3.1 and exposed systemic fragilities lying beyond microstructural protection.

JELLY was, at the time, a newly listed low-liquidity token on Hyperliquid, with an average daily trading volume of only a few million dollars on external spot exchanges. The timeline of the attack can be reconstructed as follows. First, the attacker created three independent on-chain accounts (the absence of any linked-account detection meant this step triggered no risk-control alerts) and deposited a total of about $7.17 million in USDC [16]. Second, the attacker established hedged positions across the three accounts: two accounts opened JELLY long positions totaling about $4.05 million, while the third opened a JELLY short position of about $4.1 million, whose effective leverage was such that a 400% rise in the mark price would produce a loss far exceeding the principal. The attacker then bought JELLY heavily on external spot exchanges, using its extremely thin external liquidity depth to drive the price up several-fold (reported increases range from about 400% to several tens of times depending on the source; the settlement price of $0.0095 was the attacker's opening price). The sharp move in the external price was transmitted through the oracle to Hyperliquid's mark price. As described in Section 9.4.2, the mark price takes the weighted median of external CEX spot prices as its core input and adds components such as an order-book EMA on top; when the attacker's manipulated external price carried enough weight, the oracle price and mark price shifted substantially as a result. The shift in the mark price caused the short account's maintenance margin ratio to fall below its threshold, triggering forced liquidation.

Hyperliquid's liquidation waterfall follows a specific priority sequence: the liquidation engine first attempts to liquidate the position on the order book via limit orders; if order-book depth is insufficient or slippage exceeds a preset threshold, the position is transferred to the insurance fund; and if the insurance fund's resources are insufficient to

cover it, the position is ultimately transferred to the HLP Vault as the backstop. In the JELLY incident, because the short position far exceeded the token's order-book depth on Hyperliquid (and, as analyzed in Section 9.1.7, market makers could withdraw their quotes before liquidation orders executed by exercising cancellation priority, further weakening available depth), the position rapidly broke through the first two lines of defense in the liquidation waterfall and was transferred to the HLP Vault. As the price of JELLY kept climbing, the unrealized loss on the short position absorbed by the HLP Vault reached about $13.5 million at one point (roughly 6% of the Vault's total assets); this figure exceeds the attacker's initial principal because, under high leverage, a short position's loss is theoretically unbounded. The real threat lay not in the 6% snapshot loss at that moment but in the trend: a short position's loss is theoretically unbounded and expands linearly as the mark price continues to rise. Absent timely intervention, the loss would rapidly erode the HLP Vault's total assets of about $230 million, constituting a systemic threat [17].

Hyperliquid's validator set reached consensus within about 2 minutes, voting to delist the JELLY perpetual futures and to forcibly settle all JELLY positions at the attacker's original opening price of $0.0095, rather than at the prevailing market price of about $0.50 [17]. Within 24 hours of the incident, about $200 million in funds flowed out of Hyperliquid.

9.4.4 Risk transmission and counterfactual analysis

The risk-transmission path of the JELLY incident follows a clear causal chain: external price manipulation → mark-price shift → insufficient margin → forced liquidation → absorption by the HLP Vault → widening unrealized loss → a shock to market confidence → outflow of funds → declining order-book depth → potential cascade liquidations. The roughly $200 million outflow within 24 hours accounted for a significant share of Hyperliquid's total value locked (TVL) at the time, and had this outflow continued to accelerate, it could have triggered the bank-run-style negative feedback loop described by Diamond and Dybvig (1983) [18], in which depositors' rational individual behavior (withdrawing funds to protect themselves) produces a self-fulfilling liquidity crisis at the collective level.

Counterfactual analysis helps assess the reasonableness of the intervention decision. Had the validators not intervened and had the JELLY price continued to rise, the HLP Vault's short-side loss would have grown linearly with the mark price (a short position's loss is theoretically unbounded); given the constraint of the Vault's total assets of about $230 million, a further several-fold rise in the mark price could have rendered the Vault insolvent. The Vault's insolvency would mean not only direct losses for depositors but also, through the confidence channel, a large-scale withdrawal of funds that would accelerate the reversal of the flywheel. Viewed through the lens of cross-market contagion, JELLY's vulnerability characteristics — extremely thin external liquidity depth, no position limits, and high leverage — are not an isolated phenomenon. Several long-tail token perpetual futures with a similar risk profile exist on Hyperliquid, and the correlation risk of a simultaneous attack on multiple instruments constitutes a systemic exposure that has not yet been adequately assessed.

9.4.5 Legal and governance implications of the emergency intervention

The validators' decision to force settlement at the opening price of $0.0095 rather than the market price of about $0.50 has economic implications worth analyzing in depth. This choice of settlement price protected the HLP Vault from further losses but simultaneously harmed the interests of legitimate JELLY long holders: participants who held JELLY long positions during the attack for ordinary trading reasons were forced to close out at a price far below the market price, and their profit opportunity was unilaterally taken away.

From the standpoint of legal characterization, this intervention could face varying degrees of scrutiny under different regulatory frameworks. Under the anti-manipulation provisions of the U.S. Commodity Futures Trading Commission (CFTC), settling at a non-market price could be seen as an exchange's artificial intervention in market prices. Under the European Union's MiCA framework, emergency measures must satisfy a proportionality requirement — the scope of intervention should be commensurate with the risk being guarded against. A comparable precedent in traditional finance is exchanges' power to make ex post adjustments to erroneous trades and abnormal prices (for example, Rule 588 on *trade cancellation and price adjustment* in the CME rulebook, which handles erroneous trades outside a no-review range, along with the related authority exchanges hold under market emergency conditions); such mechanisms are typically accompanied by pre-disclosed procedural rules and an ex post review process. Hyperliquid's validator intervention was completed in about 2 minutes, and this timeline reveals the double-edged nature of a small validator set in crisis response: the capacity for rapid coordination allows it to act decisively before losses widen, but the same feature also means that a handful of participants can make major decisions affecting all users within an extremely short time and without any preset governance-deliberation procedure. This tension points directly back to the qualified statement about decentralization in Section 9.1.2: validator consensus is technically *majority rule*, but in a small validator set the practical meaning of *majority* differs from the public's perception of *decentralized governance*.

9.4.6 The boundary of protection

The JELLY incident reveals the boundary of protection of Hyperliquid's microstructure system. Placing these mechanisms within a complete risk-management framework helps pinpoint their scope: pre-trade controls include margin requirements, position limits, and linked-account detection as admission controls; at-trade controls include transaction ordering, matching rules, and price protection as execution-layer mechanisms; and post-trade controls include liquidation execution, absorption of risky positions, and insurance-fund management as settlement-layer mechanisms. The protection afforded by semantic ordering, cancellation priority, and discrete-time matching is concentrated in the at-trade stage: semantic ordering eliminates bribe-based ordering manipulation, cancellation priority eliminates the within-block adverse selection risk that market makers face, and discrete time eliminates the nanosecond-level speed-race advantage. The combined effect of these three layers of protection is to compress the space for MEV extraction to the single residual dimension of ordering within the same priority cate-

gory.

The JELLY attack path, however, bypassed precisely the at-trade layer: the attacker exploited the absence of linked-account detection and inadequate position limits at the pre-trade layer, together with the liquidation-absorption rules and cross-market price manipulation at the post-trade layer. Even if semantic ordering worked perfectly, and even if every Cancel instruction executed successfully within its intended block, the JELLY attack could still be carried out along exactly the same path. This shows that microstructural protection is a necessary but not sufficient condition: a complete market-safety system also requires independent defense mechanisms at the pre-trade layer (dynamic margin, position limits, cross-market monitoring) and the post-trade layer (liquidation rules, Vault governance, insurance-fund adequacy).

9.4.7 Validator economics and centralization risk

The effectiveness of the semantic ordering rules ultimately depends on those who enforce them: the set of validator nodes. Hyperliquid uses the HyperBFT consensus algorithm (a derivative of the HotStuff family), and its current validator set is relatively small (about 16–24 active validators, roughly 21 as of early 2026) [3]. This small size offers engineering advantages in delivering high throughput and low latency, but it also raises questions about the credibility of rule enforcement and about centralization risk.

On the MonarchEV dimension, validators (block proposers in particular) have ordering discretion within a single priority category. The preceding analysis characterized MonarchEV as a *theoretical residual risk*, but the accuracy of this judgment depends on the size and incentive structure of the validator set. In a validator set composed of a few nodes, the identity of the block proposer is highly predictable owing to deterministic leader rotation, and searchers can submit priority-ordering requests directly to the validator about to produce a block. Whether validators accept such requests directly determines the extent to which MonarchEV turns from a *theoretical residual* into an *actual revenue source*.

On the operational-risk dimension, a set of about 21 validators faces multiple infrastructure risks. Key management is the foremost concern: the Hyper Foundation controls a majority of the staked share, and a leak of its keys could in theory control the consensus process. Geographic and infrastructure concentration is the second layer of risk: if a majority of validators run on the same cloud provider, a single infrastructure failure could halt the chain or degrade it severely. Client-software homogeneity is the third layer of risk: all validators run the same client implementation, so a single software bug could paralyze the entire network; the Ethereum community's experience in promoting client diversity shows that this risk cannot be ignored in high-value systems. With open interest of $6.5 billion, the consequences of any of these single points of failure could be catastrophic.

On the moral-hazard dimension, the precedent set in the JELLY incident, where the validator set overrode the settlement price, creates an implicit expectation: when a position is large enough to threaten the solvency of the HLP Vault, validators may step in to protect it. This *too big to fail* implicit guarantee may be exploited strategically by large traders, who may game the validators' intervention behavior and take on risk

exposure beyond the normal risk-control range, because they expect the system to backstop them in extreme situations. This moral hazard is structurally similar to the problem posed by systemically important institutions in traditional finance, but in a decentralized protocol there is no mature regulatory framework to constrain it.

9.4.8 The core trade-offs

Taken together, the synergy of this microstructure system can be summarized by the positive feedback loop shown in Figure 9-9.

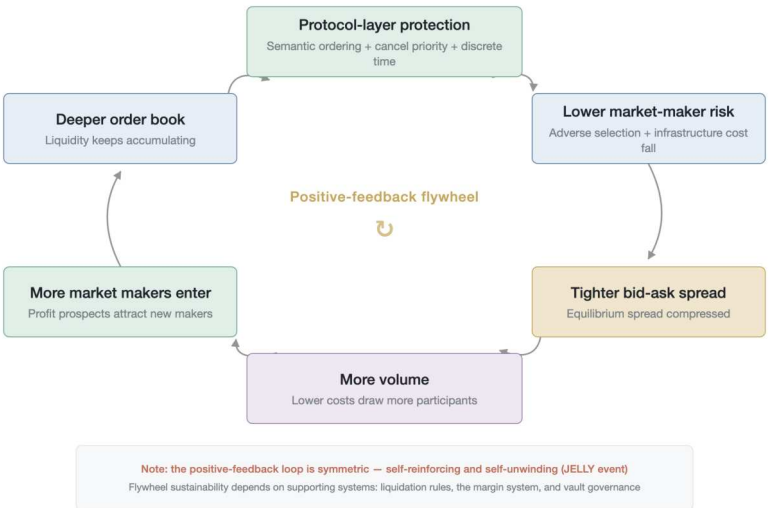

Figure 9-9. The synergy and positive feedback loop of the microstructure system (conceptual illustration, not empirical data; a six-node self-reinforcing flywheel; the footnote *symmetry of self-reinforcement and self-unraveling* is validated by the JELLY incident of March 26, 2025, per [16][17]; its sustainability depends on supporting systems such as liquidation rules, the margin system, and Vault governance)

The positive feedback loop shown in Figure 9-9 follows the transmission chain of *protocol-level protection* → *lower market-maker risk* → *narrower spreads* → *greater trading volume* → *the entry of more market makers*, and its self-reinforcing nature means that once the initial conditions are met (that is, once the mechanism's protection is sufficiently effective), the accumulation of liquidity accelerates. This positive feedback loop is not without cost, however, and Hyperliquid's microstructure system makes a series of explicit, systematic trade-offs among the goals it pursues. These trade-offs are not judgments of *right* and *wrong* but value choices among different dimensions of market quality, and together they define the platform's market characteristics. These trade-offs span multiple dimensions — liquidity versus price discovery, market-maker protection versus taker rights, transparency versus strategy privacy, security versus performance, and rule certainty versus flexibility — and on each dimension Hyperliquid makes an explicitly weighted choice. Table 9-9 systematically summarizes the choice, benefit, and cost on each dimension.

Dimension	Hyperliquid's choice	Gains	Sacrifices
Liquidity vs. price discovery	Leans toward liquidity	Tighter spreads, deeper order books, lower transaction costs	Slower price discovery, structural dependence on external markets
Market-maker protection vs. taker rights	Leans toward market makers	Lower barrier to market making, increased liquidity supply	Takers face a structural disadvantage, arbitrage space compressed
Transparency vs. strategy privacy	Leans toward transparency	Auditability, trust, decentralized verification	Market-maker strategies exposed, intensified analytical competition
Security vs. performance	Balances in the middle	A 200–400 ms block time balances security and user experience	Not as fast as a CEX, not as secure as Ethereum
Rule certainty vs. flexibility	Leans toward certainty	Rules hardcoded at the consensus layer, not unilaterally modifiable	Slower to adapt to novel attacks, as in the JELLY incident

Table 9-9. The five core trade-offs of Hyperliquid's mechanism (Data source: compiled by the author)

Hyperliquid's design philosophy explicitly chooses a value orientation of *liquidity first, market-maker friendly, and transparently verifiable*, accepting in return such costs as *externally dependent price discovery, disadvantaged takers, and a lack of strategy privacy.* Understanding these inherent, structural trade-offs is key to assessing whether the Hyperliquid model can be adopted more widely and how stable it will be over the long term.

9.5 Microstructure effects and the liquidity flywheel

The preceding analysis focused on the internal logic and trade-offs of the microstructure system; this section shifts the perspective from mechanism design to the systemic consequences at the market level. Semantic ordering, cancellation priority, and discrete-time matching do not act in isolation on individual traders; by reshaping the cost structure of market making, opening up channels for liquidity supply, and forming a self-reinforcing feedback loop, they exert a profound influence on Hyperliquid's overall market microstructure. The combined effect of these influences forms the basis of the core competitiveness that distinguishes Hyperliquid from both the CEX and the general-purpose DEX.

9.5.1 The restructuring of market-making costs and spread compression

Using the Glosten-Milgrom spread-decomposition framework established in Section 9.1.3 [5], the effect of the cancellation priority mechanism on the cost structure of market making can be analyzed quantitatively through its two dominant components: adverse selection costs and infrastructure costs. In the CEX environment, market makers must continually contend with the risk of informed traders arbitraging against stale quotes while also investing heavily in low-latency infrastructure to stay competitive in

the speed race; Hyperliquid's cancellation priority mechanism produces a direct and quantifiable compression of both components.

On the adverse selection dimension, because Cancel instructions enjoy absolute priority within a block, a market maker can, with high probability, successfully withdraw a stale quote within the one-block-time window (200–400 ms) after an external price move. This reduces the probability of an adverse selection event from a competitive outcome that, in the CEX environment, depends mainly on physical latency, to a risk confined to a very small window near the block boundary. On the infrastructure dimension, discrete-time matching raises the effective competitive time granularity from the nanosecond to the hundred-millisecond scale, so that costly infrastructure investments such as dedicated microwave towers and colocated servers are no longer a necessary condition for the market-making business. The simultaneous decline in these two costs enables market makers to quote narrower spreads while remaining profitable. Empirical data show that, during calm market periods, the bid-ask spreads on Hyperliquid's major trading pairs are typically comparable to, or even better than, those of top-tier CEXs such as Binance (the measurement basis and the static-versus-effective-depth qualifications are detailed in Section 9.5.4), while the teams engaged in market making invest far less capital in infrastructure than comparable teams in the CEX environment. This restructuring of the cost structure is precisely the cost-side root of the shift in the focus of market-making competition described in Section 9.2.3 — *from a capital-intensive speed race to knowledge-intensive competition on model quality.*

9.5.2 The HLP Vault and the democratization of liquidity supply

Hyperliquid's microstructural protection not only lowers the operating costs of professional market makers but also provides the basic conditions for an entirely new mode of liquidity supply. The HLP Vault (Hyperliquidity Provider) is a liquidity-provider vault built into the Hyperliquid protocol that allows ordinary users to deposit USDC into the vault, where automated strategies carry out market-making operations on their behalf, and users share in the market-making returns in proportion to their holdings. The core premise of this design is that cancellation priority and discrete-time matching provide the vault's market-making strategy with the same protocol-level protection as a professional market maker: the vault's Cancel instructions likewise enjoy the highest execution priority within a block, and the probability that its stale quotes are filled by arbitrageurs is likewise compressed to a structural-residual level. Without these microstructural protections, a large, publicly visible liquidity pool with a predictable strategy would become an ideal attack target for informed traders, and market-making losses would far exceed returns.

The economic significance of the HLP Vault is that it transforms market making from an exclusive activity requiring professional infrastructure and quantitative-modeling capability into a source of return in which ordinary users can participate indirectly through capital contributions. In traditional financial markets and on CEXs, market-making returns are captured almost entirely by professional institutions with speed and model advantages. Hyperliquid's mechanism protection lowers the technical barrier to market making, and the HLP Vault further lowers the capital barrier, allowing dis-

persed small amounts of capital to pool into a liquidity pool with an impact on market depth. The narrative of democratized market making, however, also requires scrutiny of participants' behavioral characteristics. Barber and Odean (2000) show that retail investors systematically exhibit return-chasing bias, overconfidence, and recency bias [19]. In the context of the HLP Vault, its substantial historical returns (promoted during some periods as a high annualized figure, though independent estimates put the 2025 annualized return at about 11%–12% and the full-period compound annual growth rate (CAGR) at about 42%) may have attracted many participants who do not understand the underlying leveraged market-making risk and who may view it as a yield-farming product rather than an investment that bears the tail risk of market making. The pattern after the JELLY incident, in which assets under management (AUM) drew down by about 15% and then gradually recovered, is highly consistent with a typical *panic-and-forget* cycle, suggesting that participants as a group may systematically underestimate risk. Moreover, the structure of the HLP Vault (an investment of money, in a common enterprise managed by others, with an expectation of profit) formally satisfies the four elements of the Howey test [20]. If it were deemed a security in a major jurisdiction, its issuance and sale would require registration or an exemption, which would fundamentally constrain the scaling of democratized market making.

The JELLY incident also revealed an inherent fragility of this model: as a large, behaviorally predictable public liquidity pool, the HLP Vault's liquidation-absorption rules can be exploited in a targeted manner by attackers. There is an inherent tension between the vault's advantage of scale and its visibility as an attack target.

9.5.3 The liquidity flywheel and ecosystem sustainability

The two levels of influence described above — the compression of professional market-making costs and the opening of retail liquidity supply — together drive a self-reinforcing liquidity flywheel. The flywheel's operation relies on two coupled engines: professional market makers, drawn by lower adverse selection costs, provide tighter quotes, while HLP Vault users, drawn by a substantial share of market-making returns, deposit capital. Professional market makers benefit from the order-book depth thickened by the vault's capital (greater depth lowers the probability that a large order will move against their positions), while vault depositors benefit from the more efficient market conditions that professional market makers create (a more efficient market means more stable market-making returns). The positive feedback between the two accelerates the accumulation of liquidity: deeper liquidity brings narrower spreads, narrower spreads attract more trading volume, more trading volume generates more market-making profit, and that profit in turn attracts further entry by professional market makers and vault depositors.

A positive feedback loop, however, inherently possesses a symmetry between self-reinforcement and self-unraveling. The noise-trader model of DeLong, Shleifer, Summers, and Waldmann (1990) and Soros's theory of reflexivity both hold that the very mechanism by which a positive feedback loop reinforces itself in the upswing also reinforces itself in the downswing [21]. The JELLY incident provides an empirical test of this symmetry: in the positive phase, the HLP Vault's high returns attracted

inflows, the inflows thickened order-book depth, and the greater depth further raised market-making returns, forming an upward spiral; in the negative phase (after JELLY), losses triggered outflows, an AUM drawdown of about 15% weakened order-book depth, and the decline in depth could further worsen market-making returns, forming a downward spiral. The recovery of AUM after JELLY suggests that the flywheel currently runs above critical mass, but the size of the safety margin is difficult to determine a priori: whether there exists a threshold of TVL or trading volume below which the flywheel would collapse irreversibly is an important question that remains to be tested.

The flywheel's scaling itself also faces endogenous constraints. The HLP Vault's current AUM of about $270 million (with a historical peak of about $500 million in mid-2025) operates within an average daily trading volume of $6.9 billion, and changes in its positions already carry significant market influence. As AUM grows, the vault faces a threefold capacity constraint: larger position adjustments produce greater price impact against limited order-book depth; a larger-scale quoting pattern is more easily identified and countered by competitors in a fully transparent on-chain environment; and a larger-scale withdrawal during emergency de-risking would intensify the market shock. These constraints imply a theoretical upper bound on AUM, beyond which market-making returns would be eroded by the vault's own scale effects.

The sustainability of this flywheel depends on the balance between protection and openness maintained by the microstructure system. If market-maker protection is too strong, tilting market conditions excessively toward market makers at the expense of takers' experience, trading volume may shrink as execution costs rise too high; if protection is too weak, market makers' profits are eroded, and both professional institutions and vault depositors may withdraw. The JELLY incident also revealed a third failure mode: the flywheel can be interrupted by an attack on the vault's infrastructure itself, even when the transaction-ordering and matching mechanisms function normally. The long-term stability of the flywheel therefore depends not only on the design quality of the microstructure mechanisms but also on the robustness of supporting systems such as liquidation rules, the margin system, and vault governance. The directions in which the Hyperliquid model evolves — the ongoing optimization of block time, the extension of semantic ordering rules, and the governance of validators' informational advantage — will all affect the flywheel's operating efficiency by altering this balance.

9.5.4 Empirical data and market performance

The theoretical predictions established in the preceding three subsections — that the compression of market-making costs narrows spreads, that the vault mechanism attracts retail capital, and that the flywheel effect drives the accumulation of liquidity — can be preliminarily validated against publicly available market data. As of March 2026, Hyperliquid's L1 TVL was about $4.4 billion and its average daily trading volume about $6.9 billion — roughly 15% of Binance Futures' daily volume — giving it about a 70% share of the on-chain perpetual futures market [22]. In terms of open interest, Hyperliquid's open interest was about $6.5 billion, roughly 30% of Binance Futures' (about $21.2 billion), while reaching more than 70 times that of dYdX (about $82

million) and more than 50 times that of GMX (about $124 million), far exceeding other on-chain competitors [23].

Before analyzing the specific data, the measurement methodology should be explained. The *spread* cited in this section is defined as the time-weighted average of the best bid and offer (BBO) spread — that is, the mean, weighted by time, of the difference between the best bid and the best offer at each moment within the observation window. *Depth* is defined as the total volume of resting orders within a certain percentage band of the mid price (typically 0.1–0.5%). The data source is public market data from CoinGecko and DefiLlama [22][23], with a sampling window of February–March 2026 and a sampling frequency of hourly snapshots. The choice of these measurement parameters directly affects the comparability and interpretability of the data.

In the BTC perpetual futures market, some snapshot data show that Hyperliquid's top-of-book bid-ask spread can be narrower than Binance's. The commonly cited specific figures (for example, a spread of about $1 versus $5.5, or mid-price depth of about 140 BTC versus 80 BTC) are difficult to trace to an independent primary source, and independent slippage estimates show that at larger trade sizes (for example, around $1 million) Binance typically offers deeper executable depth. The judgment that *Hyperliquid has better depth* should therefore be confined to the top of the book and read cautiously in light of the effective-depth discount discussed below [23]. This comparison must be qualified along two dimensions.

The first dimension is the distinction between static depth and effective depth. The 140 BTC shown in an order book snapshot is *static depth* — the total volume displayed on the order book at that moment. However, under the cancellation priority mechanism, market makers can, with high probability, withdraw their quotes within the same block before a large market order executes. Therefore, when a 100 BTC market buy order actually executes, the *effective depth* available for filling may be significantly lower than the 140 BTC statically displayed. The upper bound of effective depth equals static depth (no market maker cancels), while the lower bound equals the residual depth after all market makers simultaneously exercise cancellation priority — and this residual depth may include only passive liquidity, such as the HLP Vault, that cannot respond with a cancellation within the same block. This distinction cross-corroborates the *depth illusion* phenomenon analyzed in Section 9.2.3 and the analysis of apparent order-book liquidity in Section 8.2.

The second dimension is the HLP Vault's subsidizing effect on the spread. In his classic model of informed trading, Kyle (1985) distinguished apparent liquidity from equilibrium liquidity [24]. As a liquidity pool that aims at sharing market-making returns (rather than pure profit maximization), the HLP Vault may systematically make markets at spreads below the equilibrium level, and its narrow spreads may partly reflect an implicit subsidy rather than a pure efficiency gain. Comparing spreads across periods with high and low vault contributions would help separate the subsidy effect from the mechanism-efficiency effect, but public data for such period-by-period comparisons are currently lacking.

The growth metrics above must also be interpreted within the macro environment. The years 2024–2025 fell within the bull-market cycle following the approval of the BTC

exchange-traded fund (ETF), during which the TVL and trading volume of almost all crypto infrastructure grew substantially. To separate Hyperliquid's platform-specific excess growth from systemic bull-market beta, its growth rate over the same period should be compared with on-chain competitors such as dYdX and GMX. Preliminary data show that Hyperliquid's growth rate is significantly higher than that of comparable platforms, but the contribution of HYPE token incentives within it remains difficult to fully isolate.

The HLP Vault's operating data provide a basis for testing the theory of democratized liquidity. The vault's AUM peaked at about $510 million (mid-2025) and currently stands at about $270 million (DefiLlama, mid-2026), with cumulative net profit of about $121.8 million (roughly 50% of the total return over the period, using the vault's average AUM over the period as the denominator; as of October 2025, on the DefiLlama HLP dashboard basis, consistent with Chapter 21); according to independent estimates from OAK Research, OnchainTimes, and others, its annualized return was about 11%–12% (2025), its full-period CAGR about 42%, and its trailing-12-month return about 22%, with returns that are highly event-driven and volatile rather than a stable annualized level of 65%–70% [22]. This annualized return, however, lacks a decomposition, and its composition may include several sources: market-making spread income, HYPE token incentives, directional beta exposure (in a bull market, market makers typically hold a net long position), and profits from absorbing liquidations. Citing the 65%–70% annualized figure without decomposing the sources of return can easily give readers the mistaken impression of *65%–70% from pure market making*, when in reality a considerable proportion of the return may come from token incentives and directional exposure — sources that are not sustainable across cycles. After the JELLY incident, the vault's AUM drew down by about 15% around the event (the vault stood at about $230 million when JELLY occurred, consistent with the figure in Section 9.4.3, and drew down to about $195 million; the roughly $500 million was the historical peak in mid-2025, not the level at the time of JELLY), and then gradually recovered after the protocol repaired its liquidation-absorption rules. This data point validates both the flywheel's positive transmission and its fragility under extreme events. At the validator level, Hyperliquid currently runs about 16–24 active validators (roughly 21 as of early 2026), among which the nodes controlled by the Hyper Foundation hold a majority of the staked share [3]. Single-block finality (the time required for a transaction to become irreversible) is about 70 ms, distinct from the block time of about 200 ms; the median end-to-end order-confirmation latency is about 200 ms, with a 99th-percentile latency of about 900 ms (for a colocated client). Overall, these data support this chapter's theoretical analysis, but their limitations should be noted: the market data are snapshots at specific points in time, they cannot fully separate the contribution of mechanism effects from that of token-incentive effects to liquidity growth, and, as a rapidly evolving system, Hyperliquid's market metrics may change significantly over the short term.

9.6 Chapter summary

Taking Hyperliquid as a case study, this chapter applied the order-semantics analytical framework established in Chapter 7 and the order-book microstructure theory revealed in Chapter 8 to a specific application-chain exchange, systematically analyzing how the two mechanism innovations of semantic ordering and cancellation priority form a self-consistent microstructure system on top of the discrete-time property inherent to on-chain matching. Semantic ordering classifies the economic meaning of transactions into four tiers (System, High, Standard, and Low) at the consensus-protocol level, placing the priority of liquidity-protecting actions above that of liquidity-consuming actions, while assigning liquidation orders and system-maintenance transactions to separate priority tiers. Section 9.1.7 further analyzed the interactions of semantic ordering with the margin system, funding rate settlement, and the liquidation engine, revealing how the ordering mechanism is embedded in the broader contract-settlement system. Cancellation priority concretizes the classification rules into a protocol-level right of last look for market makers; the discrete-time property inherent to on-chain matching compresses the precision of the speed race from the nanosecond to the hundred-millisecond scale, creating the time window necessary for implementing semantic ordering and cancellation priority — a window that Hyperliquid did not invent but that is an inherent structural feature of any on-chain matching system; Hyperliquid's innovation lies in recognizing and exploiting this feature to build differentiated ordering rules. Placing Hyperliquid's semantic ordering within the broader spectrum of MEV mitigation approaches — comparing it with alternatives such as Flashbots' private mempool, the threshold-encrypted mempool, intent solving, and dYdX v4's distributed ordering rights — shows that, among the approaches surveyed in this chapter, semantic ordering is a rare one that makes an explicit value judgment at the protocol level, at the cost of a strong dependence on an application-specific chain.

The core effect of this microstructure system is to systematically reduce the adverse selection risk and infrastructure investment costs faced by market makers. Empirical data provide preliminary validation: some snapshots show that the top-of-book bid-ask spread on Hyperliquid's BTC perpetual futures can be narrower than Binance's (the commonly cited figures of about $1 versus about $5.5 and static depth of about 140 BTC versus about 80 BTC are difficult to trace to an independent primary source, and Binance's effective depth is typically better at large trade sizes, so these should be read cautiously and confined to the top of the book), while the roughly 70% share of the on-chain perpetual futures market is a more firmly established figure. The interpretive qualifications — the gap between static and effective depth, the HLP Vault's subsidizing effect on the spread, and the macro bull-market cycle — are all detailed in Section 9.5.4. With a peak AUM of about $500 million, the HLP Vault has validated the feasibility of democratized liquidity supply, but its commonly cited 65%–70% annualized return is in fact a figure that includes token incentives and directional exposure; independent estimates put it at about 11%–12%, with returns that are highly event-driven and volatile, and whose sustainability remains to be verified.

At the level of liquidity, cancellation priority exhibits a *liquidity paradox*: in normal times it lowers market-making costs and improves liquidity supply, but the same mech-

anism may accelerate liquidity evaporation during periods of market stress, and the procyclical effect of market makers exercising their cancellation right with zero friction merits the attention of market designers. The in-depth analysis of the JELLY incident revealed, along the three dimensions of attack mechanism, risk transmission, and legal governance, systemic fragilities lying beyond microstructural protection: the breach of the liquidation waterfall, the HLP Vault's forced absorption, and the validators' forced settlement at a non-market price — all of which occurred beyond the boundary of the ordering layer's protection. The limited size and rapid governance capacity of the validator set appear as advantages in crisis response but also give rise to tensions among concentrated operational risk, moral hazard, and the narrative that *rules are hardcoded at the consensus layer*. The positive feedback loop of the liquidity flywheel possesses a symmetry between self-reinforcement and self-unraveling, and its sustainability depends not only on the design quality of the microstructure mechanisms but also on the robustness of supporting systems such as liquidation rules, the margin system, and vault governance. As an adjustable hyperparameter, block time directly defines the trade-off surface between market-maker protection and price discovery efficiency, but the quantitative calibration of the U-shaped curve requires estimation of parameters specific to the crypto perpetual futures market.

As Budish et al. (2015) [14] noted, the core of market design is not to have participants reach an equilibrium under given rules but to design rules that produce a better equilibrium. Hyperliquid's experiment shows that blockchains offer the possibility of encoding market rules in a consensus protocol in a way that is transparent, verifiable, and difficult to tamper with unilaterally; and its explorations in microstructural protection, the democratization of liquidity supply, and the construction of an ecosystem flywheel, together with the boundary conditions and failure modes those explorations exposed, will provide the necessary theoretical foundation for later chapters' analysis of the concrete operating mechanisms of the HLP Vault.

Part IV
Pricing Mechanisms

Core question: How is the price of a perpetual future anchored to reality? How do funding rates, liquidation, and margin jointly maintain market order, and how do they fail under extreme conditions?

A Game-Theoretic Analysis of Funding Rates

On March 12, 2020, the cryptocurrency market suffered one of the most violent single-day crashes in its history, a day that came to be known as Black Thursday [1]. Within just 24 hours, the price of Bitcoin fell by nearly 50%, plunging from about $7,900 to a low of $3,867 [2]. This macro shock, triggered by global panic over the COVID-19 pandemic, set off an unprecedented liquidation cascade of leveraged positions in the crypto derivatives market; on BitMEX alone, liquidations exceeded $700 million [3]. Yet amid this collapse, in which evaporating liquidity intertwined with panic selling, the funding rate mechanism of the derivatives market malfunctioned severely: the price of BitMEX's XBTUSD perpetual futures traded at one point at a discount of more than 10% to spot, and the funding rate touched an extreme level of -0.375% in a single period [4].

At that particular moment, the price of the perpetual futures had fallen far below the spot price—BitMEX's XBTUSD perpetual traded at one point more than $500 below spot—exhibiting an extreme negative basis [5]. According to the standard theoretical description of the funding rate mechanism, such a negative basis should trigger a negative funding rate, under which shorts pay longs, thereby incentivizing traders to buy the perpetual and pushing its price back toward spot value. Yet even after the rate had turned extremely negative, the price failed to converge. Arbitrageurs, unable to deposit funds into BitMEX because of congestion on the blockchain network, could not execute the arbitrage [5]; the forced sell orders generated by the liquidation cascade continued to depress the perpetual price, forming a positive feedback loop of "extreme rate $\rightarrow$ still no correction $\rightarrow$ widening basis." Under conditions of evaporating liquidity, the funding rate's anchoring mechanism nearly failed entirely.

This extreme anomaly raises three fundamental questions about the underlying mechanism of perpetual futures. Where does the anchoring force of the funding rate actually come from? Is it a passive mathematical formula for correcting the price spread, or the equilibrium outcome of a complex, friction-laden game among multiple participants? Building on this, why does a mechanism that has functioned well more than 90% of the time break down so severely at exactly the moment when the market most needs it to anchor prices? And taking the analysis together, does the extreme behavior of the funding rate itself encode a deeper signal about the market's leverage state and systemic fragility?

To answer these questions, this chapter moves beyond the surface-level description of a "negative feedback loop of algorithmic anchoring" and builds a systematic game-theoretic analytical framework. It uses a three-layer decomposition model to deconstruct the economic components of the funding rate, employs an anchoring strength spectrum to measure the effectiveness boundary of the anchoring mechanism across different market states, and constructs a three-layer game model to analyze the interaction structure among longs and shorts, arbitrageurs, and exchanges. It then examines how rate polarization positive feedback explains the mechanism that generates extremes, and finally advances the funding rate as state variable hypothesis, which repositions the funding rate from a passive market "output" to a "predictor" of future volatility and systemic risk. Across these five nested frameworks, the chapter builds a chain of reasoning from foundational concepts to frontier analysis, arguing that the funding rate is a core variable for understanding the microstructure and game dynamics of the crypto derivatives market.

10.1 Mechanisms and definitions

Before turning to the game-theoretic analysis, we need a clear and rigorous shared vocabulary. The three-price system of perpetual futures, the internal structure of the funding rate formula, and the parameter differences across exchanges together set the initial conditions and payoff structure for every game that follows. They determine the profit margin available to arbitrageurs, the holding cost borne by speculators, and the resilience of the entire system under extreme stress. Before analyzing participants' strategies, we must define the rules of the game precisely.

10.1.1 The three-price system

The ability of perpetual futures to operate independently, free from the constraint of a delivery date, rests on a three-price system. Each of the three serves a distinct function, and their interaction keeps the market running. Understanding the distinctions and connections among them is a prerequisite for grasping the funding rate mechanism.

The index price is the objective value benchmark for the entire system. It is typically computed as a volume-weighted average of the latest traded prices across several major global spot exchanges, such as Coinbase, Kraken, and Bitstamp [6]. The index price is designed to provide a global-consensus value that is difficult for any single entity or large trade to manipulate. To ensure its robustness, exchanges usually build multiple anomaly-detection mechanisms into the calculation: automatically discarding price sources that deviate excessively, excluding data from periods of liquidity drought, and dynamically adjusting weights. For example, when one spot exchange's quote deviates from the median of the others by more than a certain threshold, that exchange's weight is automatically reduced or even set to zero. This design makes the index price a relatively "exogenous" variable: it reflects the aggregate state of the global spot market rather than the internal supply-and-demand dynamics of any single derivatives exchange. However, the exogeneity assumption for the index price holds only if its constituent exchanges have sufficient liquidity depth. For mainstream assets such as

BTC and ETH, the weighted average across many highly liquid exchanges makes manipulation extremely costly, so the exogeneity assumption holds reasonably well. For long-tail assets with low circulating market capitalization, however (such as ALPACA, analyzed later in this chapter), the constituent exchanges may be extremely thin, and a single medium-sized market order can move the spot price significantly and thereby affect the index price. At that point, the "exogenous anchor" assumption of the three-price system partly breaks down: a manipulator can influence both the index price and the perpetual price at once, fundamentally weakening the anchoring foundation of the rate mechanism. The Mango Markets exploit of October 2022 is a canonical case: the attacker, Avraham Eisenberg, manipulated the price of the MNGO token in a low-liquidity spot market, successfully affecting the oracle price feed and ultimately causing protocol losses of over $110 million (per CFTC and DOJ figures). This risk dimension is developed further in the analysis of funding-rate-manipulation feasibility in Section 10.6.3.

The perpetual price—the latest traded price on the derivatives order book—is a direct indicator that reflects, in real time, the internal supply and demand, leverage direction, and trading sentiment of the derivatives market. It forms directly through the bidding of longs and shorts within the exchange and is therefore highly "endogenous." When large numbers of leveraged longs pour in, the perpetual price is driven above the index price, forming a positive premium; conversely, when panic selling or short-side force dominates, the perpetual price falls below the index price, forming a negative premium (i.e., a discount). Yet precisely because of this endogeneity, the perpetual price is highly vulnerable to the impact of a single large order or short-term manipulation, and one sufficiently large market order can create a significant price deviation during a thinly traded period.

The mark price, in turn, is a design product that strikes a balance between anchoring to true value and reflecting market reality. It is typically composed of a robust index price plus a moving-averaged basis (the difference between the perpetual price and the index price) [7]. The mark price calculation differs fundamentally across exchanges: BitMEX uses a composite calculation based on the order-book mid-price and the index price, with an exponential moving average (EMA) window length that varies by contract; Binance takes a weighted average of the index price and the best-bid/best-ask mid-price, with weights that adjust dynamically to a contract's liquidity conditions; and Hyperliquid uses the oracle median price plus a small-window EMA basis. These differences directly determine the moment at which liquidation is triggered: under identical market conditions, the same trader may be liquidated on one exchange but not on another. The mark price serves two core functions. First, it is the sole basis for computing unrealized profit and loss (P&L) and assessing margin levels. Second, during extreme volatility it serves as the warning line that triggers forced liquidation. The mark price is designed to filter out short-term noise in the perpetual price, providing a buffer layer for the market. If the perpetual price were used directly to trigger liquidations, a brief wick—a sharp price deviation over a very short interval that quickly reverts—could unnecessarily liquidate large numbers of innocent positions. Through its smoothing mechanism, the mark price minimizes this risk.

The interaction among these three prices constitutes the infrastructure on which the

funding rate operates: the basis, time-weighted and averaged, becomes the premium component that drives the rate calculation, while the mark price maintains the system's solvency floor, preventing over-leveraged positions from triggering systemic risk over transient price disturbances.

10.1.2 Deconstructing the funding rate formula

The details of the funding rate calculation may vary slightly across exchanges, but the core logic is highly consistent. Taking the common formula used by major exchanges, the funding rate F can be deconstructed into the following form [8]:

$$F = P + \text{clamp}(I - P,\ -0.05\%,\ +0.05\%)$$

where F is the funding rate, P is the premium component, and I is the interest rate component.

This formula carries several layers of economic meaning: the premium component captures the market's directional preference, the interest rate component embeds the capital cost of holding a position, and the clamp function introduces nonlinear institutional friction through its boundary constraints. Their interaction gives the funding rate markedly different response characteristics across market states: it is locked to a fixed baseline under mild deviations, and only under extreme deviations does it exhibit linear sensitivity to the premium.

The premium component is the most information-dense dynamic part of the rate, directly quantifying the degree to which the perpetual price deviates from the index price. It is usually the time-weighted average of the basis over a window (such as the 8-hour settlement period) rather than a simple instantaneous snapshot. Specifically, BitMEX uses a time-weighted average price (TWAP) over the past minute, Binance uses an arithmetic mean sampled every minute within the settlement period, and Hyperliquid uses an average over a 1-hour window of samples taken every 5 seconds. These sampling differences directly affect how sensitive the rate is to short-term price shocks. This time-weighting has a direct effect: it prevents traders from manipulating the rate

by momentarily creating a large basis just before settlement, and it also makes the rate reflect a sustained directional preference over a period rather than transient noise. When P is positive, the perpetual has sustained a premium over the settlement period and long demand is strong; when P is negative, a sustained discount prevails and short-side force dominates. In short, the premium component prices the directional exposure that participants are willing to pay for, which makes it the most information-rich part of the rate.

The interest rate component reflects the capital cost of holding a synthetic leveraged position. When BitMEX pioneered perpetual futures in 2016, it set this component at a fixed 0.01% every 8 hours (approximately 10.95% simple annualized) [9]; the institutional rationale for this interest rate component—why it is not a precise macro risk-free rate, and how it was set as an institutional benchmark to incentivize arbitrageurs to provide liquidity—is discussed in the financing cost layer of Section 10.2.1. As perpetual futures were widely adopted by major exchanges worldwide, this 0.01% interest rate component became a de facto industry standard that profoundly shaped the structural characteristics of the entire market.

The clamp function is an often-underestimated part of the formula, and its influence extends far beyond what it appears to have on the surface. It is a boundary-constraint function that forces the value of $(I - P)$ into the interval $[-0.05\%,\ +0.05\%]$. Its mathematical definition is:

$$\text{clamp}(x,\ a,\ b) = \max(a,\ \min(x,\ b))$$

The clamp function does more than limit extreme fluctuations. It creates an asymmetric effect that forms the basis for understanding the structural characteristics of the funding rate. To see this intuitively, we can analyze the response curve of the funding rate F to the premium component P. When the interest rate component $I = 0.01\%$, the entire response relationship exhibits a three-segment piecewise-linear character (Table 10-1):

Range of premium component P	Value of clamp	Final rate F = P + clamp	Economic meaning
$P < -0.04\%$	$+0.05\%$ (upper bound)	$F = P + 0.05\%$, declining linearly with P	Deep-discount zone: the rate falls as the discount deepens, but is always "held up" by the $+0.05\%$ correction term
$-0.04\% \le P \le +0.06\%$	$I - P$ (no clamping)	$F \equiv 0.01\%$ (constant)	Stable band: the clamp offsets fluctuations in P, locking the rate
$P > +0.06\%$	-0.05% (lower bound)	$F = P - 0.05\%$, rising linearly with P	Deep-premium zone: the rate rises as the premium deepens, but is "slowed" by the -0.05% correction term

Table 10-1. The three-segment piecewise-linear response of the funding rate to the premium compo-

nent (interest rate component I = 0.01%) (Data source: compiled by the author)

Empirical data confirm the effect of this design [8]: BitMEX's Q3 2025 report shows that the BTC perpetual rate was exactly equal to 0.01% for 78.19% of the time and the ETH rate for 87.52% of the time. This does not mean the market was continuously at equilibrium—the premium component P in fact fluctuated continuously—but rather reflects a "stability illusion" created by the clamp function. This stable band thereby gives the funding rate a built-in positive bias: even when the market is slightly in discount, longs must still pay shorts, constituting a non-negligible "institutional friction layer." The full argument for this structural positive bias—including the width of the stable band, the critical example at $P = -0.03\%$, and data on the share of positive rates—is formalized in the "three-layer decomposition model" of Section 10.2, specifically in Section 10.2.3.

10.1.3 Cross-exchange parameter differences

The funding rate is not a single, unified standard but a design space with multiple parameters. Differences across exchanges in settlement frequency, the interest rate component, the clamp bounds, the composition of the index price, and rate caps may look like mere "technical implementation details" on the surface, but they significantly alter participants' cost-benefit structures and thereby shape markedly different game environments. Understanding these differences is key to understanding why the funding rate for the same asset can behave so differently across platforms.

Table 10-2 compares the core design parameters of three representative exchanges—BitMEX, Binance, and Hyperliquid—across five dimensions: settlement frequency, the interest rate component, the clamp range, the rate cap, and the source of the index price. These parameter differences directly determine the response speed of arbitrage capital on each platform, the feasible cost of a manipulation attack, and the magnitude of rate polarization during extreme conditions.

Design dimension	BitMEX	Binance	Hyperliquid
Settlement frequency	Every 8 hours (fixed)	Dynamic (8h / 4h / 1h) [10]	Every 1 hour (fixed) [11]
Interest rate component	0.01% / 8h	0.01% / 8h	0.01% / 8h (actual payment of $F/8$ per 1h) [11]
Clamp range	±0.05%	±0.05%	±0.05%
Rate cap	±0.75% / 8h	Major assets such as BTC/ETH: ±0.75%/8h; long-tail assets can widen to ±2% to ±4% once dynamic settlement is triggered	±4% / 1h (uniform cap)
Index price source	Volume-weighted average across multiple centralized exchanges (CEXs)	Volume-weighted average across multiple CEXs	Validator oracle (weighted median of CEX prices; permissioned validator set, execution by a centralized sequencer) [11]

Table 10-2. Comparison of core funding-rate design parameters across major exchanges (Data source: compiled by the author from each platform's public documentation)

Settlement frequency is the core variable that changes the time scale of the game. BitMEX has long adhered to settlement every 8 hours (at 04:00, 12:00, and 20:00 UTC), a classic design that leaves arbitrageurs ample buffer time to deploy capital and execute strategies. In 2025, Binance introduced a dynamic settlement-frequency mechanism that allows flexible switching among 8-hour, 4-hour, and even 1-hour intervals depending on market volatility and the characteristics of a specific contract [10]. This adjustment was a direct response by Binance to rate-manipulation events such as ALPACA: a higher settlement frequency means a manipulator must maintain its position over a shorter time window, sharply raising the cost of manipulation. Decentralized exchanges (DEXs) such as Hyperliquid, meanwhile, adopt hourly settlement [11]. In theory, the higher the settlement frequency, the tighter the price anchoring, but it also significantly increases the ongoing cost pressure on position holders in one-sided trending markets. In certain extreme cases (such as the high-frequency-settlement squeeze analyzed in detail in Section 10.7.3), shorts can lose nearly 20% of their notional principal to funding payments alone within 24 hours.

Differences in the interest rate component and the clamp range directly determine the rate's baseline and volatility. Both BitMEX and Binance use a fixed 0.01% interest rate component and a ±0.05% clamp range, which creates the structural positive bias and stable band described earlier. Hyperliquid's rate calculation adopts a "compute first, then scale" normalization architecture [11]: the formula first computes a nominal rate F using the same parameters as 8-hour-settlement exchanges (interest rate component $I = 0.01\%$, clamp bounds $\pm 0.05\%$), then sets the actual hourly payment to $F/8$, so that within the clamp-bound stable band the default hourly rate is $0.01\%/8 = 0.00125\%$. Although the formula parameters match those of 8-hour exchanges, Hy-

perliquid's premium-index sampling window is 1 hour (sampled every 5 seconds and then averaged) rather than 8 hours. The shorter sampling window makes the premium component more sensitive to short-term price shocks, which partly explains the statistical feature of higher rate volatility on Hyperliquid. More importantly, Hyperliquid's rate cap is set at 4% per hour, far above the 0.75% per 8 hours typical of centralized exchanges (BitMEX). As a result, under extreme conditions, rates on Hyperliquid can reach levels far exceeding those on centralized exchanges, giving speculators and manipulators greater strategic room.

Differences in the source of the index price affect the reliability of the "anchor" itself. Centralized exchanges typically use a volume-weighted average price across several spot exchanges, supplemented by anomaly detection and dynamic weight adjustment. As an on-chain protocol, Hyperliquid relies on price feeds provided by its validator network, with each validator independently computing the weighted median of spot prices across multiple CEXs [11]. This design has advantages in decentralization and censorship resistance, but it also introduces an additional risk dimension of oracle latency and update frequency. On closer inspection, Hyperliquid's actual degree of centralization is higher than its decentralization narrative suggests: its validator set is permissioned (about 16–24 nodes, roughly 21 as of early 2026), and the Hyperliquid team controls a substantial share of the staking weight; order matching and rate calculation are executed by a centralized sequencer, making validators closer to "confirmers" than to independent consensus participants; and actual price-feed update latency is constrained by sequencer throughput. The JELLY incident of March 2025 exposed the fragility of this architecture, as the lag in the oracle price feed was exploited by a manipulator, causing significant market distortion.

These parameter differences are clearly reflected in empirical data. BitMEX's Q3 2025 data vividly illustrate how different design choices shape markedly different rate behavior [8]:

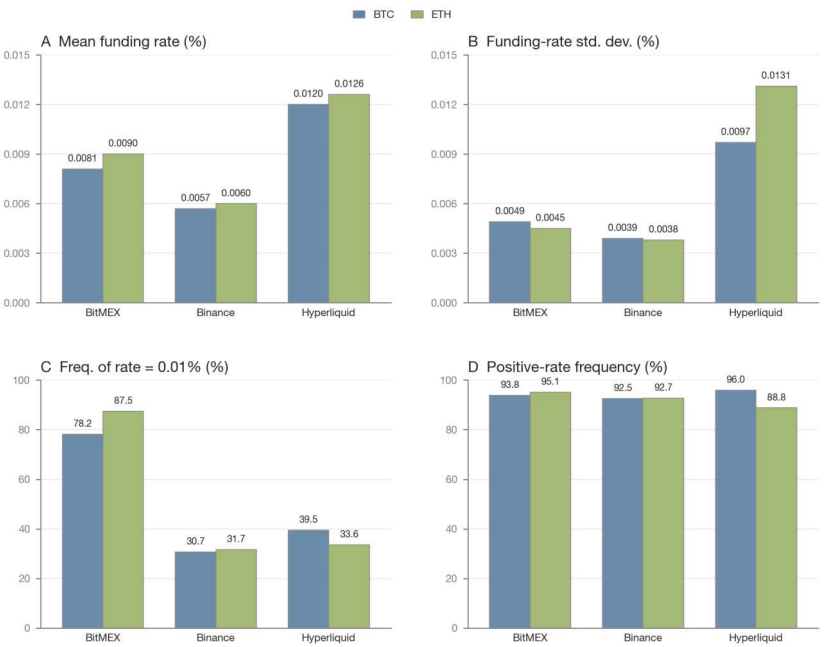

Figure 10-2. Comparison of the statistical characteristics of BTC and ETH funding rates on major exchanges in Q3 2025 [8]

As Figure 10-2 shows, the rate behavior of the three exchanges differs markedly. BitMEX's BTC rate was stable at 0.01% for 78.2% of the time (panel C), with a standard deviation of only 0.0049%, exhibiting high predictability. Binance, the world's largest exchange, had a mean rate (0.0057%) that was actually lower than BitMEX's (0.0081%), reflecting persistent short-side pressure on the Binance platform—possibly from the large numbers of hedge funds and market makers that establish short positions on Binance to hedge long exposure on other platforms. Hyperliquid's mean rate (0.0120%, panel A) and standard deviation (0.0097%, panel B) were both significantly higher than those of the two centralized exchanges, with a maximum of 0.0672%, exhibiting higher volatility and greater sensitivity to market sentiment [8].

Exchange	BTC mean rate	BTC standard deviation	Frequency of BTC rate = 0.01%	Frequency of positive BTC rate
BitMEX	0.0081%	0.0049%	78.19%	93.83%
Binance	0.0057%	0.0039%	30.70%	92.54%
Hyperliquid	0.0120%	0.0097%	39.45%	95.98%

Table 10-3. Core statistical indicators of BTC funding rates on three exchanges in Q3 2025 [8] (Data source: compiled by the author based on [8])

One shared feature stands out: despite the vast differences in design parameters and rate volatility across the three exchanges, the frequency of positive BTC rates exceeded 92% on all of them (Table 10-3). This means that throughout Q3 2025, on every platform, longs paid shorts more than 90% of the time. This phenomenon is not

accidental but the joint result of the institutional benchmark set by the interest rate component $I = 0.01\%$ and the structural positive bias of the clamp function: even in periods when the market's directional preference is relatively neutral, the "default state" of the rate is positive. In its report, BitMEX calls this phenomenon the "formula's secret positive bias" [8].

These cross-exchange parameter differences and statistical patterns are not minor technical details. They determine the thickness and response speed of arbitrage capital on each platform, the cost and feasibility of a "rate squeeze" attack by a manipulator, and the speed and magnitude of rate polarization during extreme conditions. More importantly, they constitute the initial conditions for all the analysis that follows in this chapter: the "three-layer decomposition model" of Section 10.2 explains why these parameter differences produce institutional friction layers of differing sizes; the "anchoring strength spectrum" of Section 10.3 argues how different designs affect the effectiveness boundary of anchoring; the "three-layer game model" of Section 10.4 analyzes how parameter differences alter the equilibrium structure of each layer of the game; and Section 10.7 examines settlement frequency as a core design dimension.

10.2 The three-layer decomposition model

In the crypto derivatives market, traders often treat the funding rate simply as a "directional indicator of long-short forces" or a "market sentiment gauge." This one-dimensional understanding, however, obscures the microstructural complexity of the funding rate. To accurately parse the market signal the funding rate conveys, we must abandon the view of it as a single variable and instead adopt a three-layer decomposition model. The model deconstructs the observed surface funding rate into three decomposable components with distinct economic meanings: the financing cost layer, the sentiment premium layer, and the institutional friction layer. The institutional friction layer, however, is not statistically orthogonal to the sentiment premium layer P but mechanically dependent on it through the clamp function.

10.2.1 The financing cost layer

The bottom layer of the funding rate is the financing cost layer, which represents the capital cost implied by holding a derivatives position under a risk-free-arbitrage assumption. This layer makes the funding rate of perpetual futures not merely a tool for adjusting a relative price, but also an expression of an absolute rate of return.

Before analyzing each layer, consider the architecture of the three-layer decomposition model as a whole. Figure 10-3 arranges the three components of the rate from lowest to highest by their frequency of variation.

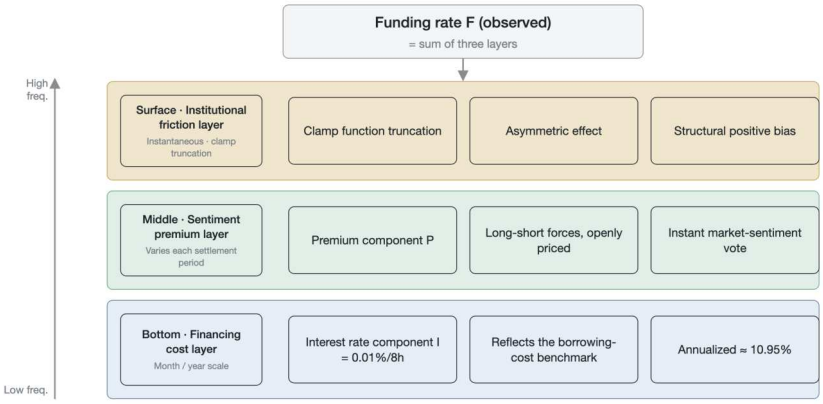

Figure 10-3. The three-layer decomposition model of the funding rate

As Figure 10-3 shows, the financing cost layer forms the base benchmark of the rate, maintaining a default state near 0.01% in the absence of extreme market deviation; the sentiment premium layer is superimposed on the financing cost layer and fluctuates in real time with shifts in long-short forces; and the institutional friction layer imposes a nonlinear truncation on the combined result of the first two layers through the clamp function, producing the structural positive bias of the rate distribution. The interaction of the three layers determines the actual observed rate at any moment.

In the funding rate formulas of most major crypto exchanges (such as BitMEX and Binance), the financing cost layer is hard-coded as a fixed interest rate component (usually denoted I). For example, BitMEX initially set the benchmark rate at 0.01% every 8 hours, equivalent to an annualized rate of about 10.95% (simple annualized, i.e., $0.01\% \times 3 \times 365$; compounded, it is about 11.57%, i.e., $(1 + 0.01\%)^{1095} - 1$) [8]. This setting is not an arbitrary mathematical constant but an empirical estimate based on the difference in borrowing costs between the U.S. dollar (or stablecoins) and Bitcoin in the early crypto market. It constitutes a form of institutional rigidity: after the Federal Reserve raised its benchmark rate to 5.25% in 2023, the premium of the crypto market's fixed 10.95% interest rate component over the traditional risk-free rate was sharply compressed (from more than 10 percentage points in the zero-rate era to about 5.7 percentage points), yet the formula itself was not dynamically adjusted.

The borrowing cost hypothesis holds that a buyer of perpetual futures is effectively borrowing the quote currency (such as USDT) to purchase the underlying asset (such as BTC), while a seller is borrowing the underlying asset to obtain the quote currency. The benchmark of the funding rate should therefore reflect the interest rate spread between these two assets in the spot lending market. Because demand for stablecoin borrowing in the crypto market has long exceeded demand for borrowing native crypto assets, this structural supply-demand imbalance has made stablecoin lending rates significantly higher than crypto-asset lending rates, which is then embedded at the formula level as a persistently positive interest rate component.

10.2.2 The sentiment premium layer

Above the financing cost layer sits the highly dynamic sentiment premium layer, the part of the funding rate that traders watch most closely. The sentiment premium layer is composed of the premium component (usually denoted P), which measures in real time the deviation between the perpetual futures price and the spot index price. The sentiment premium layer is the direct result of the game between long and short forces in the market microstructure and represents the open-market pricing of risk. When the market expects prices to rise, speculative long forces strengthen and push up the perpetual price, so that $P > 0$; conversely, when the market expects a decline, short forces dominate, so that $P < 0$. During the bull phase of November 2024, when Bitcoin broke \$100,000, the premium component of BTC perpetual futures stayed persistently in the elevated range of 0.05% to 0.15%, reflecting a concentrated influx of leveraged long demand; whereas during the AI-sector turbulence triggered by DeepSeek in late January 2025, the premium component of some altcoins plunged below -0.3%, revealing the impact of panic selling on the microstructure of the derivatives market.

In a normal market environment with sufficient arbitrage capital, the sentiment premium layer reflects the risk compensation that arbitrageurs demand for absorbing one-sided market imbalances. In their study of crypto carry, Schmeling et al. at the Bank for International Settlements note that the arbitrage returns of crypto futures are essentially a highly volatile "convenience yield," one arising from the trend-following behavior of retail investors chasing leveraged upside exposure and from the relative scarcity of arbitrage capital willing to bear basis risk [12]. The sentiment premium layer is therefore not merely a measure of sentiment but the pricing that market liquidity providers (arbitrageurs) place on the use of their capital.

10.2.3 The institutional friction layer

The component of the three-layer decomposition model that is often overlooked yet plays a significant role in actual operation is the institutional friction layer. This layer arises from the mathematical truncation mechanism—the clamp function—that exchanges deliberately introduce to prevent the funding rate from fluctuating excessively. BitMEX introduced this mechanism when it designed perpetual futures in 2016, with the aim of preventing extreme single-period rate fluctuations from triggering chain liquidations, while also providing arbitrageurs with a predictable return floor to sustain their participation. The final funding rate formula of most exchanges can be written as $F = P + \text{clamp}(I - P, -0.05\%, +0.05\%)$. This seemingly simple smoothing mechanism creates a significant asymmetric effect at the microstructural level.

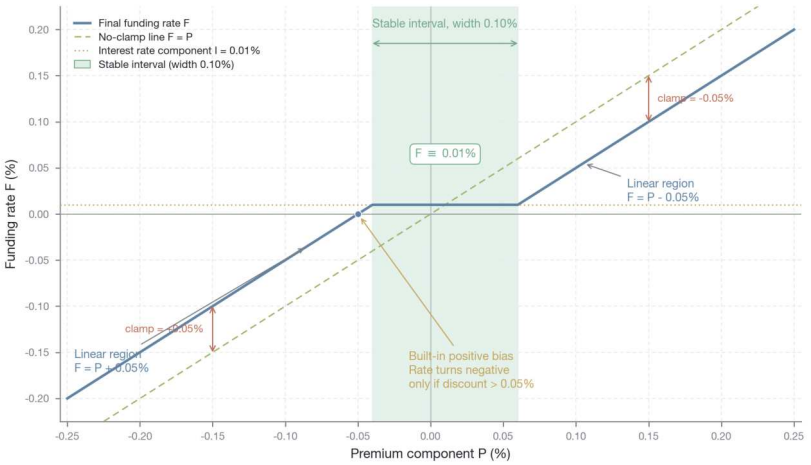

Figure 10-4. The asymmetric truncation effect of the clamp function on the funding rate and the resulting stable band (a conceptual illustration derived from the formula, not empirical data; the clamp thresholds of about ±0.05%, the interest rate component of 0.01%, and the stable-band width of 0.10% are all formula constants [8])

As Figure 10-4 shows, the clamp function creates a "stable band" 0.10% wide (when the premium component P lies between −0.04% and +0.06%). Within this band, the truncation term in the formula offsets fluctuations in the premium, forcing the final funding rate to be anchored at $I = 0.01\%$.

This mechanism produces a structural positive bias in the funding rate distribution. Even when the perpetual futures are at a slight discount (for example, $P = -0.03\%$), the intervention of the clamp function still requires longs to pay shorts a funding rate of 0.01%. Only when the discount exceeds −0.05% does the funding rate fall to zero; only when the discount is deeper still does the rate turn negative.

BitMEX's Q3 2025 derivatives report corroborates this structural feature (Figure 10-2): the BTC funding rate was exactly equal to 0.01% for as much as 78.19% of the time and remained positive 93.83% of the time [8], and even the more volatile Hyperliquid had a positive-rate share as high as 95.98%. This shows that the widespread "persistently positive rate" phenomenon in the market is largely not the result of sustained market optimism but of the institutional friction layer—that is, the formula's built-in positive bias.

10.2.4 Macro interest rate resonance and the economics of arbitrage

Having decomposed the funding rate, we can compare its financing cost layer with the macroeconomic environment to reveal the economic drivers of cross-market arbitrage. Figure 10-5 compares the divergence between the Federal Reserve's benchmark rate and the implied rate of perpetual futures from 2020 to 2025, along with the evolution of the resulting cross-market arbitrage spread.

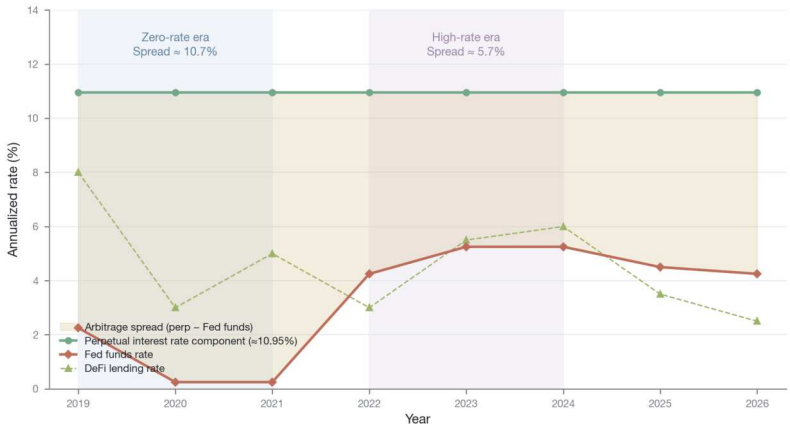

Figure 10-5. The divergence between the macro interest rate environment and the implied rate of perpetual futures, and the resulting arbitrage space (an illustrative trend chart, not a true month-by-month series; the Federal Reserve path is public macro data, the perpetual implied rate of about 10.95% annualized is an arithmetic formula constant, and the narrowing-spread trend is consistent with Bloomberg reporting [13])

As Figure 10-5 shows, the interest rate component of perpetual futures (about 10.95% annualized) was fixed at the outset. During the "zero-rate era" of 2020–2021, the Federal Reserve's benchmark rate was near zero and risk-free returns in traditional financial markets were extremely low. At that time, the crypto market's benchmark funding rate of more than 10% created a large cross-market arbitrage spread (exceeding 10%). This large spread attracted substantial traditional institutional capital (such as early crypto hedge funds) into the crypto market to execute cash-and-carry arbitrage, providing ample liquidity to the market.

Entering the "high-rate era" of 2023–2024, however, the Federal Reserve's benchmark rate climbed above 5.25% and traditional risk-free yields rose sharply. At this point, the advantage of the crypto market's fixed interest rate component over the traditional dollar risk-free rate was greatly compressed, and the arbitrage spread narrowed to around 5%. This change in the macro environment raised the marginal opportunity cost of arbitrage capital. As Bloomberg reported in early 2026, with basis yields falling to around 5%, Wall Street hedge funds began retreating from the Bitcoin basis trade [13].

Beyond the price signal of a narrowing spread, rising macro interest rates also weaken the anchoring strength of perpetual futures through two overlooked channels. The first is **structural diversion through the ETF/CME channel**: after the approval of BTC spot ETFs in January 2024, institutions could construct arbitrage using ETFs plus CME futures without bearing the counterparty risk of crypto-native exchanges. This is not merely a total retreat driven by a narrowing spread but a structural migration of arbitrage capital from crypto-native platforms to traditional financial infrastructure; institutions no longer need to bear exchange credit risk on Binance or Bybit to cap-

ture basis yield. The second is **quantity contagion and risk-appetite contagion**: rising macro interest rates weaken anchoring strength not only through the price signal (a narrowing spread) but also directly through quantity shocks (redemptions by liquidity providers, which force compliant funds to withdraw arbitrage positions) and risk-appetite contagion (a macro risk-off that drives down crypto prices and triggers a liquidation cascade). These three contagion channels—a narrowing spread, structural diversion of capital, and risk-appetite transmission—together explain why the arbitrage depth of the perpetual futures market has declined structurally since 2023.

This resonance and divergence of macro interest rates explains why the liquidity depth and the abundance of arbitrage capital in the crypto derivatives market differ significantly across macro cycles. Now that the Federal Reserve has begun its rate-cutting cycle in the second half of 2025, the decline in traditional risk-free yields will again widen the crypto market's arbitrage spread and may attract a return of the institutional capital that had previously retreated. Meanwhile, on-chain DeFi lending rates (such as the floating borrowing rate for USDC on Aave) provide a more real-time dynamic proxy for the financing cost layer, and the spread between them and the funding rate of perpetual futures constitutes a driver of cross-protocol arbitrage.

10.2.5 Empirical methods for separating the three layers

In empirical research and quantitative trading, accurately separating these three components is a prerequisite for constructing effective strategies. Quantitative researchers typically use the following methods to separate them (Table 10-4):

Component	Observation and separation method	Economic meaning	Trading strategy application
Financing cost layer (I)	The exchange's publicly disclosed fixed parameter (usually 0.01%/8h), or a dynamic proxy estimate via a DeFi stablecoin lending rate (such as the Aave USDC borrowing rate).	The time value of capital and the cross-market risk-free interest rate benchmark.	Serves as the benchmark return for cross-market arbitrage and helps assess the opportunity cost of arbitrage capital.
Sentiment premium layer (P)	Computed from high-frequency order-book data as the real-time basis between the perpetual futures (traded price/mid-price) and the spot index price.	Pure market-microstructure imbalance and one-sided speculative momentum.	Building momentum or mean-reversion strategies; identifying extreme sentiment-reversal points.
Institutional friction layer	In the frictionless limit, $F = P + (I - P) = I$ (the premium P cancels out), so the institutional friction term should be measured by the amount of truncation: friction = clamp($I - P$, -0.05%, $+0.05\%$)$-$ $(I - P)$, i.e., the extent to which the clamp truncates $(I - P)$.	The intervention and distortion of the market's natural clearing process by exchange rules.	Finding structural mismatches where the market is "at a discount but the rate is still positive" and building statistical-arbitrage strategies with a positive expectation.

Table 10-4. Empirical methods for separating the three components of the funding rate (Data source: compiled by the author)

The three-layer decomposition model is not the only framework for explaining the drivers of the funding rate. In the traditional finance literature, several competing theories exist for the pricing of the futures basis. The convenience yield hypothesis holds that holding the spot asset itself carries an implicit value (such as voting rights, staking rewards, or immediate availability), and this value should be reflected in a futures discount. In the crypto context, the convenience yield of holding spot BTC may include the opportunity cost of on-chain staking or DeFi participation. The hedging pressure hypothesis emphasizes that when producers (analogous to miners or token issuers in the crypto market) systematically short futures to lock in forward prices, the concentrated supply of shorts depresses the futures price and produces a negative basis unrelated to speculative demand. The market segmentation hypothesis notes that if participants in the spot and derivatives markets differ systematically in capital, information, or access, the prices of the two markets can diverge persistently without being arbitraged away. The three-layer decomposition model adopted in this chapter does not reject these theories but incorporates part of their insights into different layers:

the effects of convenience yield and hedging pressure are absorbed by the sentiment premium layer, while market segmentation is reflected indirectly through the arbitrage-impediment conditions (Section 10.3.3). A rigorous empirical test, however (such as a regression that decomposes the rate into convenience-yield and speculative-sentiment components), is left to future research.

Through the three-layer decomposition model, we recognize that the funding rate is not a freely floating price determined purely by market supply and demand but a hybrid indicator deeply shaped by institutional rules. In interpreting the funding rate signal, a trader must strip away the "pseudo-steady state" caused by the institutional friction layer and the "positive bias" caused by the financing cost layer in order to reach the true market-microstructure state reflected in the sentiment premium layer.

10.3 The anchoring strength spectrum

In traditional futures markets, the physical or cash delivery mechanism at expiry provides a kind of "hard anchor." No matter how far a contract deviates from the spot price during its life, at the moment of expiry the futures price and the spot price must forcibly converge, or else a risk-free, deterministic arbitrage opportunity would arise. Perpetual futures, however, have no expiry date, and the convergence of their price toward the spot price depends entirely on the funding rate mechanism. This mechanism, which relies on continuous payments, is called a "soft anchor."

The key to understanding the perpetual futures market is to recognize that this soft anchoring is not a binary, black-or-white state (either anchored or unanchored) but a continuous anchoring strength spectrum.

10.3.1 Defining anchoring strength

We can introduce a parameter α (anchoring strength) between 0 and 1 to quantify this concept. Operationally, α can be estimated from the half-life of the deviation of the perpetual futures price from the spot price: the shorter the half-life, the faster the deviation is corrected and the higher the anchoring strength. When $\alpha = 1$, anchoring is perfect, equivalent to the hard-delivery state of traditional futures at expiry, with the futures price F_t strictly equal to the spot price S_t. When $\alpha = 0$, there is no anchoring, and the perpetual futures degenerate into a purely speculative instrument entirely unconstrained by the spot price, with its price determined solely by the internal long-short game of the derivatives market. In actual perpetual futures markets, anchoring strength always lies on a continuous spectrum with $0 < \alpha < 1$. Operationally, α can be estimated with an error correction model. Let $b_t = P_t^{\text{perp}} - P_t^{\text{spot}}$ be the basis at time t; the dynamics of the basis can be modeled as:

$$\Delta b_t = -\kappa \cdot b_{t-1} + \varepsilon_t$$

where $\kappa > 0$ is the mean-reversion speed parameter and ε_t is a white-noise disturbance. The larger κ is, the faster the basis is corrected and the tighter the anchoring. The operational proxy for α is $\hat{\alpha} = 1 - e^{-\kappa}$, with a corresponding half-life of $h = \ln 2/\kappa$. In a normal market environment, based on high-frequency basis data from BitMEX and Binance, a preliminary estimate from an error correction model suggests that h is about

2 to 4 hours—that is, half of the basis is corrected by arbitrage activity within 2 to 4 hours (corresponding to a cumulative correction of about 75%–94% of the basis within 8 hours and about 94%–99.6% within 16 hours). During extreme events (such as Black Thursday in March 2020), however, h can exceed 48 hours (corresponding to $\alpha < 0.2$), indicating that the anchoring mechanism has almost completely failed. The estimated value of κ depends heavily on data frequency, and during extreme events ε_t exhibits fat tails, which may bias the OLS estimate. A more refined Markov regime-switching model can capture the switching of κ across three states—normal, stress, and crisis—though its estimation and testing are left to future research. The half-life parameters above should be understood as preliminary estimates based on descriptive analysis in this book, not as rigorous econometric test results.

In the overwhelming majority of normal market periods, α is close to 1 (for example, $\alpha \approx 0.9$), and the funding rate effectively constrains the perpetual futures price to near the spot price.

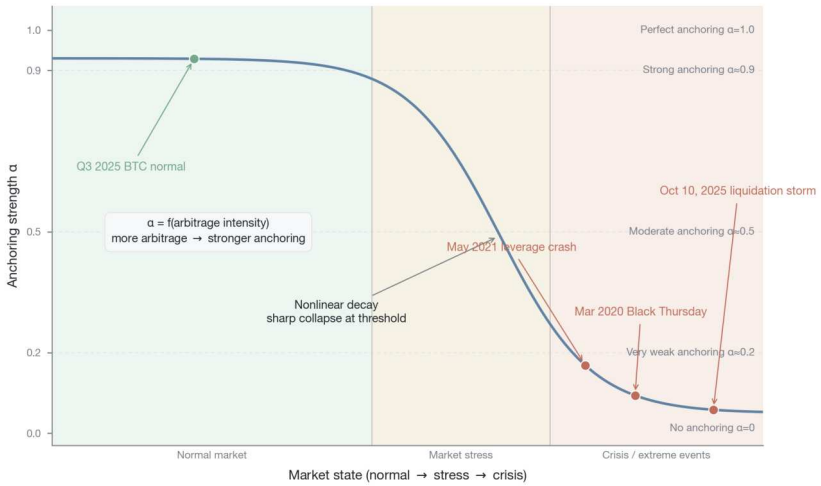

Figure 10-6. The anchoring strength spectrum and deviations during extreme events (a conceptual illustration, not empirical data; the anchoring strength α is a model parameter defined in this book and an author's estimate)

As Figure 10-6 shows, anchoring strength remains in the high range of 0.8 to 0.95 in a normal market environment, and the deviation between the perpetual futures price and the spot price is usually no more than 0.1%. When the market enters an extreme event (such as Black Thursday in March 2020 or the leverage crash of May 2021), anchoring strength plunges below 0.2, and the perpetual futures price deviates persistently from the spot price by hundreds of dollars. This nonlinear decay characteristic shows that the anchoring efficacy of the funding rate does not decline along a linear path but collapses abruptly at a particular threshold.

10.3.2 Arbitrage activity and anchoring strength

The funding rate formula is merely a calculation rule and has no direct power to pull prices. The formula does not create anchoring; it only creates the profit space for arbitrage. What truly creates anchoring is the arbitrage capital drawn in by that profit. When the perpetual futures are at a premium ($P > 0$), the funding rate is positive. Arbitrageurs construct a market-neutral portfolio by "shorting the perpetual + buying spot," thereby collecting the funding rate risk-free. This operation generates sell pressure in the derivatives market (depressing the contract price) and buy pressure in the spot market (raising the spot price), physically forcing the two prices to converge.

Ackerer, Hugonnier, and Jermann (2025) propose the AHJ framework [14] and prove this under the assumption of a frictionless, continuous-trading market. They show that the price of perpetual futures can be expressed as the risk-neutral expectation of the spot price sampled at random time points that reflect the strength of price anchoring. This anchoring strength, at the microstructural level, depends primarily on the smoothness of dynamic trading and the replication of primitive securities—that is, on the efficiency of arbitrage activity.

We can therefore draw a core conclusion: α is a monotonically increasing function of the intensity of arbitrage activity. This conclusion is highly consistent with the intermediary asset pricing theory of Gabaix and Maggiori (2015) [15]. In their framework, the degree of asset-price deviation depends not on changes in fundamentals but on the capital adequacy of financial intermediaries (in this context, arbitrageurs): when intermediary capital contracts, price deviations widen sharply even if fundamentals are unchanged. The anchoring strength of perpetual futures is precisely a direct mapping of this theory onto the crypto derivatives market: the capital condition of arbitrageurs determines the effectiveness boundary of the soft anchor. This can be formalized as $\alpha = g(A, L, \sigma)$, where A is the total amount of active arbitrage capital in the market, L is the liquidity depth for cross-market execution, and σ is the current volatility level. As long as arbitrage channels are unobstructed, capital is abundant, and volatility is within a controllable range, the funding rate can anchor prices effectively; but once A plummets because of capital retreat, L dries up because market makers pull their orders, or σ spikes above arbitrageurs' risk-control thresholds, anchoring strength slides rapidly toward 0.

10.3.3 Conditions that impede arbitrage

If arbitrage activity is the sole source of anchoring strength, then the question of "why the rate fails" becomes "why arbitrage is impeded." In extreme market turmoil, arbitrageurs often face the following six impediment conditions, which prevent them from executing the arbitrage that should flatten the basis and thereby trigger an anchoring collapse.

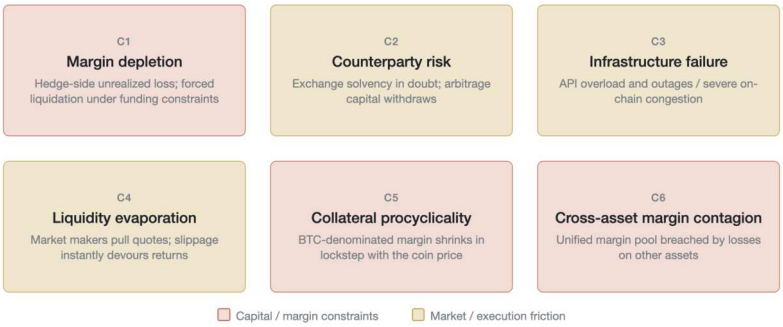

Figure 10-7. The six arbitrage-impediment conditions that cause the anchoring of perpetual futures to collapse

Margin depletion is the primary impediment. In a violent one-sided market, an arbitrageur's hedged position may face large paper losses. Although the overall portfolio is market-neutral, the paper losses on the derivatives leg require continuous margin top-ups. If an arbitrageur faces a liquidity constraint and cannot replenish fiat or stablecoin margin in time, it risks forced liquidation. This mechanism corresponds closely to the spiral between market liquidity and funding liquidity proposed by Brunnermeier and Pedersen (2009) [16]. In their theoretical framework, a decline in asset prices tightens traders' margin constraints, forcing them to cut positions; the position-cutting further depresses prices, forming a self-reinforcing deleveraging loop. Margin depletion among arbitrageurs in the crypto market is precisely the concrete manifestation of this funding-liquidity spiral in the perpetual futures market: arbitrageurs exit not because their strategy has failed but because their funding constraint has been breached. At the same time, counterparty risk intensifies. When systemic risk emerges, arbitrageurs worry about the solvency of the exchange itself. If they expect the exchange might go bankrupt or restrict withdrawals, arbitrage capital will choose to withdraw to protect principal no matter how high the funding rate, creating a vacuum of arbitrage force. In addition, infrastructure failures tend to erupt at critical moments. Arbitrage relies on high-frequency, low-latency cross-market operations, and in extreme conditions an exchange's API may become overloaded and go down, or the underlying blockchain network may become severely congested. Liquidity evaporation further worsens the arbitrage environment: as panic spreads, market makers cancel orders to avoid risk, leaving the order book extremely thin. At this point, arbitrageurs face enormous slippage costs when establishing or unwinding spot and derivatives positions, which can instantly wipe out months of funding-rate returns and make arbitrage economically infeasible. Collateral procyclicality further aggravates the situation: in the early, BTC-margined perpetual futures, when the BTC price crashed, short arbitrageurs faced not only the pressure of a falling contract price but also a simultaneous shrinkage in the fiat value of the BTC they used as margin. This double effect significantly amplified liquidation risk, forcing arbitrageurs to close positions passively at the very moment the market most needed liquidity.

Beyond these five conditions, **cross-asset margin contagion** constitutes a sixth, often-overlooked arbitrage-impediment condition. Under the unified margin mode of exchanges such as Binance and Bybit, an arbitrageur's BTC cash-and-carry position may share a margin pool with positions in other assets. When another asset (such as LUNA in 2022) collapses, losses on that asset erode the unified margin, forcing the arbitrageur to close out an otherwise healthy BTC arbitrage position. This contagion path means that the anchoring strength of BTC can fall unexpectedly during a non-BTC event: arbitrageurs exit not because of pressure in the BTC market itself but because they are breached by risk spillover from other assets. During the LUNA/UST collapse of May 2022, some arbitrage funds operating under the unified margin mode were forced to liquidate their market-neutral positions in both BTC and ETH simultaneously, providing empirical support for this contagion path.

10.3.4 The AHJ framework: applications and limitations

The AHJ framework lays a solid mathematical foundation for the no-arbitrage pricing of perpetual futures in theory, proving that under the assumption of a perfect (frictionless, continuous-trading) market, a specific funding rate setting makes the perpetual futures price converge to the spot price [14].

When this theoretical framework is applied to the real crypto market, however, its limitations become fully apparent. The core assumptions of the AHJ model are a frictionless market and continuous trading capability. As the arbitrage-impediment conditions analyzed above show, the crypto market exhibits precisely the opposite at extreme moments: extremely high friction (slippage, congestion) and discontinuity of trading (outages, circuit breakers).

The AHJ framework therefore depicts the ideal state of $\alpha \approx 1$ in Figure 10-6. It explains why the funding rate can operate effectively during the 99% of the time that is normal, but it cannot explain why a deep price dislocation arises during the 1% "crisis moments." The no-arbitrage condition exhibits significant fragility when confronting a systemic liquidity shock.

10.3.5 The anchoring paradox

Taken together, these observations point to a core microstructural paradox of the crypto derivatives market: the anchoring paradox. When the market is calm and volatility is low, the natural deviation between the perpetual futures price and the spot price is already small. At such times, arbitrage channels are unobstructed, liquidity is ample, the funding rate mechanism operates effectively, and anchoring strength is extremely high. Yet at such times the market does not truly "need" a powerful anchoring mechanism, because prices themselves have no impetus to derail.

Conversely, when the market suffers a black swan event, volatility spikes, and derivatives prices deviate sharply from spot prices out of panic or greed, this is precisely the moment when the market most needs the funding rate to anchor. But it is exactly at this moment that, because the six arbitrage-impediment conditions are triggered simultaneously, arbitrage capital retreats on a large scale or is even forcibly liquidated,

causing the transmission mechanism of the funding rate to break down entirely and anchoring strength to fall to its lowest level.

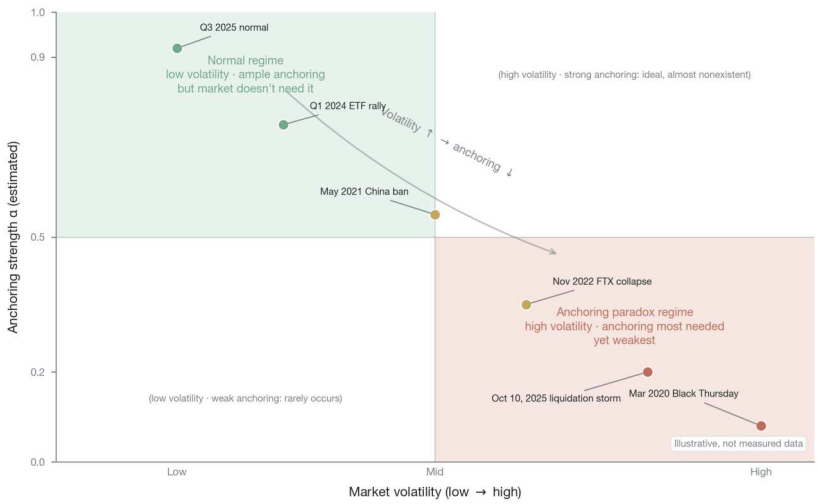

Figure 10-8. The inverse relationship between market volatility and anchoring strength (a conceptual illustration, not empirical data; the anchoring strength α is an estimate, the volatility axis is a qualitative scale of low, medium, and high, and the event points are qualitatively positioned)

As Figure 10-8 shows, the historical extreme events of the crypto market fully validate this paradox.

During the Black Thursday crash of March 12, 2020, the price of Bitcoin was cut in half in a single day. A post-mortem report by Multicoin Capital notes that, because of extreme congestion on the blockchain network and evaporated liquidity on BitMEX, arbitrageurs could not deposit BTC into BitMEX to flatten the spread [5]. Only about $20 million in bids remained on the entire BitMEX order book, yet it faced more than $200 million in long liquidations. The funding rate mechanism failed completely, causing the perpetual futures price on BitMEX to fall hundreds of dollars below other spot exchanges at one point (a discount of more than $500 at its peak, as noted in the chapter introduction) and nearly flash-crashing to zero.

Similarly, during the $19 billion liquidation storm of October 10, 2025, geopolitically induced panic caused liquidity across the entire market to evaporate instantly. Arbitrage capital was powerless in the face of extreme slippage and high network gas fees, causing the anchoring function of the funding rate to fail briefly and the basis to widen substantially [17].

The anchoring paradox reveals an inherent flaw of the funding rate as a "soft anchor": its effectiveness depends on market liquidity, yet it cannot itself create liquidity when liquidity dries up. This paradox is, in essence, a precise mapping of the "limits of arbitrage" theory of Shleifer and Vishny (1997) onto the crypto derivatives market [18]. Shleifer and Vishny note that real-world arbitrageurs are not the unconstrained agents of textbooks; they rely on external capital, and capital providers tend to withdraw funds precisely when arbitrage is most needed, because paper losses are most severe at that

time. The anchoring paradox of perpetual futures is exactly the crypto version of this logic: arbitrageurs easily earn rate income when the market is calm but cannot perform their price-correction function under extreme deviations because of capital constraints and execution friction. This is the fundamental game-theoretic reason why the funding rate "works most of the time but occasionally fails at the most critical moment."

Several mechanism-design paths might alleviate the anchoring paradox, though each introduces new trade-offs. At least three are worth discussing. The first is **the insurance fund as arbitrageur of last resort**: the exchange actively executes cash-and-carry arbitrage during extreme basis events (as Hyperliquid's HLP vault plays a similar role in normal markets), but this turns the exchange from a neutral rule-setter into a direct market participant, introducing new conflicts of interest, and the size of the insurance fund may be far too small to fill the arbitrage vacuum in a systemic crisis. The second is **an extreme-basis circuit breaker**: pausing the liquidation engine when the basis exceeds a threshold, but pausing liquidations may cause greater risk accumulation (the paper losses of unliquidated positions keep expanding), and an intervention requiring human judgment is difficult to implement in a decentralized protocol. The third is **dynamic rate-cap increases**: automatically raising the rate cap in extreme states to strengthen negative feedback. But as the ALPACA case in Section 10.6.3 shows, an extreme rate can itself become a manipulation tool rather than a corrective force. Fully resolving the anchoring paradox may require introducing additional stabilization mechanisms beyond the rate mechanism, which constitutes an open research frontier in derivatives mechanism design.

10.4 The three-layer game model

The funding rate is not merely the result of a mathematical calculation but the product of a continuous game among multiple participants within a specific rule framework. To understand deeply how this mechanism operates in the crypto derivatives market, we construct a "three-layer game model." The model systematically deconstructs the formation and fragility of the funding rate's dynamic equilibrium at three levels: the microstructural confrontation of positions, the meso-level of cross-market arbitrage, and the macro-level of rule attack and defense.

10.4.1 The anchoring game

At the most microstructural level, the funding rate is essentially a near-zero-sum "war of attrition" between the long and short camps. When the perpetual futures price exceeds the spot index price, the funding rate is positive and longs must pay shorts periodically; the reverse holds otherwise. This mechanism is designed to force prices back to their spot anchor by raising the holding cost in the direction of the deviation.

Figure 10-9 arranges the three games in a concentric-circle structure by participant scope and time scale.

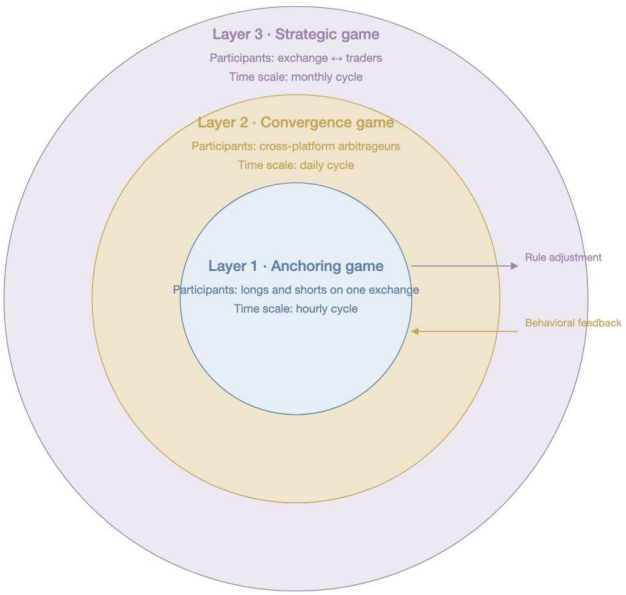

Figure 10-9. The nested structure of the three-layer game model of the funding rate

As Figure 10-9 shows, the three games exhibit a nested structure from the inside out: the innermost anchoring game determines the balance of long-short forces and the direction of the basis within a single exchange; the middle convergence game pulls prices and rates across platforms toward consistency through cross-market arbitrage; and the outermost strategic game determines the evolutionary path of the rules themselves. Feedback runs bottom-up among the three layers: imbalance in an inner game propagates outward, while rule adjustments in an outer layer alter the game structure of the inner layers.

To characterize the equilibrium structure of the anchoring game precisely, we model it as a 2×2 normal-form game. Consider a simplified single-period game in which longs and shorts each choose to "hold" or "exit." Let F be the current funding rate (paid by longs to shorts when positive), Δ the directional payoff expectation (positive favors longs), and λ the liquidation-risk loss triggered by a counterparty's exit. The payoff matrix is shown in Table 10-5:

	Short: hold (H)	**Short: exit (E)**
Long: hold (H)	$(\Delta - F,\ -\Delta + F)$	$(\Delta + \lambda,\ -\lambda)$
Long: exit (E)	$(-\lambda,\ F + \lambda)$	$(0,\ 0)$

Table 10-5. The 2×2 normal-form payoff matrix of the anchoring game (Data source: compiled by the author)

The Nash equilibrium of this game depends on the size of the rate F relative to the directional payoff Δ and the liquidation risk λ. When $F - \lambda \leq \Delta \leq F + \lambda$ (i.e., $|\Delta - F| \leq \lambda$), longs and shorts are mutual best responses, and (hold, hold) constitutes the unique pure-strategy Nash equilibrium (the upper bound $\Delta \leq F + \lambda$ is the short's tolerance condition and is the economically more binding side); both sides have an economic incentive to maintain their positions, and the anchoring game is in a steady state. When the rate rises to $F > \Delta + \lambda$, the long's best response to the short holding becomes to exit (because $-\lambda > \Delta - F$), while the short's best response to the long exiting is to hold (because $F + \lambda > 0$); the two are mutual best responses, and the equilibrium jumps to (exit, hold), which is precisely the condition under which the funding rate's negative feedback mechanism takes effect. When the directional payoff expectation becomes extreme ($\Delta \quad F$), however, the long's incentive to hold becomes unshakable, and even a persistently rising rate cannot trigger an equilibrium jump. In this state, the game slides from the "both hold" steady state into a positive-feedback regime, and the funding rate loses its corrective function. The analysis above assumes a single-period static game; in a multi-period dynamic game, reputation effects, learning, and strategic adaptation would further enrich the equilibrium structure, though its core dependence on the rate threshold would remain unchanged.

The analysis above also treats the directional payoff expectation Δ as an exogenous, commonly known parameter, but in practice longs and shorts hold systematically biased estimates of it. The heterogeneous-beliefs model of Scheinkman and Xiong (2003) [19] shows that overconfident longs systematically overestimate Δ, while shorts in a panic systematically underestimate it. More importantly, Δ is itself endogenous to the game: longs adding leverage and driving up the price raises the realized value of Δ ex post, forming a self-fulfilling prophecy. Treating Δ as an exogenous parameter obscures this reflexivity: longs and shorts do not face the same Δ but different values Δ_L and Δ_S weighted by their respective subjective probabilities, and these subjective beliefs are partly self-validating through their effect on the market price. This methodological qualification does not affect the qualitative conclusions of the equilibrium analysis above, but it indicates that a complete theoretical treatment requires a dynamic game framework with heterogeneous beliefs.

In actual operation, however, this war of attrition often exhibits strong reflexivity [20]. The noise-trader-risk model of De Long, Shleifer, Summers, and Waldmann (1990) provides a theoretical basis for understanding this phenomenon [21]. In their framework, even when rational arbitrageurs know that a price has deviated from fundamentals, the irrational behavior of noise traders may push the deviation further in the short run, exposing arbitrageurs to the risk of "being liquidated while on the right side." In the perpetual futures market, this noise-trader risk is sharply amplified by high leverage: arbitrageurs must bear not only the risk that the price deviates further but also the cash-flow pressure of the rate each settlement period, which can lead rational arbitrageurs to stay out even when the rate is extreme. In a bull cycle, longs expect the asset's price appreciation to far exceed the funding-rate cost they pay. Thus, even facing high holding costs, longs not only refuse to close positions but may use paper profits to add further leverage. This behavior widens the contract premium further, which in turn pushes the funding rate higher. At this point, the high funding rate is no longer

a resistance that suppresses speculation but instead becomes a "confirmation signal" of the market's extreme optimism, attracting more speculative capital and forming a self-reinforcing loop of "rising price → rising rate → reinforced expectations → further position-adding."

The outcome of this war of attrition depends on the limits of each side's tolerance for cost. Although shorts can continuously collect risk-free rate income, they must bear the liquidation risk from further price increases. When market sentiment is extremely euphoric, the short camp may be forced to close positions because it cannot withstand the pressure of margin calls; this not only causes the price to spike instantly but also leaves the funding rate without a "counterparty" in the short term, further distorting the anchoring mechanism.

10.4.2 The convergence game

Without the intervention of an external force, the long-short war of attrition of the first layer easily falls into extreme imbalance. The core participants of the second-layer game are funding rate arbitrageurs, who, through cross-market operations, objectively bring about a dual equilibrium—price convergence and rate convergence—while pursuing risk-free returns.

Price convergence is achieved mainly through "cash-and-carry arbitrage." When the perpetual premium is too high (a positive funding rate), an arbitrageur buys the asset in the spot market while shorting an equal-size position in the perpetual futures market. This operation not only locks in the risk of price fluctuations but also steadily earns the funding rate. The arbitrageur's short-selling directly adds short-side force to the contract market, depressing the contract price and pushing it back toward the spot price.

Rate convergence is achieved through "cross-exchange arbitrage." Because different exchanges differ in liquidity depth, user composition, and rate-calculation details, the funding rate for the same asset often differs across platforms. Arbitrageurs short on the exchange with the higher rate and go long on the exchange with the lower rate, earning the rate spread between them. This capital flow ultimately flattens the rate differences across platforms. This convergence is limited, however, by the friction of transferring funds across platforms: transfers between CEXs involve withdrawal fees, on-chain confirmation delays (BTC takes 30–60 minutes), and anti-money laundering (AML) screening; transfers between CEXs and DEXs additionally involve the smart-contract risk of cross-chain bridging. These frictions determine the existence of a "no-arbitrage band": rate differences within the cost of cross-platform transfer cannot be eliminated by arbitrage, constituting the equilibrium width of the rate difference rather than a transient state converging to zero. According to Boros Finance's 2025 empirical research, cross-exchange rate arbitrage in BTC and ETH between Hyperliquid and Binance can achieve weighted-average fixed annualized returns of 5.98% to 11.4%, with peak returns in certain extreme periods exceeding 23% [22]. Because Boros is a provider of funding rate swap products, it reports gross returns before execution costs; actual net returns must deduct cross-exchange fund-transfer costs, the capital-efficiency loss from locking margin on two exchanges, slippage, and position-rebalancing friction, and

may be significantly lower than the nominal figures.

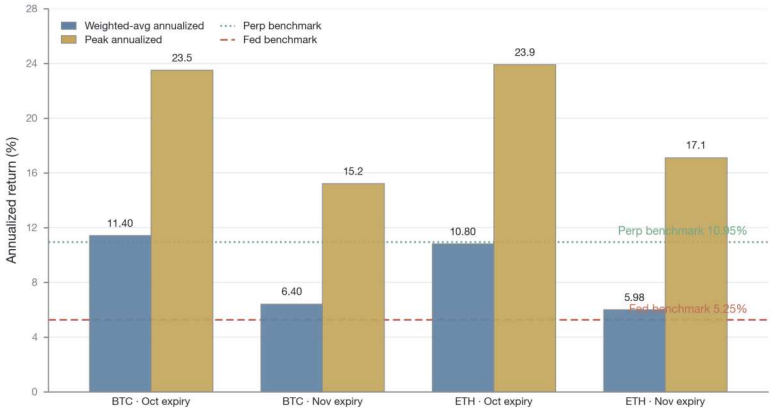

Figure 10-10. Annualized returns of cross-exchange funding rate arbitrage for BTC and ETH (gross returns before execution costs; BTC and ETH correspond to different maturities and are not a single-asset constant) [22]

As Figure 10-10 shows, the cross-exchange rate arbitrage returns for BTC and ETH exhibit pronounced time variation. The weighted-average annualized return for BTC was 11.4% (for the October 31 maturity) and 5.98% for ETH (for the November 28 maturity); note that the two correspond to different maturities and are not a single-asset constant, and the report shows gross returns before execution costs. Returns peaked in certain periods (exceeding 23%), typically corresponding to a widening cross-platform rate spread driven by extreme market sentiment. These high-return windows provide an economic incentive for arbitrage capital to enter, objectively promoting cross-platform convergence of the rate.

10.4.3 The strategic game

The third-layer game takes place between the rule-setters (exchanges) and the rule-adapters (traders). The exchange's goals are to maintain stable anchoring of the contract price, guard against systemic risk, and maximize trading volume; the trader's goal is to find loopholes within the rule framework to maximize profit.

To prevent excessive funding-rate fluctuations from causing large-scale chain liquidations, major exchanges generally set a rate clamp function and rate caps/floors. For example, BitMEX's empirical data show that under its clamp mechanism, the funding rate was fixed at the default 0.01% (every 8 hours) for as much as 78.19% of the time, equivalent to a benchmark annualized rate of about 10.95% [8]. Although such rules reduce day-to-day fluctuations, they also create space for rule arbitrage.

As the market has matured, this strategic game has intensified. For example, when some exchanges raised the settlement frequency from every 8 hours to every 1 hour or even real-time settlement, high-frequency traders quickly developed a "second-scale front-running" strategy, entering positions momentarily before settlement and exit-

ing immediately afterward to capture rate income at no cost. As a countermeasure, exchanges (such as Binance in its September 2025 algorithm update) introduced a frequency normalization factor to eliminate this time-arbitrage space by smoothing the calculation window. This dynamic game of "rule-loophole discovery → strategy exploitation → rule patching" constitutes the underlying driver of the funding rate mechanism's evolution.

10.4.4 State dependence and the decay of anchoring efficacy

The validity of this three-layer game model is not fixed but highly dependent on the current market state. As the market moves from calm to extreme, the anchoring efficacy of the funding rate exhibits a pronounced nonlinear decay (Table 10-6).

Market state	Basis characteristics	Core dominant force	Assessment of anchoring efficacy	Representative historical case
Normal state	Very small ($< \pm 0.1\%$)	Rate arbitrageurs, market makers	Strong: arbitrage capital is ample, small deviations are quickly flattened, and the funding rate stays near its default benchmark.	Most of the calm trading periods in 2024–2025
Stress state	Significant ($\pm 0.1\%$ to $\pm 1\%$)	Speculators (one-sided sentiment) vs. arbitrageurs	Weakened: one-sided sentiment widens the arbitrage space, but the execution constraints on arbitrage capital begin to appear, and the rate shows sustained positive or negative polarization.	The August 2024 yen carry-trade unwind shock; the AI-sector turbulence triggered by DeepSeek in late January 2025
Crisis state	Extreme ($> \pm 1\%$)	Liquidation mechanism (forced liquidation)	Failed: arbitrage channels break down entirely because of liquidity drought or network congestion, the liquidation mechanism takes over the market, and the rate mechanism no longer anchors but may instead accelerate the collapse.	Black Thursday on March 12, 2020; the leverage crash of May 19, 2021 [23]

Table 10-6. State-dependent decay of the funding rate's anchoring efficacy (Data source: compiled by the author)

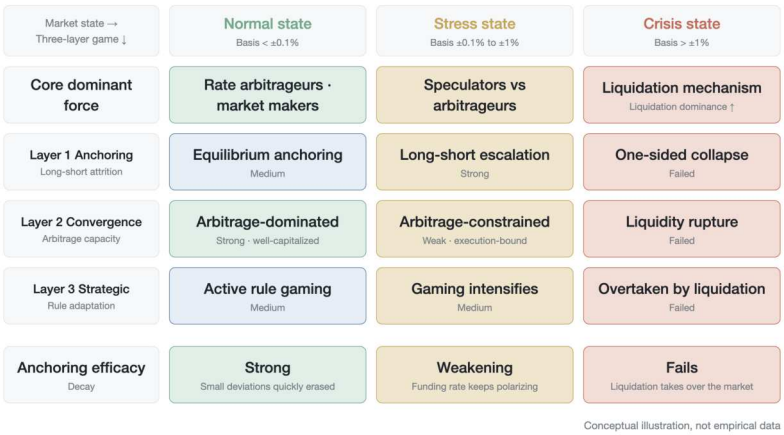

Figure 10-11. The relative strength of the three layers of game forces and the decay of anchoring efficacy across market states (a conceptual illustration, not empirical data; the strength of each layer is a qualitative rating of strong, medium, weak, or failed, and the basis thresholds are drawn from Section 10.4.4)

In the normal state, the second-layer convergence game (arbitrageurs) dominates, and the funding rate effectively anchors. When the market enters a crisis state, however (such as the May 19, 2021 crash in which the crypto market plunged 30% and more than $8 billion was liquidated market-wide [23]), arbitrageurs cannot execute cross-market operations because of spot-liquidity drought and severe network congestion. At this point, the second-layer game fails entirely, the first-layer long-short war of attrition devolves into one-sided chain forced liquidations, and the funding rate not only fails to pull prices back but its extreme negative values instead become a gauge of market panic.

In the crisis state, when the funding rate's anchoring mechanism fails and the liquidation cascade unfolds fully, the exchange's insurance fund and auto-deleveraging mechanism become the last line of defense for maintaining market continuity. The core function of the insurance fund is to absorb shortfall losses: when a position's liquidation price is worse than its bankruptcy price, the difference is borne by the insurance fund, thereby avoiding passing the shortfall on to the winning side. During Black Thursday on March 12, 2020, BitMEX's insurance fund drew down by about $8 million to $13 million (roughly 1,600 to 2,600 BTC) within a few hours, yet this was still insufficient to cover all shortfall losses [5]. When the insurance fund is exhausted, the auto-deleveraging (ADL) mechanism is triggered: the system automatically reduces counterparty positions according to a specific ranking algorithm to make up the shortfall. The ADL ranking algorithms of different exchanges differ significantly: BitMEX and Binance use a two-factor ranking of profit percentage and effective leverage,

whereas Hyperliquid first uses HLP vault funds to absorb shortfall losses and triggers ADL against traders only when the HLP is insufficient. Systematic public data on the historical trigger frequency of ADL are currently lacking (flagged as an empirical-data gap), but Hyperliquid's on-chain transparency provides a data foundation for future empirical research.

The ADL mechanism fundamentally changes the payoff function of the game. In an ideal world without ADL, a trader's return is a deterministic function of directional judgment and leverage choice. But the existence of ADL means that even a trader who is right about direction and maintains prudent leverage may have profitable positions forcibly reduced during a liquidation cascade. The shortfall losses of a "neighbor who is right about direction but over-leveraged" are transmitted to the winning side through ADL. This creates a unique negative externality: the risk-taking of high-leverage speculators threatens not only their own survival but also, through the ADL mechanism, the return certainty of prudent traders. For the equilibrium of the anchoring game, the existence of ADL weakens arbitrageurs' incentive to participate: although arbitrageurs construct market-neutral portfolios, their profit leg still faces the tail risk of being forcibly reduced by ADL. This mechanism-design tension—the conflict between protecting system continuity and incentivizing arbitrage participation—remains an unresolved open problem in the mechanism design of perpetual futures.

Moreover, under a unified margin system, the rate polarization of one asset affects not only the game equilibrium of that asset itself but may also be transmitted to other assets through a shared margin pool. For example, when extreme negative rates on SOL cause SOL shorts to be liquidated, if those shorts hold ETH longs in the same margin pool, the ETH longs may also be liquidated by association, even if the ETH market itself shows no anomaly. This cross-asset contagion mechanism is developed further in the liquidation-cascade analysis of Chapter 11.

10.4.5 The structural boundaries of arbitrageurs

If arbitrageurs are the core force sustaining the funding rate's anchoring mechanism, why do they collectively "disappear" during extreme conditions? This stems from three structural boundaries that arbitrageurs face. As Figure 10-12 shows, all three constraints are loose in a normal market and arbitrage activity is unimpeded; when the market enters an extreme state, all three constraints tighten simultaneously and arbitrage capacity shrinks sharply.

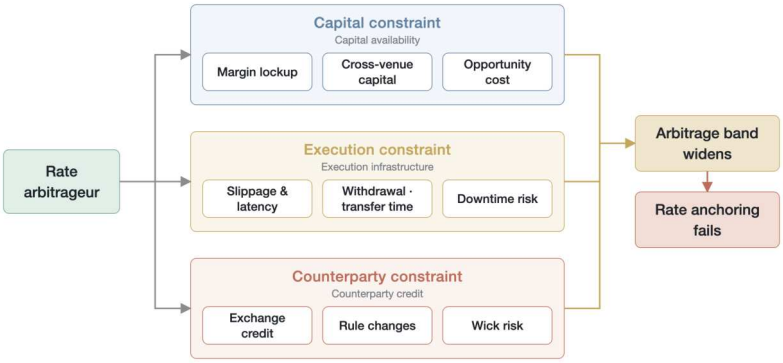

Figure 10-12. The three structural constraints faced by funding rate arbitrageurs

Gromb and Vayanos (2002) rigorously prove, from a general-equilibrium perspective, the systemic impact of capital constraints on arbitrageur behavior [24]. In their model, when arbitrageurs face funding constraints, the degree to which market equilibrium deviates from no-arbitrage pricing depends on arbitrageurs' wealth level: the poorer the arbitrageurs, the larger the price deviation and the more severe the welfare loss. This conclusion applies directly to the perpetual futures market: the persistent deviation of the funding rate (i.e., the decline in anchoring strength) essentially reflects the inadequacy of arbitrage capital relative to speculative demand.

These three constraints correspond mechanistically to the six arbitrage-impediment conditions of Section 10.3.3; rather than restate each one's operational details, we note only the core of each constraint. The capital constraint stems from the capital-intensity of cash-and-carry and cross-exchange arbitrage: arbitrageurs must reserve large redundant margins across multiple platforms to guard against one-sided liquidation, so capital efficiency is significantly reduced, and when the arbitrage space widens while idle capital runs out, the rate deviation persists. The execution constraint manifests as rate-limiting, latency, or even outages of exchange APIs during extreme conditions (such as the service disruptions at some leading exchanges on May 19, 2021 [25]), as well as delayed fund transfers caused by on-chain congestion and spiking gas fees. The counterparty constraint is the arbitrageur's passive exposure to the credit risk of centralized exchanges and to unilateral rule changes (such as forcibly rolling back trades, adjusting rate caps, or suspending withdrawals). These tail risks lead rational arbitrageurs to withdraw and wait on the sidelines precisely when the market most needs liquidity supply.

Together, these three constraints determine the capacity ceiling of the funding rate's anchoring mechanism. In quantitative terms, this ceiling depends on the total capital arbitrageurs can deploy, the speed of cross-platform fund transfers, and the credit rating of exchanges. In the BTC perpetual futures market, thanks to the participation of systematic arbitrage entities such as Ethena, arbitrage capacity is usually ample, whereas in the long-tail altcoin market, arbitrage capacity may be only a few million dollars, and a single medium-sized directional trade can breach this ceiling. When the

corrective demand generated by a market deviation exceeds arbitrageurs' structural capacity, the equilibrium of the three-layer game model tends to collapse.

10.5 Rate polarization and positive feedback

In classical financial theory, the funding rate is designed as a negative feedback system: when the contract price deviates from spot, a rising rate increases the holding cost on the deviating side, forcing it to close positions or attracting arbitrageurs to enter, ultimately returning the price to spot and pulling the rate back down. In the extreme conditions of the crypto market, however, this negative feedback mechanism can flip and evolve into a self-reinforcing positive feedback system, driving the rate into extreme polarization.

10.5.1 Trigger conditions for positive feedback

The mathematical trigger condition for the flip from negative to positive feedback can be formalized as the following proposition.

Proposition (necessary condition for continued position-holding). Let $E_t[\Delta P_{t+1}]$ be a trader's conditional expectation at time t of the next-period price change, F_t the current funding rate, γ the trader's risk-aversion coefficient, and $\mathrm{Var}_t[\Delta P_{t+1}]$ the conditional variance of the price change. When the following condition holds, a rational trader chooses to maintain the position and the funding rate's negative feedback mechanism fails:

$$E_t[\Delta P_{t+1}] > F_t + \gamma \cdot \mathrm{Var}_t[\Delta P_{t+1}]$$

The left side of this inequality is the expected return of holding the position, and the right side is the total cost of holding, comprising the deterministic rate outlay F_t and the risk-aversion-adjusted directional risk premium $\gamma \cdot \mathrm{Var}_t[\Delta P_{t+1}]$. In the simplified version (setting $\gamma = 0$, i.e., the risk-neutral assumption), the condition reduces to $E_t[\Delta P_{t+1}] > F_t$—that is, the expected directional profit merely needs to exceed the rate cost. The full version introduces the risk-aversion coefficient, meaning that even if the expected return exceeds the rate, a risk-averse trader may still choose to exit if the directional risk is too large (high Var_t). When the market narrative is highly certain (such as the ALPACA delisting announcement), traders tend to establish positions immediately, and positive feedback is more easily triggered. This analysis requires a finer distinction, however: a delisting announcement provides directional certainty (the price should fall) but increases uncertainty in magnitude and time path, and the price path before delisting may exhibit violent fluctuations and a short squeeze (as events indeed proved). The "focusing illusion" of behavioral finance (Kahneman 2011 [26]) may better explain this phenomenon: traders focus excessively on the directional narrative ("delisting = crash") while underestimating path risk, causing them to systematically overestimate the net expected return of establishing a position immediately.

The inequality above characterizes only the static decision condition under which a holder does not exit; it is necessary but not sufficient for positive feedback to form. Positive feedback also requires a dynamic signal loop: position-holding sustains the premium → the high rate is read by the market as confirmation of trend continuation

→ more same-direction capital is drawn in → the premium widens further. A complete formalization of this loop requires a multi-period model with information feedback and is left to future research. A final note, on the dimension of γ: it has the dimension of the reciprocal of the variance of the price change (i.e., if ΔP is measured in percent, the unit of γ is $\%^{-2}$), and its economic meaning is the additional risk compensation a trader demands per unit of variance risk exposure.

For a concrete numerical example, if a trader expects a token to rise 20% over the next three days, while the funding rate is 0.3% every 8 hours (about 0.9% cumulative per day), then the total rate cost over three days is about 2.7%, far below the 20% expected return. Under such a return expectation, even if the rate rises further to 1% every 8 hours, the trader still has an economic incentive to maintain the long position.

Consider the ALPACA token delisting event of April–May 2025. Binance announced that it would delist ALPACA spot and settle its perpetual futures on May 2 [27]. The market widely expected the delisting to cause a price crash, so large numbers of speculators poured into the perpetual futures to short, driving the funding rate quickly to a negative extreme (−1.24% every 8 hours, with some reports of a peak of −2.0%).

By negative-feedback logic, such a high shorting cost should have forced shorts to close, thereby relieving downward price pressure. In reality, however, the shorts expected the price drop upon spot delisting to far exceed the funding-rate cost of roughly 3.72% per day (−1.24% × 3). As long as the expected directional profit is large enough, speculators are willing to endure an extreme, sustained rate outlay. This "the math still works out" game led shorts not to close but instead to add further, ultimately producing a large-scale short squeeze: the ALPACA price did not crash before delisting but instead surged more than 1,100% (from about $0.024 to about $0.29), and large numbers of shorts were liquidated after paying extremely high funding rates [27].

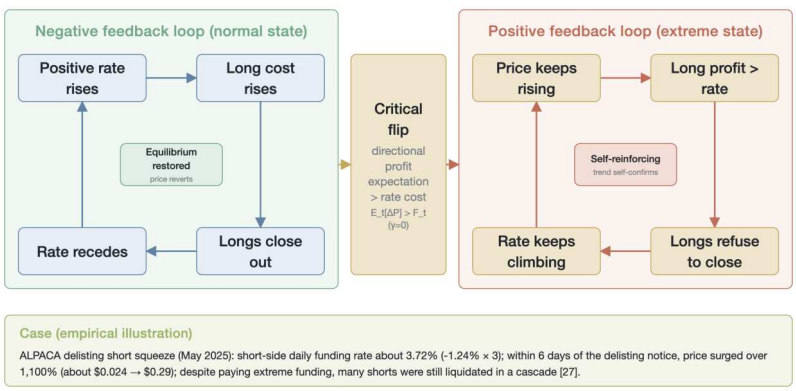

Figure 10-13. The flip of the funding rate mechanism from negative to positive feedback (a mechanism illustration based on a conceptual process, not empirical data; in the ALPACA event, −1.24%/8h is the peak negative rate, the daily total of 3.72% is extrapolated over three periods, and the price range of $0.024 to $0.29 is a conservative figure [27])

As Figure 10-13 shows, the flip proceeds in clear stages. In the normal state, a con-

tract premium induces a positive rate, the rate cost suppresses longs and attracts arbitrageurs, forming a negative feedback loop of price convergence. Once the expected directional profit exceeds the rate cost, holders no longer close positions under rate pressure; instead, the rising rate is read as confirmation of trend continuation, drawing in more same-direction capital and flipping negative feedback into positive feedback. In the ALPACA event, this flip completed within six days of the delisting announcement, accompanied by a price increase of more than 1,100% and chain forced liquidations of shorts [27].

10.5.2 A behavioral finance explanation

In the positive-feedback phase, the market exhibits a counterintuitive phenomenon: "the higher the funding rate, the more the paying side refuses to close." Beyond the pure mathematical profit calculation above, the behavioral-finance research of scholars such as Skwarek (2025) offers a deeper explanation for such irrational behavior in the crypto market [28].

The sunk cost fallacy and the disposition effect are the primary factors. After paying substantial funding rates and enduring paper losses, traders are often unwilling to accept the loss and exit. The disposition effect shows that investors tend to sell winning assets too early and hold losing assets too long. In a high-rate environment, closing a position means converting the paper loss and the rate already paid into a realized loss, and this psychological pain leads traders to keep holding. Confirmation bias reinforces the same behavioral pattern. In a polarized market, traders tend to selectively seek information supporting their position direction while ignoring the risk signal sent by a high funding rate. For example, at a bull-market peak, longs rationalize the extreme positive rate they pay with narratives of institutional entry or technical breakouts. Herding intensifies this dynamic further. The crypto market has pronounced social and community-driven characteristics. When the funding rate is extremely skewed to one side, it actually reflects the highly homogeneous expectations of market participants. Retail traders often believe the crowd's judgment is more accurate and thus establish positions in the crowd's direction, further intensifying rate polarization. At the theoretical level, two herding mechanisms must be distinguished: the rational information cascade described by Banerjee (1992) [29], in which each trader infers others' private information from their behavior and rationally imitates it, versus pure social conformity. The on-chain position transparency of the crypto market (such as Hyperliquid's public whale-position leaderboard) significantly accelerates the information-cascade effect by lowering the cost of observing behavior: traders can observe the direction and size of large positions almost in real time, which has no direct counterpart in the traditional-finance herding literature. Together, these factors point to gambling-like sensation-seeking behavior; Delfabbro and colleagues note that the behavior of some crypto traders is structurally similar to pathological gambling [30]. The extreme high-leverage, high-rate environment not only fails to deter but instead provides the high volatility and thrill they seek.

10.5.3 Termination paths of polarization

Once the funding rate falls into a polarized positive-feedback loop, it usually terminates in only one of two ways, whose effects on market structure differ starkly. Along the two dimensions of leverage concentration and liquidity depth, Figure 10-14 compares the two termination paths of polarized positive feedback: mild mean reversion and liquidation cascade.

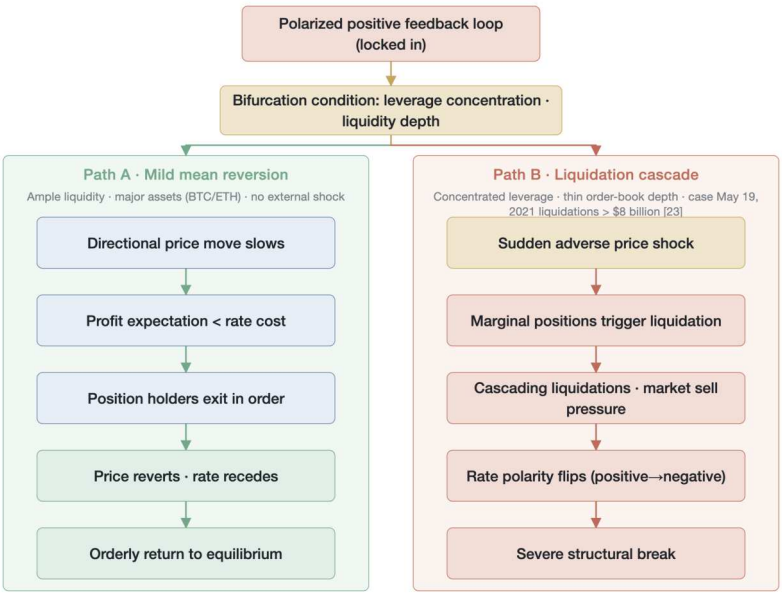

Figure 10-14. A comparison of the two termination paths of funding rate polarization positive feedback (a conceptual illustration based on synthetic trajectories, not empirical data)

In the case of mild mean reversion, the one-sided movement of the asset price begins to slow or stall, the expected directional profit falls accordingly, and the mathematical trigger condition reverses (expected profit $<$ rate cost). Holders realize that continuing to pay a high rate is no longer worthwhile and begin to close positions actively, in an orderly, staged manner. As one-sided positions decline, the contract price moves back toward the spot price and the funding rate gradually falls to normal levels. This path usually occurs in mainstream assets with good liquidity and ample arbitrage capital (such as BTC and ETH), absent a major external macro shock.

By contrast, the liquidation cascade path is far more destructive. When polarized one-sided positions (usually accompanied by high leverage) encounter a sudden adverse price move, some marginal positions are triggered into forced liquidation. In the case of positive-rate polarization (a crowded long side), long liquidations generate large numbers of market sell orders that instantly depress the contract price, in turn triggering long stop-losses and liquidations at lower price levels. This chain of forced long liquidations drives the contract price far below the spot price in a very short time, and the funding rate not only instantly returns to zero but may even flip polarity, from

an extreme positive rate to an extreme negative rate. The crash of May 19, 2021 is a canonical case: more than $8 billion in leveraged longs were liquidated within about 24 hours, and the funding rate fell from a sustained high positive value to an extreme negative value [23].

10.5.4 Rate polarization and the leverage cycle

Rate polarization is not an isolated event; it is the crypto derivatives market's counterpart to Hyman Minsky's "financial instability hypothesis" [31]. Minsky argues that prolonged stability breeds overconfidence, which in turn drives the accumulation of debt leverage and ultimately leads to collapse (the "Minsky moment").

The mapping is not exact, and its limits are worth stating precisely. The core causal chain of the Minsky framework is the gradual deterioration of the debt-to-income ratio and the hard constraint of repaying principal at maturity. Perpetual futures holders face no maturity-repayment constraint, and what triggers deleveraging is not "cash flow failing to cover interest" but the forced liquidation of margin. This changes the temporal profile of the crisis: the traditional Minsky cycle is gradual (usually unfolding over months to years of leverage accumulation), whereas a liquidation cascade in the crypto market can complete within minutes, so the transition from "boom" to "bust" is several orders of magnitude faster. The crypto market's leverage cycle is therefore more accurately described as an "accelerated Minsky," which retains the leverage-driven positive-feedback core while compressing the unfolding of the crisis from the quarterly scale of the macroeconomy to the minute scale of the microstructure.

In the crypto market, the evolutionary trajectory of the funding rate exhibits a close mapping to the leverage cycle. Figure 10-15 decomposes this mapping into four phases: leverage accumulation, criticality, deleveraging, and recovery.

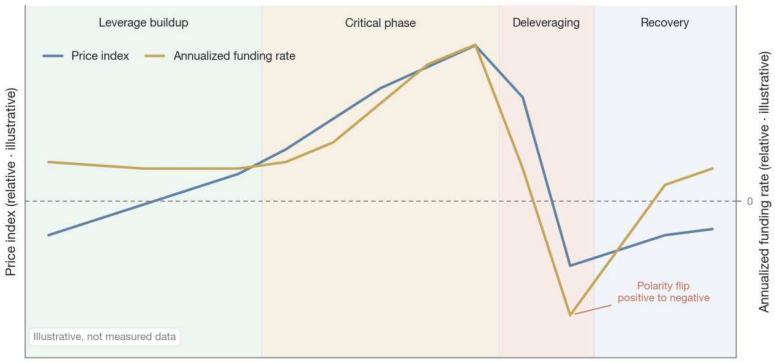

Figure 10-15. The mapping between the crypto-market leverage cycle and the evolution of the funding rate (a conceptual illustration, not empirical data; the horizontal axis shows qualitative cycle phases and the vertical axis shows relative levels, not measured scales)

The leverage accumulation phase (hedge finance) marks the start of the cycle: the market rises steadily, the funding rate stays at a mild positive value slightly above 0.01%,

arbitrageurs participate actively, and the market appears to be in a stable equilibrium. As the market advances, it enters the criticality or euphoria phase (speculative and Ponzi finance). Prices accelerate upward, speculators use paper profits to add positions and become desensitized to the rate cost. The funding rate soars and stays elevated, arbitrageurs' capital is exhausted, and negative feedback flips into positive feedback. At this point, an extreme funding rate is a clear signal that market leverage is over-concentrated and the system is highly fragile. When this fragility peaks, it triggers the deleveraging phase (the Minsky moment). A small external shock can set off a liquidation cascade, causing a price collapse. The funding rate flips polarity, from positive to negative, deeply reflecting the market's panic and liquidity drought. After violent turmoil, the market finally enters the recovery phase. Leverage is thoroughly washed out, the market enters a low-volatility phase, and the funding rate slowly returns toward zero or its default benchmark, quietly awaiting the gestation of the next cycle.

A persistently polarized funding rate is therefore not only a cost indicator but also a state variable measuring the market's systemic risk and leverage fragility. In practice, quantitative traders and risk managers can incorporate the duration and magnitude of rate polarization into early-warning models: when the funding rate stays above its historical 90th percentile for more than 48 hours, the market is in a high-probability window for a deleveraging event. Section 10.8 tests this hypothesis systematically and empirically.

10.5.5 The reconfiguration of participant behavior

When the market enters an extreme rate environment, the original three-layer game ecosystem breaks down, and the behavioral patterns and risk-return profiles of each participant are reconfigured. Figure 10-16 compares the changes in profit impact and risk exposure of five participant types under an extreme rate environment, revealing the transition from an arbitrageur-dominated orderly equilibrium to a liquidator-dominated disorderly state.

Figure 10-16. The reconfiguration of profit impact and risk exposure for each type of participant under an extreme funding rate environment (an illustrative relative assessment, not empirical data; the relative impact is assigned by the author)

Speculators and retail traders come under pressure first in rate polarization, becoming the net payers of the high rate, facing the largest profit drawdown and extremely high liquidation-risk exposure; their irrational persistence is precisely the driver that sustains the extreme rate. At the same time, the position of rate arbitrageurs also changes subtly. Although they can in theory earn excess rate income, they are constrained by the three boundaries of capital, execution, and counterparty, so their actual participation declines sharply, and they instead must bear extremely high exchange credit risk and wick risk. In this environment, liquidators replace arbitrageurs as the dominant market force. They earn substantial liquidation-penalty income by taking over and liquidating bankrupt positions, at relatively low risk. Market makers' behavior further aggravates the turmoil: amid violent fluctuations, they typically widen the bid-ask spread or pull orders outright to protect their inventory, which further worsens liquidity and intensifies the extremes in price and rate. By contrast, informed traders act more strategically. They use rate polarization as a contrarian indicator, positioning in the opposite direction ahead of a violent liquidation cascade, or providing liquidity to buy the dip after a cascade occurs.

In sum, the flip of the funding rate from negative to positive feedback marks a state transition of the market microstructure from orderly arbitrage to disorderly deleveraging. Understanding this polarization process directly informs the design of resilient crypto-asset trading strategies and risk-management frameworks.

10.6 The spectrum of strategic behavior

The funding rate mechanism was originally designed to anchor perpetual futures to spot prices, but in actual operation this mechanism inevitably breeds a complex game around its rules. Market participants are no longer merely price-takers but players of the mechanism. As the derivatives market's microstructure has matured, trading strategies around the funding rate have grown from simple cash-and-carry arbitrage into a full spectrum of more complex behaviors. This section systematically reviews this strategy spectrum and, through data and empirical cases, analyzes the impact of different strategies on market equilibrium and the internal logic of their evolution toward systemic manipulation.

10.6.1 A three-tier classification

By their contribution to market pricing efficiency and their manner of exploiting trading rules, funding-rate-related trading strategies can be divided into three tiers, forming a continuous spectrum from compliant arbitrage to systemic manipulation. Figure 10-17 arranges these three tiers along the two dimensions of compliance and market impact.

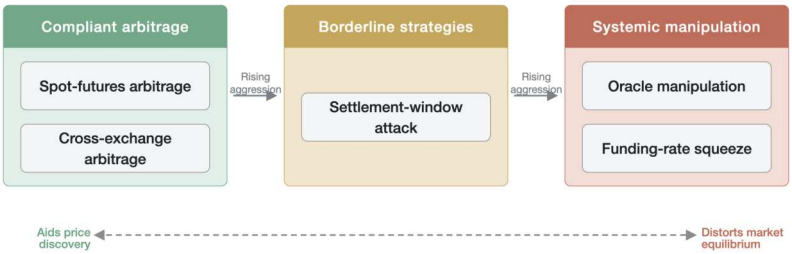

Figure 10-17. The spectrum of funding rate strategic behavior

The first tier is compliant arbitrage, mainly comprising traditional cash-and-carry arbitrage and cross-exchange rate arbitrage (the specific operating mechanisms of both are described in Section 10.4.2). These strategies earn rate income while bearing very low market risk, supply important liquidity, and perform the core function of eliminating price deviations and promoting price discovery, all of which supports the healthy functioning of the market.

The second tier comprises edge strategies. These strategies begin to operate in the gray area of the rules, their main feature being to profit by exploiting microstructural flaws in the mechanism design. A typical edge strategy is the "settlement window attack." Under a fixed-time settlement mechanism (such as traditional 8-hour settlement), a trader closes positions a few seconds before settlement to avoid the rate payment and re-establishes them immediately afterward. Although this behavior does not violate the trading rules, it causes severe liquidity fluctuations during the settlement window and reduces the effectiveness of the funding rate's anchoring mechanism.

The third tier is systemic manipulation. When edge strategies combine with a specific market structure (such as low liquidity and high concentration), they can evolve into systemic manipulation. Systemic manipulation no longer passively exploits rate differences but actively controls the spot or contract price to artificially create an extreme funding rate environment, forcing counterparties to be liquidated because they cannot bear the enormous funding cost or run out of margin. Typical systemic manipulation includes oracle manipulation and rate squeezes. In these strategies, the funding rate has been transformed from a tool for maintaining price anchoring into a tool for attacking counterparties. This chapter treats rate squeezes as game-theoretic cases for descriptive analysis, but such behavior may legally constitute market manipulation. In traditional securities markets, using an information advantage to control supply and engineer a forced-liquidation cascade in the derivatives market is a criminal offense in most jurisdictions. The U.S. Department of Justice filed criminal charges against Avraham Eisenberg in January 2023 (commodities fraud, commodities manipulation, and wire fraud), with the CFTC and SEC filing parallel civil enforcement actions at the same time; in April 2024 a jury found him guilty on three counts [32] (the criminal conviction was vacated in May 2025 by a federal judge on grounds including venue, and prosecutors have appealed). This shows that such behavior faces substantial enforcement risk in the digital-asset market, even though its ultimate legal characterization remains uncertain. In addition, an exchange's changing the settlement frequency dur-

ing the life of a contract (such as the shift from 8 hours to 1 hour in the ALPACA event) constitutes, under contract-law frameworks, a unilateral modification of a core contractual term. Although an exchange's terms of service usually reserve such modification rights, their legal validity and their legitimacy with respect to user interests remain contested across jurisdictions.

10.6.2 Equilibrium characteristics under normal markets

In a normal market where no systemic manipulation occurs, the funding rate exhibits specific statistical distribution characteristics. These characteristics reflect the equilibrium state of market participants within a compliant-arbitrage framework. Through a statistical analysis of 2,190 8-hour settlement rate data points for Binance's BTCUSDT perpetual futures from January 2024 to December 2025 ($365 \times 3 \times 2 = 2{,}190$, excluding the data points generated at higher frequencies during the 2025 dynamic-settlement-frequency period), we can clearly observe this equilibrium characteristic.

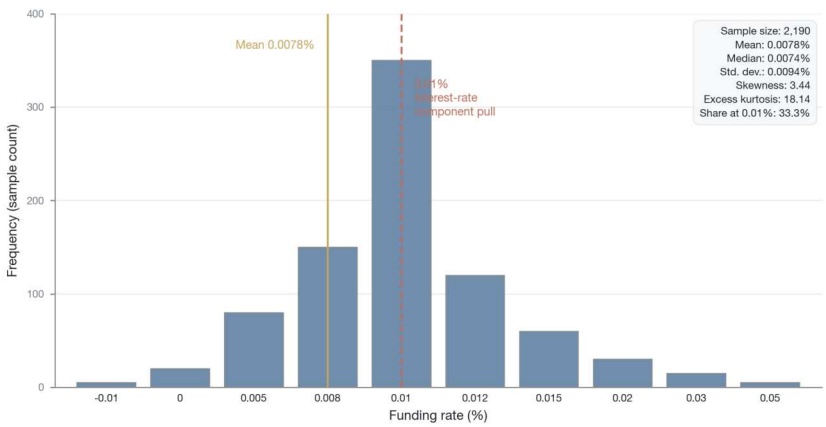

Figure 10-18. The distribution characteristics of BTCUSDT perpetual futures funding rates (computed by the author from the Binance BTCUSDT 2024–2025 funding rate history; descriptive statistics; the histogram is drawn in equal-width bins with stylized bar heights, and the excess kurtosis is highly sensitive to extreme observations)

As the figure above shows, the funding rate distribution under normal conditions has a pronounced leptokurtic (sharp-peak, fat-tail) character. The data's excess kurtosis reaches 18.14, far above the normal-distribution baseline of 0 (corresponding to a raw kurtosis of 21.14). This means the funding rate is highly concentrated at a specific level most of the time but occasionally exhibits extreme deviations. Note that the funding rate time series has a significant autocorrelation structure (volatility clustering), and the excess kurtosis of 18.14 may be partly attributable to this time dependence rather than to true fat tails under an i.i.d. assumption. After removing the autocorrelation structure (for example, via GARCH filtering), the excess kurtosis of the residuals may decline somewhat but still deviate significantly from normality.

Moreover, the distribution of the funding rate is markedly right-skewed (skewness of 3.44), with a mean of 0.0078%, slightly above zero. This structural positive deviation

reflects the long-standing long premium in the cryptocurrency market. Because market participants generally tend to use leverage to go long, the contract price is often above the spot price, and longs must pay shorts the funding rate.

The data show one more prominent feature: in fully 33.3% of all samples, the funding rate stays exactly at 0.01%. This phenomenon is not the result of natural market trading but a direct expression of the "interest rate component" in the mechanism design. In Binance's older formula, the base rate was fixed at 0.03% per day (i.e., 0.01% every 8 hours), and when the market premium was within the clamp band, the funding rate was dominated by this fixed rate. This "gravitational effect" shows that under normal conditions, the mechanism rules often determine the rate more than actual market supply and demand do.

10.6.3 The ALPACA funding rate squeeze case

When fragility appears in the market microstructure, the normal equilibrium is broken and the funding rate can become a tool for systemic manipulation. The ALPACA rate squeeze that occurred on Binance in April–May 2025 is a canonical case of this phenomenon. The event exhibited the contract paradox of "a negative catalyst triggering an extreme positive price reaction."

On April 24, 2025, Binance announced that it would delist the ALPACA spot trading pair on May 2 and settle the perpetual futures on April 30. In traditional market logic, a delisting announcement is a strong bearish signal. This news quickly formed a consensus expectation among retail traders that "the price will inevitably go to zero," causing large amounts of short capital to pour into ALPACA perpetual futures and forming an extremely crowded short camp.

The manipulator, however, recognized this structural weakness. At the time, ALPACA's circulating market capitalization had shrunk to about $5 million, and the token was highly concentrated. The manipulator used very little capital to buy continuously in the spot market, driving up the spot price, while establishing long positions in the contract market. Because of the large presence of shorts, the contract price was severely depressed, causing the funding rate to take an extreme negative value (shorts paying longs).

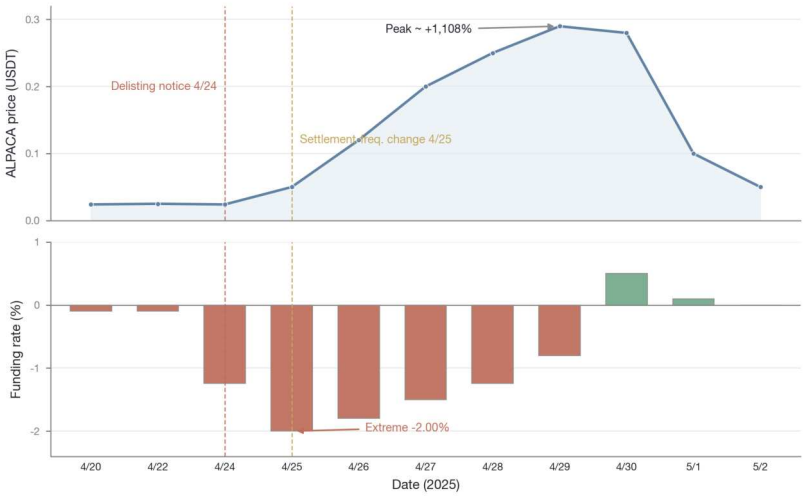

Figure 10-19. Price and funding rate movements during the ALPACA funding rate squeeze (illustrative movements, event reconstruction); the price range of \$0.024 to \$0.29 is a conservative figure, the rate cap moved from ±2% to ±4%, and the total liquidations of about \$50 million (of which about \$43 million were shorts) have been verified value by value [27]

As the figure above shows, after the delisting announcement, the ALPACA price did not crash but instead surged violently, with a peak gain of more than 1,100%. At the same time, the funding rate hit its floor deeply. To respond to the extreme market conditions, Binance activated the dynamic settlement-frequency mechanism on April 25, gradually shortening ALPACA's settlement frequency from every 8 hours to every 1 hour and adjusting the rate cap to ±2% (and subsequently widening it to ±4%).

This mechanism adjustment was intended to raise the cost of manipulation, but objectively it sharply accelerated the depletion of short margin. Under 1-hour settlement and a ±2% rate cap, a short position had to pay as much as 2% in funding every hour, amounting to a daily cost as high as 48% (this calculation applies to the old algorithm before the September 2025 normalization update. The ALPACA event occurred in April–May 2025, when Binance had not yet introduced the frequency normalization factor; note also that the rate is calculated on the notional position value, and because the ALPACA price rose more than 1,100% during this period, the absolute amount of each later period's rate was far larger than that of the early periods, a nonlinear amplification effect). At this rate level, the funding rate is no longer a marginal trading cost but a cash-flow burden the holder cannot bear. Facing enormous funding costs and a continuously rising price, shorts were forced to close (buy), and this chain of forced short liquidations pushed the price higher still, ultimately producing total liquidations of about \$50 million (of which about \$43 million were shorts). In this case, the actual effect of the funding rate mechanism ran counter to its corrective intent, becoming a tool for the manipulator to amplify counterparty losses.

From the ALPACA case, we can distill a more general model of rate-manipulation feasibility. The manipulator's expected profit can be expressed as:

$$\Pi = V_{\text{squeeze}} - C_{\text{spot}} - C_{\text{funding}}$$

where V_{squeeze} is the gain from squeezing the counterparty (including the price-impact profit from the counterparty's forced closing and the rate income), C_{spot} is the capital cost of establishing and maintaining control in the spot market, and C_{funding} is the funding-rate outlay the manipulator's own side bears over the manipulation period. This simplified model omits nonlinear execution costs: on an extremely thin order book, the manipulator's position-building self-inflates the price, and the closing slippage of the squeezed shorts amplifies actual losses; a more complete model should add a market-impact function (such as the Almgren-Chriss framework) to capture these nonlinear frictions. Even so, the feasibility of manipulation still depends on three key parameters: the circulating market capitalization M (the lower M, the smaller C_{spot}), the short concentration ρ (the higher ρ, the larger V_{squeeze}, because crowded shorts are more easily liquidated in a chain), and the settlement frequency f (under the un-normalized old algorithm, the higher f, the faster the counterparty's cumulative rate burden $C_{\text{funding}}^{\text{opponent}}$ grows). ALPACA happened to satisfy all three conditions simultaneously—low M (circulating market capitalization of about \$5 million), high ρ (delisting expectations made shorts extremely crowded), and high f (Binance raised the settlement frequency from 8 hours to 1 hour)—making the expected profit of manipulation far exceed its cost. This framework indicates that in assessing a token's manipulation risk, regulators and exchanges should systematically monitor the combined state of these three parameters.

The ALPACA event and similar high-frequency-settlement squeezes exposed a systemic vulnerability in early funding rate mechanisms under extreme conditions. In particular, when the settlement frequency is dynamically raised, if the calculation of the per-settlement rate remains unchanged, the daily cumulative rate cost is amplified many times over, giving manipulators an opening.

To patch this vulnerability, Binance made a major update to the funding rate formula on September 18, 2025. The core of this update was the introduction of a "frequency normalization factor."

In the old algorithm before the update, the per-settlement funding rate formula was:

$$F = \bar{P} + \text{clamp}(I - \bar{P},\ -0.05\%,\ +0.05\%)$$

where $\bar{P}$ is the average premium index over the settlement period. Under the old algorithm, when the settlement frequency was shortened from 8 hours to 1 hour, although each settlement covered a shorter time, the part of the formula determined by the premium index did not scale down proportionally. This means that if the market has a persistent extreme premium, the per-settlement rate under 1-hour settlement can be of the same order of magnitude as the per-settlement rate under 8-hour settlement, amplifying the daily cumulative rate eightfold.

The updated new algorithm introduces the frequency normalization factor, where N is the number of hours in the settlement period:

$$F = \frac{N}{8} \cdot \left[\bar{P} + \text{clamp}(I - \bar{P},\ -0.05\%,\ +0.05\%)\right]$$

The logic of this formula is to first compute a nominal rate using the standard 8-hour formula, then multiply by $N/8$ to scale. Note that the clamp bounds $(-0.05\%, +0.05\%)$

do not scale with the settlement frequency in the formula; the scaling applies only to the overall result. For a concrete numerical example: assume the average premium index $\bar{P} = 0.5\%$ and the interest rate component $I = 0.01\%$. When $N = 8$ (the old algorithm), $F = 1 \times [0.5\% + (-0.05\%)] = 0.45\%$, and the daily cumulative rate is $0.45\% \times 3 = 1.35\%$; when $N = 1$ (the new algorithm with 1-hour settlement), $F = \frac{1}{8} \times 0.45\% = 0.05625\%$, and the daily cumulative rate is $0.05625\% \times 24 = 1.35\%$—the two daily cumulative rates are exactly identical.

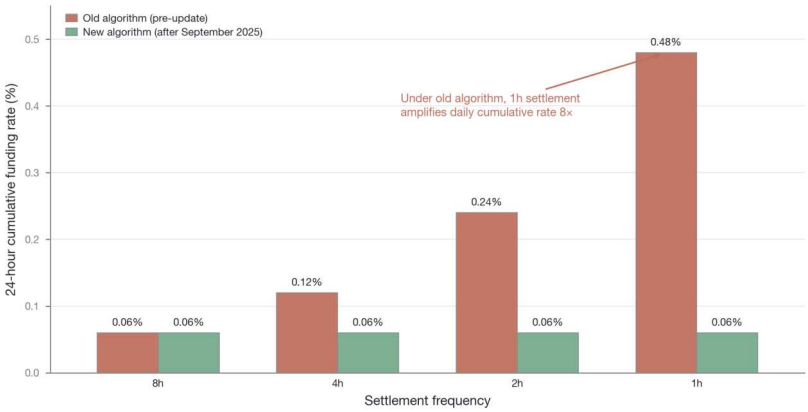

Figure 10-20. A comparison of daily cumulative rates before and after Binance's funding rate algorithm update (a formula-derived illustration with a real mechanism; the example values are constructed and are not the 0.45%/1.35% worked example in the main text [10])

As Figure 10-20 shows, by introducing the frequency normalization factor, the new algorithm ensures that at the same market premium level, regardless of how the settlement frequency changes (8 hours, 4 hours, 2 hours, or 1 hour), the theoretical upper bound of the cumulative funding rate over 24 hours remains consistent. This mechanism evolution effectively seals off the attack path by which manipulators used high-frequency settlement to amplify counterparty costs, and it is a concrete improvement of the funding rate mechanism toward manipulation resistance. Binance also shortened the calculation baseline of the mark price from 1 minute to 30 seconds, improving the system's responsiveness to abnormal price fluctuations and further compressing the space for manipulation.

10.7 The settlement frequency game

In the early design of perpetual futures, the settlement frequency of the funding rate was usually static and fixed (such as every 8 hours). This design had advantages in reducing the system's computational load and providing predictability. As market volatility increased and strategies grew more complex, however, static settlement frequency gradually revealed its fragility under extreme market conditions. Beginning in 2025, major exchanges successively introduced dynamic settlement-frequency mechanisms, a shift that is less a technical upgrade than a change in mechanism-design philosophy, from passive reaction to active management.

10.7.1 From passive reaction to active management

The traditional 8-hour static settlement mechanism is essentially a "passive reaction" system. It assumes that the market has enough time (8 hours) to digest information and restore equilibrium, with the funding rate serving merely as a mild corrective tool. In the crypto market, however, asset prices can fluctuate violently within minutes, and an 8-hour settlement period means the system is in a "blind spot" most of the time, providing ample room for edge strategies such as the settlement window attack.

The introduction of the dynamic settlement-frequency mechanism marks the beginning of exchanges adopting an "active management" posture. Take the dynamic mechanism that Binance fully implemented in May 2025: the system automatically switches the settlement frequency among 8 hours, 4 hours, and even 1 hour according to the real-time state of the market premium. Binance's dynamic settlement-frequency mechanism is not fully algorithmic, however: the decision to switch frequency involves a manual or semi-automated approval step, and the trigger condition depends not only on the rate itself but also on a multidimensional assessment of the absolute value of the premium index, its duration, and the overall market risk situation. The mechanism's transition "from passive to active" therefore spans two levels—algorithmic automation and human risk-control judgment—and the latter has inherent limitations in transparency and predictability.

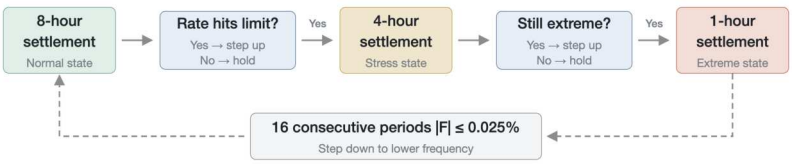

Figure 10-21. The state-transition logic of the dynamic settlement frequency mechanism (a mechanism illustration; the recovery threshold of 16 consecutive periods with $|\text{rate}| \leq 0.025\%$ is the author's illustrative rendering of the mechanism's logic, not a published specification)

As Figure 10-21 shows, the core logic of the mechanism is that when the funding rate repeatedly hits the set upper and lower bounds, the system automatically raises the settlement frequency (for example, from 8 hours to 4 hours, then to 1 hour). Only when the market returns to calm (for example, when the absolute value of the funding rate is less than or equal to 0.025% for 16 consecutive periods) does the system gradually restore a lower settlement frequency. This design turns the settlement frequency itself into an endogenous game variable, enabling the mechanism to adaptively adjust the strength of correction according to market stress.

10.7.2 The game-theoretic implications of different settlement frequencies

Different settlement frequencies have starkly different game-theoretic implications for participant behavior and market microstructure. Table 10-7 compares in detail the

market characteristics under three main settlement-frequency modes:

Dimension	8-hour static settlement	1-hour high-frequency settlement	Continuous settlement
Arbitrageur behavior	Concentrated around settlement (settlement window attack), causing periodic liquidity fluctuations	Trading is distributed more evenly, arbitrage opportunities are fleeting, and high automated-trading capability is required	Arbitrage behavior is fully smoothed, eliminating the traditional settlement window attack, but the EMA reference window it relies on (such as dYdX v4's 8-hour EMA) itself creates a new microstructural manipulation dimension, as an instantaneous price shock can affect the rate throughout the entire EMA window
Funding cost accumulation	Step-wise jumps; each payment is large in amount, but there is ample time to close and avoid it	Rapid accumulation; continuous cash-flow pressure; high holding cost	Real-time interest accrual; continuous deduction; extremely high margin requirements
Suppression of one-sided markets	Weaker; within 8 hours the price may already have deviated irreversibly	Stronger; the high holding cost forces the disadvantaged side to surrender quickly	Extremely strong; a price deviation is immediately converted into a cash-flow penalty
System-performance requirements	Low; suitable for large-scale concurrent computation	Higher; requires more frequent snapshots and liquidations	Extremely high; usually implemented only on-chain in perpetual futures protocols or specific architectures

Table 10-7. Comparison of the game-theoretic implications of three settlement-frequency modes (Data source: compiled by the author)

Under the old algorithm system, because of the lack of frequency normalization, 1-hour settlement not only increased the frequency of payments but also amplified the cumulative funding cost many times over (with a premium index of 0.5%, under the old algorithm 1-hour settlement amplified the daily rate about eightfold; the mechanism and worked example are given in Section 10.6.3). Even after the introduction of the normalization factor, high-frequency settlement still significantly changes the game equilibrium between longs and shorts by increasing friction costs and reducing decision time. The compression of decision time forces trend traders to set tighter stop-losses, because the faster depletion of margin means that a countertrend position that could originally be held for several days may hit the liquidation line within hours under 1-hour settlement.

10.7.3 The PIPPIN case analysis

The PIPPIN perpetual futures event of December 2025 is a canonical case of how a high-frequency-settlement mechanism reshapes the long-short game under extreme conditions. As an emerging AI-agent-themed token, PIPPIN attracted large amounts of short capital trying to "call the top" as its price climbed rapidly and repeatedly set new highs (a closing high of about $0.54 within December). Because shorts were overcrowded, the perpetual futures price fell far below the spot price, triggering Binance's dynamic settlement mechanism and adjusting the settlement frequency to once every hour.

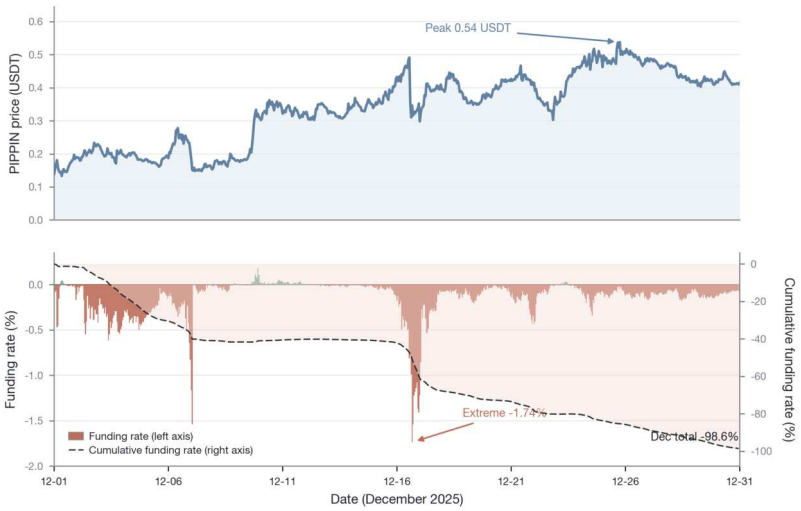

Figure 10-22. Price and funding rate dynamics for PIPPIN under extreme conditions (Data source: Binance PIPPINUSDT perpetual, 1-hour settlement, hourly observations for December 2025; as of June 30, 2026; the extreme single-period rate within the month was −1.74%, and the cumulative funding rate for the full month was about −98.6%)

As Figure 10-22 shows, during the extreme conditions of mid-December, PIPPIN's funding rate stayed for a long time in a deeply negative range. In particular, from December 16 to 17, there were dozens of hours of continuous high negative rates. According to live data, in the most extreme 24 hours (18:00 on December 16 to 17:00 on December 17), a short position's cumulative funding-rate outlay was as high as −19.77%. Over the whole of December, PIPPIN experienced 26 consecutive high-negative-rate cycles, the longest lasting 80 hours, during which the cumulative funding rate reached −27.81%.

Such high-frequency, high-magnitude funding rates dealt a devastating blow to shorts. For a trader holding a short with a notional value of about 3.53 million USDT, one day's funding-rate outlay alone could approach 700,000 USDT.

From the operational-risk dimension, the PIPPIN event also exposed two problems that are easily overlooked but critically important for live trading in a high-frequency-settlement environment. The first is **liquidation-engine pressure**: when large numbers of shorts trigger forced liquidation simultaneously, the liquidation engine must

execute large numbers of buy market orders in a very short time, placing extreme pressure on order-book depth and matching-system throughput and potentially causing shortfall losses and accelerated insurance-fund depletion. The second is **the margin-management dilemma**: under an hourly deduction mechanism, traders face multiple execution dilemmas including congested deposit channels, delays in cross-exchange fund transfers, and the automatic reduction of notional position size through partial liquidations. In PIPPIN's extreme rate environment, these operational-level frictions may be the decisive factor in a trader's final P&L, rather than merely a minor assumption in a theoretical model.

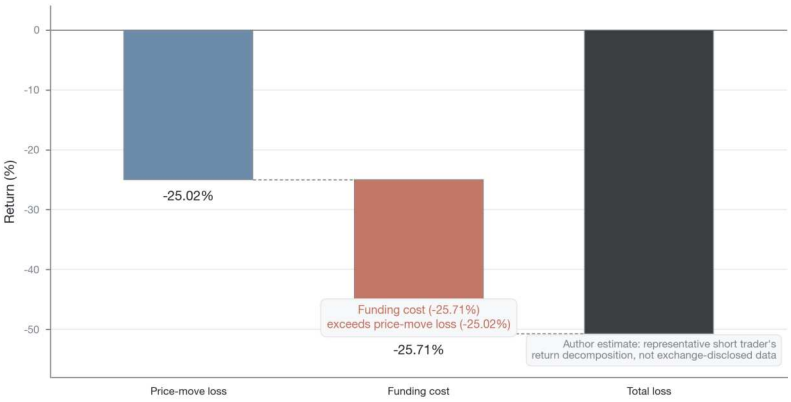

Figure 10-23. A decomposition of the return of a PIPPIN short trader (a representative/illustrative decomposition, estimated by the author, not measured from a specific account)

Through a decomposition of the return of a typical short trader (Figure 10-23), a counterintuitive pattern emerges: of the total loss of −50.73%, the loss from price movement was −25.02%, while the loss from funding-rate outlays reached −25.71%. The cost of the funding rate had exceeded the loss caused by price movement itself. This decomposition demonstrates forcefully that under a high-frequency-settlement mechanism, the funding rate is no longer a secondary friction cost but the core variable determining a trade's P&L outcome.

10.7.4 Microstructure effects of dynamic settlement

The introduction of dynamic settlement frequency has had a profound systemic impact on the microstructure of the derivatives market, and different types of participants have been forced to adjust their behavioral patterns:

Market makers and liquidity providers are directly affected: high-frequency settlement requires market makers to have stronger inventory-management capability and faster hedging speed. On on-chain derivatives DEXs, because there is no centralized risk control, market makers often must bear large unrealized profits and extremely high funding-rate outlays. This forces them to complete their pump and distribution within a very short time, or else the enormous interest outlays will rapidly erode their operating capital. The strategies of trend traders also face severe challenges. For a trend

trader holding a one-sided position, the dynamic mechanism significantly increases the time cost of holding. When holding a countertrend position, high-frequency settlement accelerates the depletion of margin, so that the risk of the traditional hold-and-endure strategy rises significantly, forcing traders to stop out earlier, which may in turn intensify one-sided price movement in the short run. The survival space of arbitrageurs is likewise reconfigured. Dynamic settlement compresses the space for the settlement window attack but also creates new arbitrage opportunities based on expectations of frequency switching. Arbitrageurs must build more complex models, forecasting not only the price's return but also the state transition of the settlement frequency.

10.7.5 The costs of high-frequency settlement

Although the dynamic high-frequency-settlement mechanism demonstrates strong corrective power when addressing extreme market deviations, it is not without cost. From a game-theoretic perspective, the widespread application of this mechanism prompts deep reflection on the boundaries of market design.

The first problem is intensified liquidity friction. Although high-frequency settlement smooths the payment of funding, the frequent cash-flow transfers themselves constitute a systemic friction. When market liquidity is insufficient, a high funding rate may cause liquidity providers to exit because they cannot bear the interest cost, which in turn widens the bid-ask spread and worsens market depth.

The risk of mechanism perversion also arises. As the ALPACA and PIPPIN cases show, when the market has a structural flaw (such as low circulating market capitalization or highly concentrated holdings), the funding rate mechanism—designed to penalize deviation—may instead be exploited by manipulators to become a tool for engineering short or long squeezes. High-frequency settlement objectively shortens the disadvantaged side's reaction time and accelerates the onset of liquidation.

In sum, the settlement frequency of the funding rate is no longer a purely technical parameter but a game lever for regulating participant behavior. Future mechanism design must find a finer balance between "timely correction" and "preventing abuse of the mechanism." For example, the frequency normalization factor introduced by Binance is a successful attempt that limits the unbounded amplification of the single-day cost while retaining the deterrent power of high-frequency settlement, marking a step toward a more mature and resilient derivatives market.

From a broader mechanism-design perspective, the linear rate function currently used by most major exchanges ($F = P + \text{clamp}(I - P, a, b)$) is not the only design choice, and its alternatives merit systematic exploration. A quadratic rate function ($F \propto P^2 \cdot \text{sgn}(P)$) can impose a mild penalty for small deviations and a sharply growing penalty for large deviations, thereby strengthening corrective force under extreme states without adding friction in normal markets. A dynamic-clamp-bounds scheme allows the width of the clamp band to adjust adaptively with market volatility or open interest: narrowing the stable band in a low-volatility environment to increase the rate's sensitivity to the premium, and widening it in a high-volatility environment to prevent the rate from over-amplifying liquidation pressure. In addition, Drift Protocol (Solana) has deployed a nonlinear rate function based on the degree of long-short imbalance in open interest

(rather than the price premium). This design directly targets the asymmetry of long-short open interest: even if a manipulator widens the premium by pumping the spot price, the rate does not move substantially as long as the ratio of long-short open interest does not change significantly, which in theory offers better resistance to price manipulation.

In theory, continuous settlement is the most thorough way to eliminate the time-arbitrage space of discrete settlement windows, and it brings the rate closer to a real-time feedback signal. Yet the EMA reference window it relies on introduces a new manipulation dimension. Continuous settlement faces severe engineering constraints, however. The current major on-chain perpetual futures protocols (Hyperliquid, dYdX v4) no longer run on Ethereum mainnet. Hyperliquid runs on its own L1 chain (subsecond block time, zero gas fees), and dYdX v4 is a standalone chain based on the Cosmos SDK. In these app-chain environments, the engineering constraints on continuous settlement come mainly from state consistency (all validators must reach consensus on the rate calculation at the same instant) and sequencer throughput, rather than from gas fees in the traditional sense; centralized exchanges have no such limitation, but continuous settlement requires real-time margin snapshots and equity calculations, placing far higher demands on back-end infrastructure than discrete settlement. Whether these alternatives can improve the anchoring performance and manipulation resistance of the rate mechanism while maintaining computational efficiency constitutes an open research frontier in derivatives mechanism design.

10.8 Funding rate as a state variable

In traditional microstructure analysis, the funding rate is usually treated as an output of the market state: a passive result of the imbalance between long and short forces, a friction cost the anchoring mechanism produces to correct a price deviation. When we move from the microstructural view of mechanism design to the macro view of market dynamics, however, the nature of the funding rate changes fundamentally: it is no longer merely a passive result but an information-rich state variable and a forward-looking predictor. This section advances the chapter's fifth core theoretical contribution: the funding rate as state variable hypothesis. The hypothesis holds that, because of the absolute dominance of perpetual futures in the crypto derivatives market, the funding rate not only records historical trading traces but also encodes participants' directional preferences about the future, the fragility of leverage accumulation, and the distribution of systemic risk. This shift in thinking is analogous to the paradigm evolution in traditional finance from viewing the interest rate as a passive output of monetary policy to viewing the yield curve as an active predictor of the economic outlook. The sections below deconstruct the information content of the funding rate along three dimensions—rate level, rate volatility, and the cross-asset rate surface—and draw out its fundamental differences from traditional sentiment indicators.

10.8.1 The information content of the rate level

The absolute level of the funding rate is the most intuitive signal in the market. At the first order, it conveys directional information: a positive rate means the market is net

long, and a negative rate means the market is net short. The deeper value of the rate level, however, lies in its second-order information—that is, it quantifies the intensity of leverage accumulation.

Applying the three-layer decomposition model of Section 10.2, after stripping away the financing cost layer (the institutional benchmark, such as BitMEX's 0.01% every 8 hours, about 10.95% annualized) and the institutional friction layer (the truncation effect of the clamp function), the absolute value of the remaining sentiment premium layer directly measures the "overheating" of market leverage. The higher the sentiment premium layer, the deeper the leverage accumulation, and the closer the "leverage cycle" discussed in Section 10.5 is to its critical point.

In a fully efficient market, the presence of arbitrageurs should quickly return the funding rate to a neutral level. When the funding rate deviates from the neutral level for an extended period, however, it reveals the depletion of arbitrage capital or the overwhelming advantage of directional speculative force. Such a persistent deviation usually means the market is entering a fragile one-sided state. When the rate stays elevated for a long time (an extreme positive rate), longs are not only bearing a large holding cost, but the accumulation of this cost continuously erodes longs' margin buffer. This state is analogous to "potential-energy accumulation" in physics: a high rate does not directly cause a price crash, but it creates an extremely fragile system state in which any small negative shock can trigger a chain of long deleveraging. Conversely, when the rate is at an extreme negative value, shorts are paying a high price to maintain their positions, and the market is likewise extremely taut, liable to a short squeeze at any moment.

A high positive rate does not equal "market consensus bullishness"; it means only that leveraged longs are overcrowded. When crowding reaches its limit and begins to collapse, relying on the rate signal to make directional decisions faces serious risk. November 2021 is a canonical case: the funding rate of BTC perpetual futures stayed above 0.1% every 8 hours around the time the price hit its $69,000 all-time high, appearing on the surface to send a strong bullish signal; in reality, this signal reflected the over-crowding of leveraged longs rather than fundamental support. Over the subsequent two months, BTC fell more than 40%, and the long positions established during the high-positive-rate period suffered the double loss of directional loss and rate outlay. The rate mainly reflects leverage sentiment rather than a market view, and this distinction is fundamental to correctly interpreting the rate signal.

This chapter validates this mechanism with empirical data. Based on measured 8-hour funding rate data for Bitcoin and Ethereum perpetual futures on Binance from 2024 to March 2026, we divide the absolute rate value into three ranges (low rate, medium rate, high rate) and observe their power to predict rate volatility over the next 7 days.

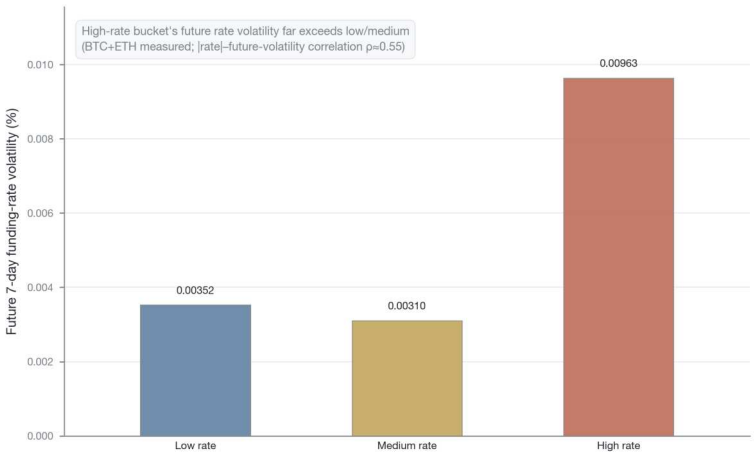

Figure 10-24. The relationship between the current absolute rate level and the funding rate volatility over the next 7 days (Data source: measured 8-hour funding rates for BTC and ETH perpetuals on Binance, 2024 to March 2026; as of June 30, 2026; the future 7-day rate volatility is averaged within tertile buckets, and the correlation between |rate| and future volatility is about 0.55)

The data show that the degree to which the current rate level is extreme is positively correlated with future volatility. When the market is in the "high rate" range (whether positive or negative), the rate volatility over the next 7 days is higher than in the "low rate" and "medium rate" ranges. This confirms that a high-rate state is essentially a high-potential-energy, high-fragility market structure: the rate level is not only a static snapshot of long-short forces but also a forward-looking indicator of future market turmoil.

10.8.2 The information content of rate volatility

If the rate level measures the degree of leverage accumulation, then rate volatility directly measures the uncertainty at the market-microstructure level and the degree of disagreement in consensus. Rate volatility is an information dimension independent of price volatility; it captures the frequency and magnitude of the swings in long-short forces within the derivatives market.

In a calm market environment, the funding rate usually fluctuates within a narrow band (dominated mainly by the benchmark rate). When the market faces a major information shock, liquidity drought, or an impeded arbitrage mechanism, however, the funding rate oscillates violently. This oscillation reflects the chaotic state of market participants repricing risk, as well as the higher risk compensation that liquidity providers (arbitrageurs) demand in the face of high volatility. Specifically:

When rate volatility is low, market consensus on direction tends to be stable. This may mean a trend has been established, or it may mean the market has fallen into complacency—the calm-before-the-storm trap. Conversely, when rate volatility is high, directional preference is switching frequently, meaning the market is full of high uncertainty. This is often a leading indicator of a market state transition (such as from

trend to range, or from range to reversal). Further, a sharp rise in rate volatility is a clear signal that the market is entering a new state, analogous to a jump in VIX in traditional markets, but it more directly reflects the sudden change in uncertainty within the leveraged market.

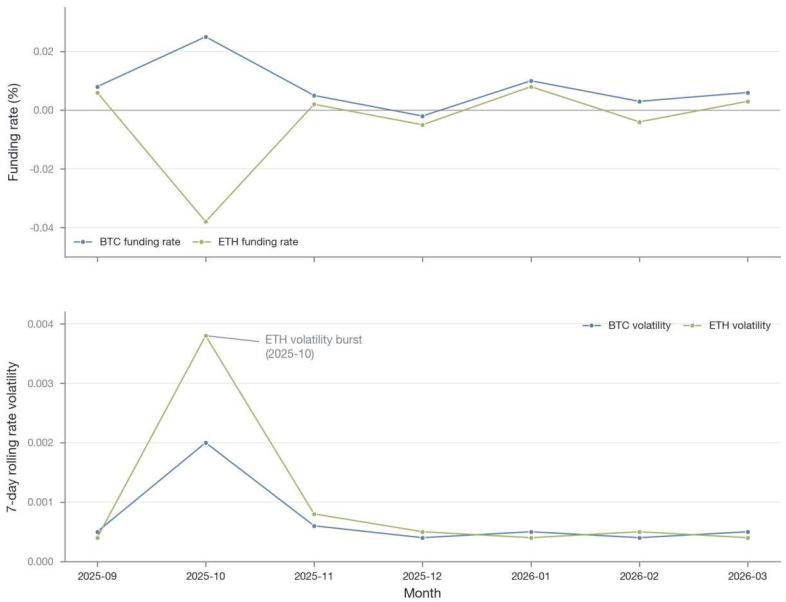

Figure 10-25. Time series of BTC and ETH funding rates and 7-day rolling rate volatility (computed by the author from the Hyperliquid API; descriptive; sample period September 2025 to March 2026, single exchange) [33]

As Figure 10-25 shows, the rate volatility of BTC and ETH is not uniformly distributed but exhibits pronounced episodic clustering. In particular market phases, rate volatility suddenly spikes, usually accompanied by violent spot-price movements or major macro events. ETH's rate volatility is significantly higher than BTC's in several periods, reflecting the structural feature of relatively shallower arbitrage depth and relatively stronger speculative force in the ETH derivatives market.

At a deeper level, a rise in rate volatility often signals a weakening of the "anchoring strength" discussed in Section 10.3. When arbitrage capital retreats because of risk aversion or capital constraints, even a small change in speculative force can cause large ripples in the rate. Rate volatility can therefore be viewed as an inverse indicator of the effectiveness of the arbitrage mechanism: the higher the volatility, the more fragile the arbitrage mechanism and the more vulnerable the market is to one-sided force.

To further quantify the impact of an extreme rate state on subsequent market behavior, we analyze the change in market activity after extreme-rate days.

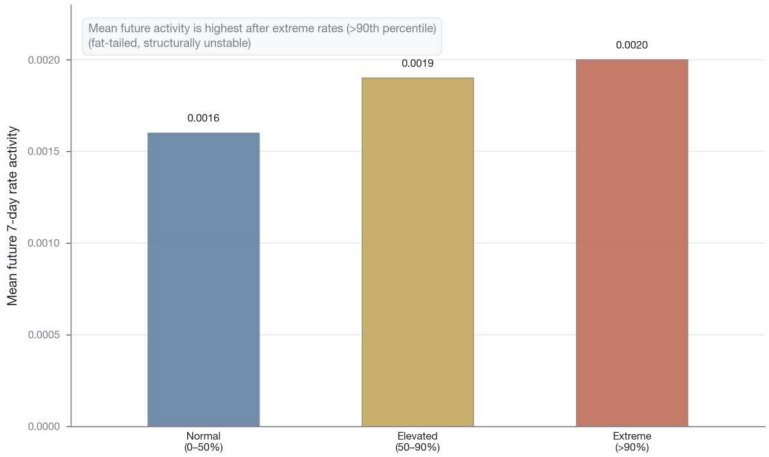

Figure 10-26. The distribution of funding rate activity over the next 7 days following an extreme rate state (computed by the author from the Hyperliquid API; descriptive; sample period September 2025 to March 2026, single exchange) [33]

Figure 10-26 clearly shows that when the market is in an "extreme rate" state (above the 90th percentile of the historical absolute-value distribution), the rate activity over the subsequent 7 days (i.e., the sum of absolute rate changes) exhibits a pronounced fat-tailed distribution, with a mean significantly higher than in the normal and elevated rate states. This means that an extreme rate not only foreshadows future high volatility but also foreshadows a structural instability. Once the rate enters the extreme range, the market rarely calms down quickly; instead, it undergoes a sustained period of turmoil until leverage is thoroughly cleared and a new equilibrium is established.

10.8.3 The cross-asset funding rate surface

Extending the view from a single asset to the entire market, the funding rate constructs a multidimensional cross-asset surface. Strictly speaking, perpetual futures have no "term structure" in the traditional sense (because there is no expiry date), but we can construct an analogous information surface along two dimensions: the cross-asset dimension and the cross-exchange dimension. This surface is one of the high-frequency indicators for characterizing the cross-asset distribution of speculative heat.

Along the cross-asset dimension, the rates of BTC, ETH, SOL, and various altcoins reflect the intensity of directional preference for different assets. Altcoin rates are usually far higher than BTC's, reflecting stronger speculative preference and lower arbitrage efficiency. Along the cross-exchange dimension, the rate differences for the same asset across platforms such as Binance, Bybit, Hyperliquid, and dYdX reflect differences in each platform's user composition and liquidity structure. Boros Finance's data show that the rate difference between Binance and Hyperliquid can reach a significant level, providing considerable return space for cross-exchange arbitrage (the specific return ranges are given in Section 10.4.2 and Figure 10-10) [22].

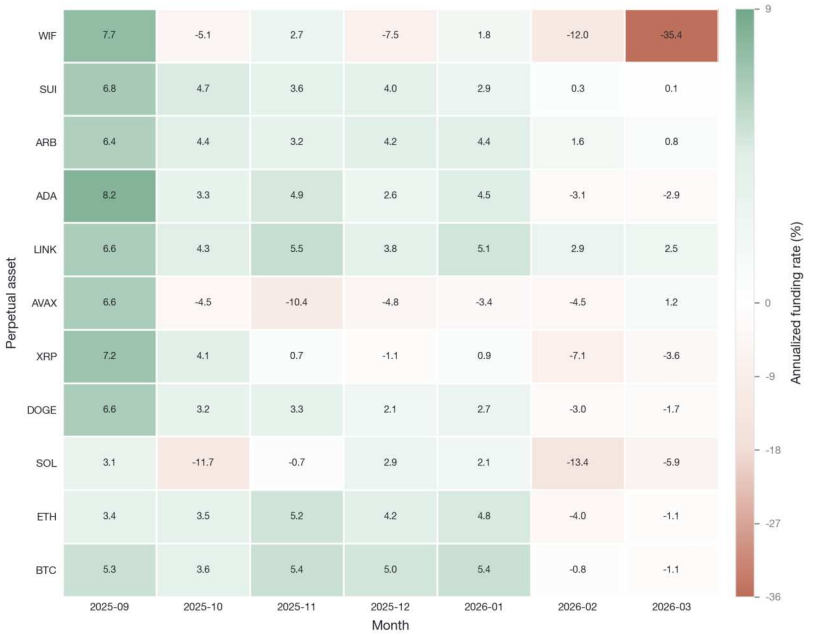

Figure 10-27. A monthly heatmap of cross-asset funding rates (all values are measured funding rates for Binance USDT perpetuals, annualized from each asset's mean per-period rate for the month; sample period September 2025 to March 2026, as of June 30, 2026)

The cross-asset heatmap in Figure 10-27 reveals several patterns. The cornerstone assets exhibit high stability: the rates of BTC and ETH are relatively stable, staying in a mild positive range in most months (about 3%–5% annualized) and turning slightly negative only in early 2026, with a volatility clearly smaller than that of altcoins, reflecting their status as market benchmarks and the ample arbitrage liquidity in their derivatives markets. Long-tail assets fluctuate more widely: relative to BTC, long-tail assets (such as WIF, SOL, and OP) exhibit extreme rate fluctuations. For example, according to measured Binance data, WIF's annualized rate plunged to about −35.4% in March 2026 and SOL's fell to about −13.4% in February 2026, indicating that these assets were undergoing intense shorting pressure or a liquidity crisis. Sector rotation is the final dimension: by watching which assets carry high rates from month to month, one can track the movement of speculative capital. In September 2025, most altcoin rates rose collectively (ADA and WIF reached about 8.2% and 7.7%, respectively), but by early 2026 most turned negative (for example, AVAX fell from about 6.6% in September to about −10.4% in November), while LINK maintained a stable positive rate throughout the observation period. When the assets of a sector collectively exhibit high positive rates, this is often a clear signal that the sector is overheated.

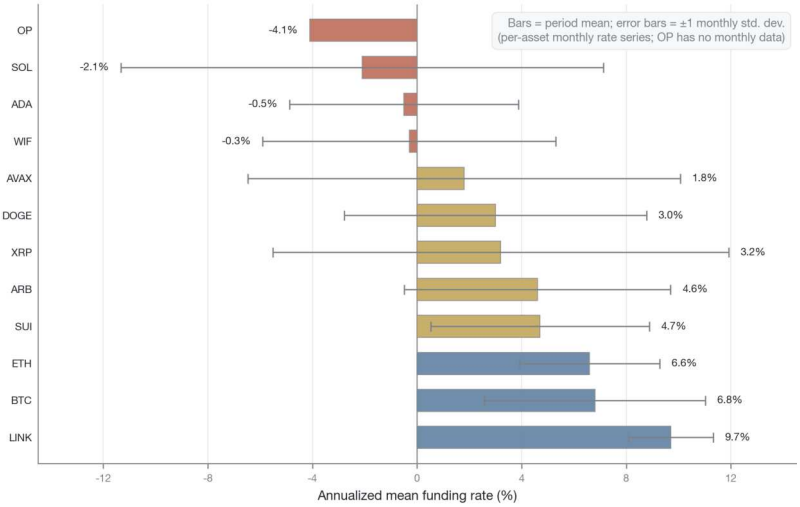

Figure 10-28. A comparison of cross-asset annualized average funding rates with standard-deviation ranges (computed by the author from the Hyperliquid API; descriptive; sample period September 2025 to March 2026, single exchange) [33]

Figure 10-28 further shows the overall rate characteristics of different assets over the observation period. LINK (9.7%) and BTC (6.8%) maintained relatively high positive rates, while OP (−4.1%), SOL (−2.1%), and ADA (−0.5%) exhibited a structural negative rate. Such a long-term structural difference often stems from microstructural friction in a particular asset's spot lending market, or from the specific role the asset plays in hedging strategies (such as cash-and-carry arbitrage or staking-mining hedges).

In addition, the rate correlation between BTC and ETH constitutes an independent macro state variable. When their rates are highly positively correlated, the market is being driven by a unified macro force (such as Federal Reserve policy expectations or ETF inflows) and systemic risk is highly concentrated; when the correlation falls or even turns negative, capital is being allocated differentially based on asset-specific narratives (such as an Ethereum upgrade or a Bitcoin halving), and the market is in a phase of structural divergence. For a trader holding a multi-asset portfolio, a sudden change in rate correlation is a key signal for adjusting the hedge ratio.

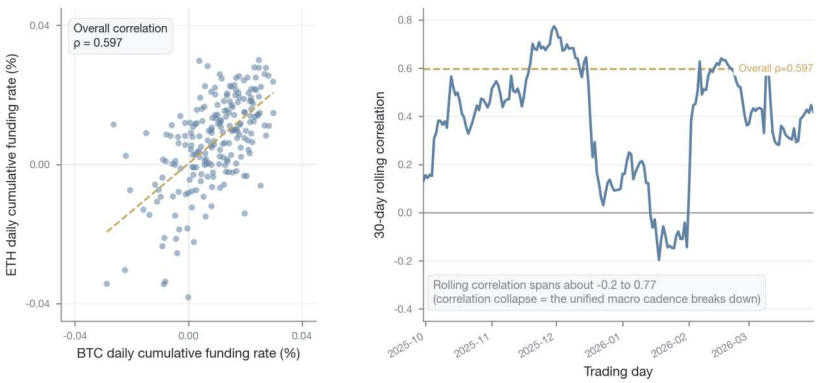

Figure 10-29. A scatter plot of daily BTC and ETH funding rates and their 30-day rolling correlation (Data source: measured daily cumulative funding rates for BTC and ETH perpetuals on Binance, September 2025 to March 2026; as of June 30, 2026)

As Figure 10-29 shows, although BTC and ETH maintained an overall positive correlation of about 0.597 over the sample period, their 30-day rolling correlation coefficient exhibited pronounced time variation (ranging from about -0.20 to 0.77). A collapse in correlation often carries far-reaching systemic implications. When the rates of BTC and ETH diverge, it usually means that the unified pace of macro capital has been broken and the market has entered a phase of structural divergence based on asset-specific narratives (such as expectations of an Ethereum upgrade or Bitcoin ETF inflows). Conversely, when the correlation rises sharply to a high level, it often means the market is in a state of systemic risk-on or risk-off, with all assets driven by the same macro force.

Two methodological qualifications are in order. First, a correlation collapse may partly reflect a macro-level flight-to-quality effect (BTC receiving safe-haven inflows on the "digital gold" narrative while ETH comes under pressure from DeFi deleveraging), rather than pure crypto-native narrative rotation. A formal attribution analysis should introduce macro control variables (such as the U.S. Dollar Index (DXY) and the global risk-appetite gauge VIX) to distinguish the relative contributions of macro transmission and crypto-native factors. Second, the BTC-ETH bivariate analysis can naturally be extended to a principal component analysis (PCA) of the full-sample (10+ assets) rate correlation matrix. If the variance explained by the first principal component surges from about 40% in normal periods to more than 80% in a crisis, it would confirm the hypothesis that "rates collapse into a single systemic factor in a crisis." This constitutes a natural extension for future research.

10.8.4 Comparison with traditional sentiment indicators

In both traditional financial markets and the crypto market, there are many indicators for measuring market sentiment and state. The funding rate, however, has advantages over survey- or text-based sentiment indicators along two dimensions—directness and economic consequence—the core reason being "the price paid in real money."

Most traditional sentiment indicators are indirect, inferential, or soft indicators based

on questionnaires and text analysis. The funding rate, by contrast, is a cash flow that market participants must actually pay to maintain their directional exposure. Table 10-8 systematically compares the funding rate with the main traditional sentiment indicators:

Indicator	Data basis	Update frequency	What it measures	Directness for the perpetual futures market
Funding rate	Long-short imbalance in perpetual futures	Every 1–8 hours	Leverage cost = a direct measure of risk	Extremely direct: generated by the market itself, with real economic consequences
VIX	Implied volatility of S&P 500 options	Continuous	Expected volatility over the next 30 days	Indirect: measures the traditional market, not directly corresponding to crypto
Put/call ratio	Options volume	Daily	Bearish vs. bullish sentiment	Indirect: the crypto options market is far smaller than the perpetual futures market
Fear and Greed Index	Multi-factor composite	Daily	A composite measure of fear/greed	Indirect: factor weights are subjective and not reproducible
Social-media sentiment	Text sentiment analysis	Real-time	The direction of public sentiment	Indirect: noisy and easily manipulated
Open interest	Derivatives position size	Continuous	Total leverage accumulation	Relatively direct: but contains no directional information

Table 10-8. A multidimensional comparison of the funding rate with traditional sentiment indicators (Data source: compiled by the author)

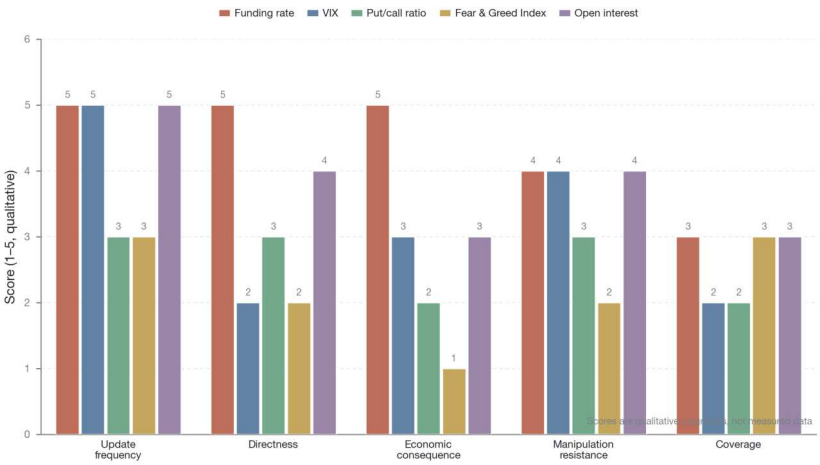

Figure 10-30. A multidimensional comparison of the funding rate with traditional sentiment indicators (subjective/qualitative 1–5 scoring, assessed by the author, not quantitative measurement; the dimensions correspond to Table 10-8 in the main text, the figure shows a selection of five representative indicators, and the cross-comparison reflects the author's judgment)

The predictive value of the rate stems from its directness: it is not a sentiment indicator derived indirectly through an intermediate model but a price signal, with real economic consequences, generated by the perpetual futures market itself every 1–8 hours. Traders actually pay or receive the rate each period, which gives the rate higher credibility than survey- or model-based indicators.

As the comparative analysis in Figure 10-30 shows, the funding rate demonstrates unique advantages along several dimensions. On directness and economic consequence, an extreme value of the Fear and Greed Index does not directly bankrupt any market participant, but an extreme funding rate does: a high rate genuinely erodes margin and forces traders to close positions, thereby directly triggering a chain price reaction. It not only measures risk; it is itself a catalyst of risk. On update frequency, most traditional indicators are daily, whereas the funding rate is updated continuously or at high frequency (such as hourly or every 8 hours), capturing instantaneous shifts in market sentiment at extremely fine granularity. On manipulation resistance, social-media sentiment or questionnaires are easily manipulated by bots or coordinated behavior, whereas to manipulate the funding rate, a manipulator must build a real, large one-sided position in the derivatives market and bear the enormous price risk and friction cost that entails. On directional clarity, unlike total open interest, which can show only the scale of leverage, the sign of the funding rate directly gives the direction of the leverage tilt.

The funding rate is not a description of market sentiment but the pricing of market sentiment. This distinction carries important methodological significance: the Fear and Greed Index or social-media sentiment analysis belongs to the category of "observation," and a researcher can obtain and interpret these signals at no cost; the funding rate belongs to the category of "pricing," and every position holder is paying for its directional view with real cash flow. This economic constraint makes the noise in the rate

signal inherently lower than that in cost-free observational indicators, because traders holding positions in the wrong direction are continuously drained by the rate until they exit.

10.8.5 Empirical evidence and limitations of predictive power

Based on the analysis above, the funding rate as a state variable exhibits, at the descriptive level, statistical associations consistent with systemic fragility, volatility bursts, and cross-asset rotation. Existing academic research also supports this judgment. Inan (2025) shows that the funding rate of perpetual futures has significant out-of-sample predictability, indicating that the rate encodes forward-looking information about the state of the Bitcoin market [34]. Presto Research (2024) finds a statistically significant but weak positive correlation between rate changes and contemporaneous price changes (R^2 of about 12.5%), but near-zero out-of-sample predictive power for the next-period price change of a single asset; that study did not specifically test extreme rates or price reversals [35].

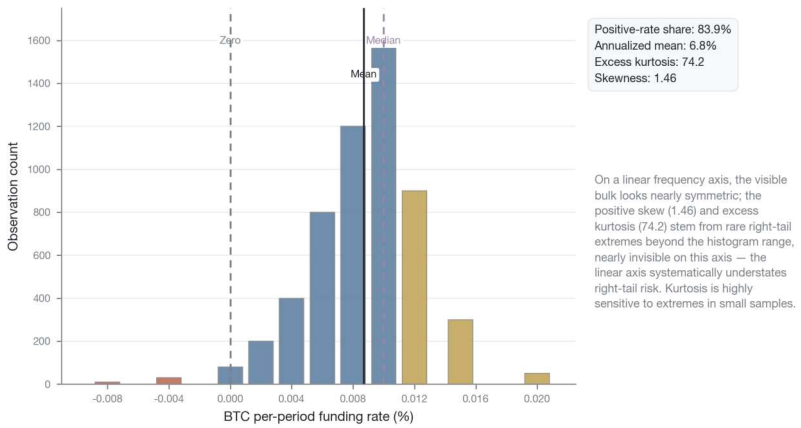

Figure 10-31. The asymmetry and long-tail characteristics of the BTC funding rate distribution (the distribution statistics—skewness, excess kurtosis, positive-rate share, annualized mean, etc.—are computed by the author from the Hyperliquid API; descriptive and sensitive to extreme values in small samples [33]; the predictability $R^2 \approx 12.5\%$ is cited from [35] and the out-of-sample predictability from [34])

Figure 10-31 shows the empirical distribution of the BTC funding rate. Its distribution exhibits extreme positive skew (skewness = 1.46) and very high kurtosis (excess kurtosis = 74.2, i.e., the deviation relative to the normal-distribution kurtosis of 3; note that this estimate is highly sensitive to extreme observations in small samples). The positive-rate share is as high as 83.9% and the annualized mean is about 6.8%, confirming the long-standing "structural long bias" of the cryptocurrency market. This extreme non-normal distribution means that traditional finance models based on the normality assumption will fail severely when handling the funding rate, and the rate's tail risk (especially the right tail) far exceeds theoretical expectations.

The empirical evidence presented in this section is descriptive rather than a formal inferential test. The conditional relationship between the rate level and future volatility shown in Figures 10-24 through 10-26, although consistent with economic intuition, has not been rigorously validated through multivariate regression controlling for other predictor variables (such as realized volatility and the rate of change of open interest) or through Granger causality tests. In addition, the Hyperliquid data [33] used in this chapter have the limitations of a short sample period (September 2025 to March 2026, about six months) and a single-exchange source; differences in user composition and liquidity characteristics across exchanges may cause heterogeneity in rate dynamics, and conclusions drawn from a single platform are not necessarily universally applicable across platforms. Elevating the descriptive findings to formal predictive regressions and out-of-sample tests is a priority direction for future research. Specifically, a standard predictive regression specification can be written as:

$$\sigma_{t+7} = c + \beta_1 |FR_t| + \beta_2 \sigma_t + \beta_3 OI_t + \varepsilon_{t+7}$$

where σ_{t+7} is the realized volatility over the next 7 days, $|FR_t|$ is the absolute value of the current rate, σ_t is the current realized volatility (controlling for the volatility-clustering effect), and OI_t is the rate of change of open interest. Because the overlapping 7-day window of σ_{t+7} introduces moving-average autocorrelation, a formal inferential test should use Newey-West heteroskedasticity- and autocorrelation-consistent standard errors, with a lag truncation parameter no less than the window length (i.e., 7 periods). If β_1 remains statistically significantly positive after controlling for σ_t and OI_t, the incremental predictive power of the rate level for future volatility can be formally confirmed. The current evidence supports this direction at the level of the conditional distribution, but rigorous statistical inference is left for subsequent research on a longer sample period and multi-exchange data.

At the methodological level, two technical issues also warrant attention. The first is **collinearity**: $|FR_t|$ and σ_t may be highly collinear, since in a high-volatility environment the rate itself tends to be more extreme, which may destabilize the estimate of β_1. Mitigations include orthogonalization or principal-component methods, or using a HAR-RV-style multi-scale benchmark model (introducing daily/weekly/monthly realized-volatility components) and testing $|FR_t|$ as an incremental predictor to gauge its marginal contribution after controlling for known volatility persistence. The second is **the characterization of the evidence**: the nature of the current evidence should be labeled more explicitly. The conditional-distribution comparisons shown in Figures 10-24 through 10-28 are descriptive analysis, and moving from descriptive findings to a formal predictive-causal claim requires completing out-of-sample tests with multivariate controls (such as rolling-window out-of-sample R^2). These two methodological improvements are the necessary steps for turning the chapter's descriptive findings into a rigorous predictive model.

Using the funding rate as a predictor, however, also has inherent limitations that must be treated with care.

On timeliness, an extreme funding rate can signal with high confidence that the system is fragile, but it cannot pinpoint the timing of a collapse. A market can persist in an irrationally high-rate state for weeks or even months (as in the first quarter of 2021

or the early-2024 bull phase), and shorting too early on the basis of a high rate may lead to severe paper losses. The rate's predictive power lies mainly in the volatility dimension: it can indicate that the probability of a volatility increase is rising, but it cannot pinpoint direction or timing. This is similar in nature to the predictive power of VIX and is an inherent limitation of the funding rate as a state variable. Structural shifts are a second confounding factor. As noted in Section 10.2, the rate contains a financing cost layer, and when the macro risk-free rate changes sharply (such as during a Federal Reserve hiking cycle) or when structural friction appears in the spot lending market, the center of the rate shifts. Without using the three-layer decomposition model to strip away these structural factors, looking only at the absolute rate level may produce false overheating or over-cooling signals. In addition, the trend of rate financialization is lowering the rate's signal-to-noise ratio as a sentiment indicator: with the rise of systematic arbitrage entities such as Ethena, extreme rates are flattened faster, and when large amounts of capital systematically short perpetual futures to earn a positive rate, their collective behavior itself becomes a force depressing the rate, forming a new reflexive loop in which more rate changes reflect only the entry and exit of arbitrage capital rather than genuine speculative sentiment. This structural impact of rate financialization and its dilution of the state variable hypothesis are developed in Section 10.8.6.

In sum, the funding rate is a powerful state variable that requires careful interpretation. It is not a simple "overbought/oversold" oscillator but a comprehensive macro indicator reflecting the market's leverage structure, liquidity condition, and arbitrage-game equilibrium. Using it correctly requires combining the three-layer decomposition model to strip away structural factors, the volatility dimension to judge uncertainty, and the cross-asset surface to locate the risk distribution. Only in this way can the rate be refined from a crude directional signal into a precise diagnostic tool for the market state.

10.8.6 Rate financialization: Ethena and the funding rate swap market

The analytical framework of the funding rate as a state variable is facing a structural challenge: the funding rate itself is evolving from a passive holding cost into a financial asset that can be independently traded, hedged, and structured. This transformation, represented by the Ethena protocol and Boros Finance's funding rate swap products, marks the arrival of the era of "rate financialization."

Ethena's USDe stablecoin is the most systemically significant instance of rate financialization. USDe's core mechanism is to hold spot ETH (or BTC) and establish an equal-size short position in the perpetual futures market, thereby systematically collecting the positive funding rate in a market-neutral manner. As of early 2026, USDe's size has reached billions of dollars, making Ethena an important structural short seller in the perpetual futures market (accounting for several percent of ETH perpetual open interest, per reports from outlets such as The Block). Ethena's scale effect has a dual impact on the rate market. On the supply side, billions of dollars in persistent short positions inject stable sell-side liquidity into a positive-rate environment, accelerating the rate's return to equilibrium in normal markets and objectively strengthening the

anchoring mechanism. On the crisis side, however, when the rate suddenly turns negative (as during the panic selling triggered by the DeepSeek event in late January 2025), Ethena's enormous short positions face reverse rate-outlay pressure. At that point, Ethena not only cannot collect income but becomes a net payer of the rate, and its forced position-reduction may further intensify market volatility.

More systematically, the risks Ethena faces can be analyzed along three dimensions. On the **economic-risk contagion path**: a persistently negative rate → USDe yield turns negative → large-scale redemptions by holders → Ethena is forced to close short positions (executing large buys in the contract market) → an upward price shock is produced → if the redemption pressure causes USDe to depeg, its role as widely used collateral in DeFi lending protocols will amplify cross-protocol contagion. On the **operational-risk** dimension: Ethena holds billions of dollars in short positions on centralized exchanges, facing exchange custody risk (the roughly $1.5 billion hack of Bybit in February 2025 is a real-world warning of this kind of risk), account-freeze risk, and execution-slippage risk when rebalancing large positions across exchanges. On the **regulatory-risk** dimension: USDe's yield mechanism may be characterized by the SEC as an unregistered investment contract (the Howey test)—users deposit funds and expect returns from an actively managed strategy run by the team, which fits the characteristics of an investment contract closely; in addition, the stablecoin classification and reserve requirements under the EU's Markets in Crypto-Assets (MiCA) framework may also constrain USDe's compliance.

Funding rate swap products such as those of Boros Finance push rate financialization from another dimension. A funding rate swap allows a trader to convert floating funding-rate exposure into a fixed yield (or vice versa), essentially creating a derivatives market with the funding rate as the underlying asset—a "derivative of a derivative." Such products enable institutional investors to express a view on rate direction or volatility purely, without holding any perpetual futures position.

The core impact of rate financialization on the state variable hypothesis is a decline in the signal-to-noise ratio. As a growing share of rate changes reflect the capital inflows and outflows of arbitrage entities such as Ethena rather than genuine shifts in speculative sentiment, the rate's signal value as a "market thermometer" is systematically diluted. Quantifying this dilution effect (for example, by decomposing rate changes into a component from systematic arbitrage capital and a component from directional speculation) is an important topic for future research. Chapter 18 will further analyze the long-term impact of Ethena's scale expansion on the market microstructure from a systemic-risk perspective.

10.9 Chapter summary

This chapter has conducted a systematic game-theoretic analysis of the core mechanism of perpetual futures—the funding rate—from micro mechanism to macro state. The funding rate is not a simple interest-payment formula but an automatic regulator arising from the interaction of multiple layers of games in the crypto derivatives market. The chapter's analysis is organized around five nested theoretical frameworks.

The three-layer decomposition model deconstructs the apparently single funding rate into a financing cost layer (a slowly varying institutional benchmark, about 10.95% annualized), a sentiment premium layer (the high-frequency directional preference of the market), and an institutional friction layer (the stable-band effect created by the clamp function; BitMEX research shows the rate is locked exactly at 0.01% for 78.19% of the time [8]). This framework shows that the rate is in fact a hybrid product of the macro interest rate, market speculative preference, and microstructural contract design, and that only by separating the three layers can the meaning of the rate signal be accurately diagnosed.

Building on this, the anchoring strength spectrum reveals the nonlinear character of the funding rate's effectiveness. Anchoring strength is a monotonically increasing function of the intensity of arbitrage activity, and arbitrage weakens systemically in extreme markets because six conditions—capital constraints, counterparty risk, liquidity drought, execution risk, liquidation risk, and cross-asset margin contagion—deteriorate simultaneously. The resulting anchoring paradox—that anchoring strength falls to its lowest precisely when the market most needs anchoring—is validated in events such as the March 12, 2020 episode when the BTC perpetual price fell hundreds of dollars below spot [5] and the October 10, 2025 episode with a visible 24-hour liquidation notional of about $19 billion [17].

The analytical framework of anchoring strength extends further into the three-layer game model, which abstracts the dynamic evolution of the funding rate into three nested games: the innermost anchoring game (the war of attrition and reflexive loop between longs and shorts over the basis), the middle convergence game (cash-and-carry arbitrageurs driving price convergence and cross-exchange arbitrageurs driving rate convergence; the annualized return ranges of cross-exchange arbitrage are given in Section 10.4.2 [22]), and the outermost strategic game (the rules attack and defense between exchanges and attackers). The balance of forces among the three layers determines the markedly different dynamics the rate exhibits in the normal, stress, and crisis market states.

When the game equilibrium is broken, the rate polarization positive feedback mechanism is set in motion. The condition for the flip from negative to positive feedback is that the directional profit exceeds the rate cost, while the disposition effect, confirmation bias, and herding jointly drive holders' refusal to close. Polarization terminates in only one of two ways: mild mean reversion or a liquidation cascade. In the PIPPIN case, shorts' rate outlay alone reached -19.77% of notional principal within 24 hours, illustrating the effect of positive feedback amplified by high-frequency settlement. Rate polarization thereby becomes a directly observable signal that the leverage cycle is approaching its critical point, which leads to the chapter's fifth framework—the funding rate as state variable hypothesis—elevating the rate from a passive output variable to an active macro state variable.

Figure 10-32 integrates the three information dimensions of the rate (level, volatility, and the cross-asset surface) with their corresponding analytical outputs into a systematic analytical framework.

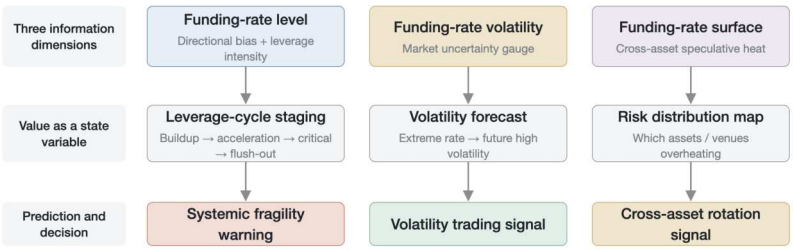

Figure 10-32. The analytical framework and application path of the funding rate as a state variable (a conceptual illustration based on the analytical framework, not empirical data)

As Figure 10-32 shows, the rate's level, volatility, and cross-asset surface together form a multidimensional analytical matrix capable of identifying the phase of the leverage cycle, predicting future volatility bursts, and mapping the risk distribution of the entire market. Compared with indirect indicators such as VIX, the funding rate can reflect the market's leverage-structure state at higher frequency and with lower latency. The spot price reflects the market's instantaneous supply and demand, while the funding rate reveals the market's leverage structure: the rate continuously prices the positions of longs and shorts through actual cash-flow transfers, and the flow of arbitrage capital delineates the effectiveness boundary of the anchoring mechanism. At the same time, the trend of rate financialization is creating a new game dimension: when the rate itself becomes a tradable asset, the game around it will grow more complex still.

The funding rate does not exist in isolation. It is closely linked to the accumulation of leverage, the triggering of the liquidation mechanism, and the depth of liquidity pools. The chapter's analysis points to a core conclusion: the boundary of the funding rate's anchoring efficacy is precisely the starting point at which leverage and liquidation risk begin to dominate the market. When the rate loses its anchoring force in a crisis state, what takes over the market is no longer the game of long-short willingness but the forced execution of the liquidation mechanism. The next chapter starts from this breaking point of rate failure and enters the extreme-risk domain of the liquidation cascade, analyzing how the forced-liquidation mechanism operates and fails when the price breaches the maintenance-margin floor. The funding rate determines the cost of leverage, while the liquidation mechanism determines the survival of leveraged positions.

The Endogenous Reflexivity of Leverage and Liquidation

On October 10, 2025, a macroeconomic report about an unexpected deadlock in U.S.–China trade negotiations—the U.S. president's announcement of a 100% tariff on Chinese imports—stirred only mild ripples in traditional financial markets. When the same news reached the crypto perpetual futures market, which trades around the clock, it unexpectedly triggered a systemic liquidation event of unprecedented scale. Within roughly 24 hours, visible market-wide forced liquidations exceeded $19 billion in notional value; measured over the full deleveraging process, the window spanned about 36 hours. The event affected roughly 1.62 million trading accounts, of which about 87% held long positions [1]. The price of Bitcoin plunged from an intraday high of about $122,500 and reached a low of roughly $104,800 on the spot/aggregate-index basis (an intraday drawdown of about 14.5%; because depth had dried up, perpetual futures printed even deeper wicks, with individual venues briefly touching about $102,000). Market-wide open interest evaporated by about $19.2 billion within the 40-minute cascade window (a peak-to-trough decline of about 25%), order-book depth on major exchanges collapsed by more than 99%, bid-ask spreads widened abruptly by several orders of magnitude, and liquidity dried up suddenly amid violent price swings (the complete microstructure data appear in Section 11.9.2, Table 11-7) [2].

This constitutes a structural paradox. In the weeks before the event, the vast majority of traders operated at leverage in the seemingly "safe" range of 5x to 10x. They set stop-losses, kept margin buffers, and believed their risk management was prudent. Yet when the market began to fall, these individual-level prudential measures not only failed to prevent a systemic crisis but intensified it: every stop-loss and liquidation that was triggered injected fresh selling pressure into the market, and together they drove a systemic collapse. This phenomenon, in which individual rationality leads to collective irrationality, reveals a structural blind spot in the microstructure of perpetual futures markets: when everyone manages risk "rationally" in the same direction, their collective behavior itself constitutes the greatest systemic risk.

The "10.10 event," along with the many similar crashes in crypto history—from the "3.12" COVID crash of March 2020 to the shock of China's mining ban in May 2021—was not a mere "black swan" or a chance accident. Such episodes are the periodic eruption of a predictable systemic risk driven by the market's own internal structure. This risk originates in an endogenous reflexivity feedback loop that forms between

leverage and automated liquidation mechanisms: under specific conditions, leverage combines with the automated execution of the liquidation engine to become a counter-intuitive risk amplifier, forming a positive-feedback mechanism that can self-reinforce and drive systemic collapse. As the systematic analysis of liquidation mechanisms in Sections 11.1 and 11.6 reveals—examining, from a mechanism-design perspective, how the liquidation engine seeks a balance between protecting system solvency and maintaining market stability—the liquidation mechanism is meant to "clear bad debt and protect the system," yet under conditions of high leverage, limited depth, and positive feedback, liquidation itself becomes the creator of systemic risk rather than its solver.

To dissect this complex dynamic process, this chapter builds a two-layer theoretical framework. At the philosophical level, it introduces George Soros's theory of reflexivity, which supplies a macro perspective for understanding the non-equilibrium nature of markets; at the mechanism level, it applies the liquidity spiral model of Brunnermeier and Pedersen, which supplies the economic tools for dissecting market micro-processes. With their extremely high leverage ceilings (up to 125x), around-the-clock trading, automated liquidation, and global access, perpetual futures have become the most extreme and purest testing ground for these two frameworks. This chapter first dissects the micro transmission chain of leverage and liquidation, clarifying the mechanical process that runs from a price move to forced liquidation; it then establishes the two-layer theoretical foundation of reflexivity. Building on this, the chapter constructs five core theoretical tools in turn: the liquidation reflexivity equation, which formalizes the liquidation cascade; the compound positive feedback that couples the funding rate with liquidation; the impossible trinity of liquidation-mechanism design; the time-compression effect unique to perpetual futures; and the information paradox of liquidation together with mechanism-induced volatility. Finally, it applies these tools jointly to a complete reflexivity dissection of the "10.10 event," testing the explanatory power of the entire analytical framework.

11.1 The transmission chain of leverage and liquidation

The core function of leverage is capital efficiency: it allows a trader to control a position far larger than their own capital. The price of this privilege, however, is a precise, stringent, code-automated risk-management system—the margin and liquidation system. This system builds a deterministic transmission chain that runs from continuous fluctuations in the market price to the forced liquidation of a trader's position. Understanding each link in this chain—how margin constrains leverage, how the mark price defines "truth," how the liquidation engine enforces its verdict, and how the margin mode determines the path of risk transmission—is a necessary precondition for understanding how systemic risk emerges from individual behavior.

11.1.1 Margin and the leverage constraint

In perpetual futures trading, leverage does not arise from nothing; it rests on the margin system. Initial margin is the minimum amount of a trader's own capital that must be committed to open a leveraged position. Its formula is straightforward:

> Initial margin = position notional value / leverage multiple

For example, a trader who wants to open a $100,000 BTC long at 10x leverage must post $10,000 as initial margin. The initial margin rate directly determines the maximum leverage a trader can use: if the initial margin rate is set at 5%, the trader can use up to 20x leverage; if it is 1%, up to 100x; and in the lowest tier at some exchanges, an initial margin rate of 0.8% implies an extreme 125x leverage.

The minimum capital level required to keep a position open is called maintenance margin, and this ratio is typically far below the initial margin. For the same $100,000 position, for instance, the maintenance margin requirement might be only 0.4% to 0.5%, or $400 to $500. The difference between initial margin and maintenance margin constitutes the trader's liquidation buffer. The size of this space directly reflects the fragility of the position: when the market price moves adversely and the account's margin balance (initial margin plus or minus unrealized profit and loss, or P&L) falls below the maintenance margin level, the liquidation process is triggered automatically. For a long position, the liquidation price can be expressed, in simplified form, as:

> Liquidation price (long) $\approx$ entry price $\times$ (1 $-$ initial margin rate + maintenance margin rate)

This formula is a first-order approximation that ignores the continuous erosion of margin by trading fees and funding payments (the latter is addressed by the dynamic formula below). It essentially represents a lower bound on the price decline required to trigger liquidation. In actual trading, because funding costs and fees accumulate, the true liquidation price is closer to the entry price than the formula's estimate.

The formula above, however, assumes that the margin balance is affected only by price changes and ignores the continuous consumption of margin by the funding rate (see Section 11.4). Once the time effect of the funding rate is included, the liquidation price is no longer a static constant but a dynamic variable that rises monotonically with holding time. For a long position, the time-dependent liquidation price can be expressed as:

$$P^{\text{liq}}(t) = P_0^{\text{liq}} + \frac{1}{Q}\int_0^t r(s)\cdot V\,ds$$

where P_0^{liq} is the static liquidation price at the moment the position is opened, $r(s)$ is the funding-rate density at time s (the rate per unit time, positive for the party paying on a long position), V is the position notional value, and Q is the position size (the number of coin-denominated contracts). Since $V = Q \cdot P$, the integrand $r(s) \cdot V$ is the cumulative funding payment per unit time (with dimensions of dollars per unit time); dividing by Q converts it into the rate at which the liquidation price rises (dollars per coin per unit time), consistent with the dimensions of the left-hand side $P^{\text{liq}}(t)$ (dollars per coin). Equivalently, this can be written as $P^{\text{liq}}(t) = P_0^{\text{liq}} + \int_0^t r(s)\,P(s)\,ds$. Contract type must be distinguished: for a linear contract (USDT-margined), $1/Q$ is simply the reciprocal of the number of coins held, and the expression can be written directly as $r(s)\,P(s)$; for an inverse contract (coin-margined), the face

value is denominated in coin terms, so a nonlinear transformation of the coin price must be layered on top of $1/Q$. The convention for $r(s)$ must also be specified: taken as the rate density per unit time, $\int r\,P\,ds$ is the cumulative price rise; if it is recorded per exchange convention as a discrete fraction per settlement period, the integral is replaced by a discrete sum over the settlement times. Moreover, this integral is a continuous approximation of discrete settlement: most exchanges settle the funding rate every 8 hours (some, such as OKX, have shortened this to every 4 hours or even every hour), and the margin deduction occurs at the settlement moment rather than continuously. This discreteness introduces a "funding-settlement-timing fragility": a single deduction at the settlement instant may push a marginally safe position into the liquidation zone, especially when settlement coincides with intensifying volatility. For this reason, some protocols (such as Hyperliquid) have moved to a continuously accruing funding rate, smoothing settlement from a discrete jump into a continuous micro-adjustment and eliminating the concentration of fragility at the settlement instant.

When the funding rate stays positive, the integral term accumulates over time and the liquidation price $P^{\text{liq}}(t)$ moves steadily toward the current market price. The core implication of this formula is that, even if the market price does not change at all, the continuous consumption by the funding rate alone can drive the liquidation price to reach the market price within a finite time, forcing the position into liquidation. This formula is demonstrated numerically in the analysis of the margin-erosion effect in Section 11.4.

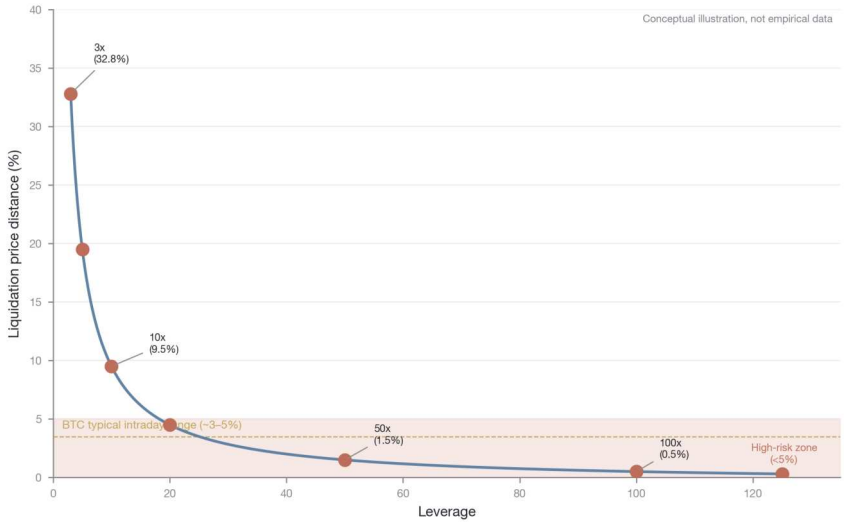

Figure 11-1. Relationship between the leverage multiple and the distance to the liquidation price (a first-order approximation based on the simplified liquidation formula, excluding funding and fees; the orange dashed band marks typical BTC intraday volatility; conceptual illustration)

The core insight is that the higher the leverage and the lower the initial margin rate, the closer the liquidation price is to the entry price, and the sensitivity of the position to price fluctuations rises nonlinearly and sharply. As shown in Figure 11-1, the orange dashed line marks the typical range of BTC intraday volatility (about 3%–5%), and at

leverage above 20x the liquidation distance already falls within this range: at 3x leverage the price must fall by about 32.8% to trigger liquidation, which is a rare and extreme event in BTC's history; at 10x leverage a decline of about 9.5% suffices; at 50x leverage a move of less than 1.5% (which does not even constitute a meaningful intraday move) is enough to force liquidation; and at 100x leverage the liquidation distance is only 0.5%, so almost any random price noise can trigger liquidation. Leverage is therefore an amplifier that transforms "normal market volatility" into "liquidation events," mapping tiny fluctuations in price space into enormous changes in margin space.

Across crypto exchanges, setting the initial margin rate is a core design decision and an ongoing competitive game. Table 11-1 compares the margin parameters for BTC perpetual futures at major exchanges as of 2025 (note: actual margin rates increase in tiers with position size; the lowest tier is shown here):

Exchange	Max leverage	Min initial margin rate	Maintenance margin rate (lowest tier)	Liquidation buffer	Type
Binance	125x	0.80%	0.40%	0.40%	CEX
OKX	125x	0.80%	0.40%	0.40%	CEX
Bybit	100x	1.00%	0.50%	0.50%	CEX
dYdX v4	20x	5.00%	3.00%	2.00%	DEX
Hyperliquid	40x	2.50%	1.25%	1.25%	DEX

Table 11-1. Comparison of margin parameters for BTC perpetual futures at major exchanges (Data source: exchanges' official documentation. CEX figures are lowest-tier/small-position parameters using dynamic tiering, with leverage falling sharply for large positions; DEX figures are BTC-market parameters. Hyperliquid lowered its ceiling from 50x to 40x on March 12, 2025, and the dYdX v4 BTC ceiling is about 20x; data collected in 2025)

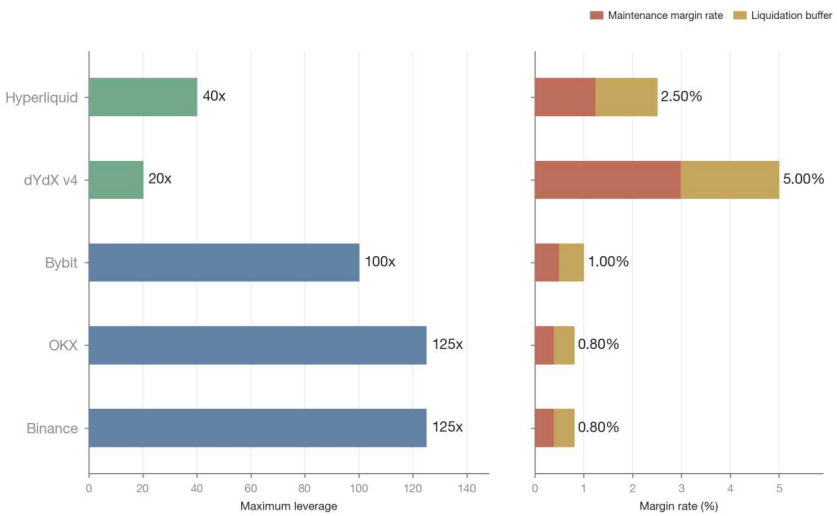

Figure 11-2. Visual comparison of margin parameters across major exchanges (Data source: exchanges' official documentation, as of 2025; CEX = blue, DEX = green; headline leverage is for the

lowest-risk tier and declines dynamically with position size; Hyperliquid lowered its ceiling from 50x to 40x on March 12, 2025, and the dYdX v4 ceiling is about 20x)

As shown in Figure 11-2, centralized exchanges (CEXs) generally offer higher leverage (100x–125x) and correspondingly very narrow liquidation buffers (only 0.4%–0.5%), whereas decentralized exchanges (DEXs) such as dYdX and Hyperliquid take a relatively conservative approach, capping BTC's maximum leverage at about 20x–40x with buffers of about 1.25%–2.0%. This difference reflects different risk appetites under different market positionings: an overly low margin requirement permits extremely high leverage and, while it can attract high-yield users and boost trading volume, markedly increases systemic fragility; an overly high margin requirement limits capital efficiency and drives users away. This game between market share and system safety often devolves into a "race to the bottom." As the risk-substitution theorem of Chapter 5 ("risk cannot be eliminated, only transferred") reveals, there is a structural trade-off between capital efficiency and system safety, and under competitive pressure safety is often the first dimension to be sacrificed (here the capital-efficiency–safety tension is a derived reparameterization of Chapter 5's service-provider impossible trinity from the perspective of leverage risk, rather than that trinity itself; see Section 11.6.5).

Most exchanges use a tiered margin system, in which the initial and maintenance margin rates rise step by step as the position grows. Binance, for example, has more than a dozen tiers for BTC perpetual futures, with position sizes ranging from $50,000 in the lowest tier to hundreds of millions of dollars in the highest, and corresponding maintenance margin rates rising from 0.40% to more than 5%. The purpose of this design is to limit the leverage available on large positions and reduce the potential impact of a single whale on the market.

The tier boundaries themselves, however, can become a counterintuitive risk trigger—the phenomenon of "cross-tier liquidation." Consider a concrete scenario: a trader holds a BTC long with a notional value of $49,000, which sits in the first tier (maintenance margin rate 0.4%), so the required maintenance margin is only $196. When a rise in the BTC price lifts the position's notional value to $51,000 and into the second tier (maintenance margin rate 0.5%), the required maintenance margin jumps to $255, an increase of 30%. If the trader's margin balance happens to be between $196 and $255, a price increase that should have produced a profit instead triggers liquidation, creating the paradox that "the higher it rises, the more dangerous it becomes." This discontinuity, caused by the jump at a tier boundary, is especially pronounced for large positions at high leverage. To mitigate it, some exchanges have begun to introduce smoothed margin curves, replacing the discrete tier steps with a continuously increasing function and thereby eliminating the jump in margin at the boundaries.

The tiered system also introduces a subtle nonlinear effect: when price fluctuations push a position's notional value across a tier boundary, the maintenance margin requirement rises in a jump, which can cause an otherwise safe position to trigger liquidation suddenly. This threshold effect is formalized in the liquidation reflexivity equation of Section 11.3.

11.1.2 The mark-price mechanism

If the liquidation system used the last traded price on a single exchange directly as its trigger condition, then in a thin market a single anomalous trade—or a malicious manipulator using a small amount of capital to "wick" the price (i.e., instantaneously create an extreme price)—could trigger the erroneous liquidation of many other positions. To guard against this risk, almost all major exchanges have introduced the mark price as the benchmark for triggering liquidation, rather than relying on their own last traded price.

The mark price is usually constructed by aggregating the real-time prices of several major spot exchanges (such as Coinbase, Kraken, and Bitstamp) and taking a volume-weighted average. Some exchanges also add a moving average of the funding rate to reflect the basis between perpetual futures and spot.

Take Binance's mark-price calculation as an example: it uses a median-of-three method, where Mark price = Median(Price_1, Price_2, Contract price), with Price_1 = Index price $\times$ (1 + latest funding rate $\times$ fraction of time to next settlement) and Price_2 = Index price + EMA(fair contract price − index price). The median function provides implicit resistance to outliers: even if one of the three components is contaminated or anomalous, the other two still anchor the mark price within a reasonable range. Different exchanges use different mark-price formulas (OKX uses a weighted-moving-average method and Bybit an exponentially weighted scheme), and this difference in calculation means that the same asset can have a slightly different mark price at the same moment on different exchanges, leading to different liquidation-trigger sensitivities. In extreme market conditions, this difference can determine whether a position is liquidated.

Behind this design lies a game-theoretic point: the cost of simultaneously manipulating multiple highly liquid, mainstream spot markets is far higher than the cost of manipulating a single derivatives market. The mark price is therefore considered a better reflection of an asset's "fair value," providing a more robust anchor for liquidation decisions.

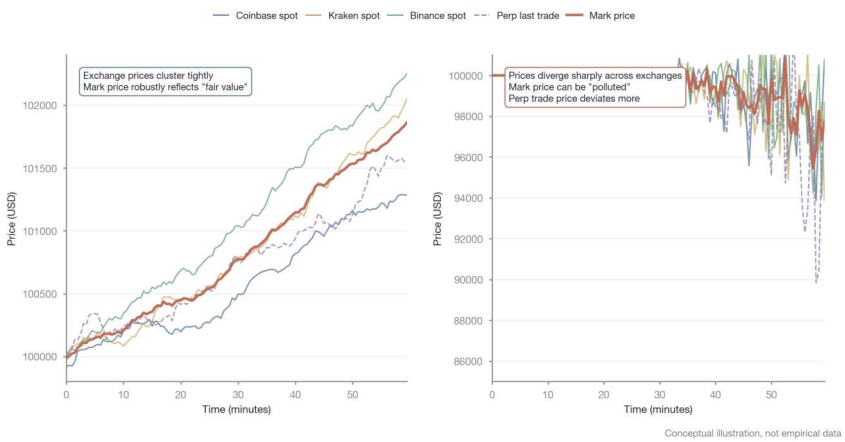

Figure 11-3. Comparison of the mark-price construction mechanism in normal and extreme states (conceptual illustration, not empirical data)

The mark price, however, is not an absolutely reliable benchmark but a derived reference price whose robustness depends on a set of assumptions that hold in normal markets but can break down in extreme conditions. As shown in Figure 11-3, the left panel shows that in a normal market the prices of the various exchanges cluster tightly and the mark price (the thick red line) robustly reflects fair value; the right panel shows that under an extreme shock, spot prices diverge markedly, the perpetual traded price (the purple dashed line) departs substantially from the mark price, and the mark price itself may be "contaminated." When these assumptions collapse in extreme conditions, the mark-price mechanism can turn from a risk buffer into a risk conduit:

On the oracle-risk front, the mark price relies on real-time price feeds from external price sources. For centralized exchanges, this usually means obtaining data via API from other exchanges; for decentralized exchanges (such as dYdX and Hyperliquid), it relies on on-chain oracles (such as Chainlink and Pyth). Either way, the price-feed system can be subject to attack, network latency, or failure. Specifically, oracle failure modes can be grouped into several categories. First, intrusion at the data-source level: an exchange's API keys are stolen, or the exchange itself reports manipulated price data, contaminating the price-feed input at its source. Second, transport-layer attacks: a man-in-the-middle attack or DNS hijacking can tamper with price data as it travels from the source exchange to the oracle node, which is especially insidious in a centralized API price-feed architecture. Third, smart-contract vulnerabilities in on-chain oracles, including reentrancy attacks, access-control flaws, or exploited upgrade mechanisms, through which an attacker can directly tamper with the price stored on-chain via a contract-level vulnerability. Fourth, economic-manipulation attacks: an attacker uses a flash loan to temporarily distort, within a single transaction, the on-chain price source on which the oracle relies (such as the spot price of a Uniswap pool); these attacks mainly target scenarios in DeFi protocols that use an instantaneous on-chain price as the oracle. Fifth, latency arbitrage: exploiting the time lag between the oracle's update frequency and actual price movements, an attacker executes trades when the oracle price has not yet updated but the market price has already moved substantially, profiting from the stale mark price. Once an erroneous mark price is adopted, catastrophic and unfair liquidations follow. As discussed in Chapter 6, maximal extractable value (MEV)—the economic gain an attacker obtains by manipulating or front-running state changes, including oracle price updates—makes this risk especially prominent in the DeFi environment.

On the data-quality front, the quality of the mark price depends on the data quality of its constituent exchanges. If one constituent exchange itself experiences a liquidity drought or a price anomaly (for example, a flash crash), its anomalous price will "contaminate" the weighted average and cause the mark price to deviate from true fair value. During the "10.10 event," when USDe traded at a severe discount on Binance, the prices of USDe-denominated pairs became sharply distorted, and the extent to which this distortion seeped into the mark-price calculation remains a focus of industry debate to this day [3].

During periods of extreme volatility, the basis between the spot market and the perpetual futures market can widen sharply. The last traded price of perpetual futures may depart substantially from the mark price because order-book depth has dried up.

At such times, although the mark price is still "correct" mathematically, there can be an enormous gap between the "fair value" it reflects and the execution price a trader can actually obtain in the perpetual futures market. This means that even when the mark price has not yet reached the liquidation line, a trader may be in de facto distress because they cannot close out at a reasonable price.

The design of the mark-price mechanism is essentially a trade-off between robustness and sensitivity. A mark price that is too robust (for example, one using a long-window moving average) may lag the true price in a rapid decline, delaying the triggering of liquidations and increasing bankruptcy risk; a mark price that is too sensitive is easily affected by short-term noise and manipulation, causing unnecessary liquidations. This trade-off has no perfect solution; it is one of the intrinsic conflicts in liquidation-mechanism design and is analyzed more systematically in the "impossible trinity" framework of Section 11.6.

11.1.3 The liquidation engine

Once the mark price confirms that an account's margin balance is below the maintenance margin requirement, the liquidation engine takes over the position. The liquidation engine is essentially an automated trading program with the highest execution priority, whose sole objective is to force-close a position on the brink of bankruptcy as quickly as possible and with as little market impact as possible, thereby preventing the system from incurring bad debt from underwater positions. The system has an absolutely deterministic character: once the conditions are met, the code executes strictly according to preset rules, regardless of market depth, the trader's wishes, or potential consequences.

Figure 11-4. The transmission chain from a price move to liquidation execution

As shown in Figure 11-4, this transmission chain presents in full the process running from the assessment of the margin balance, through mark-price verification and the choice of liquidation mode, to the liquidation order's impact on the market and, in turn, the triggering of a new batch of liquidations that forms positive feedback. The design of the liquidation engine has undergone a marked shift over time, from a pursuit of efficiency to a balance that also weighs impact, and the mainstream liquidation-execution modes today can be grouped into the following four.

Cliff-edge liquidation is the earliest and most direct mode. When the trigger condition is met, the liquidation engine dumps the entire position onto the market at once as a market order, clearing bad debt with great speed and high execution certainty but with an enormous impact on the order book: in extreme conditions where liquidity is already thin, a single large liquidation market order may "eat through" multiple price levels at once, driving the price down further and triggering more liquidations. BitMEX around 2019 was known for this mode, and the price impact it produced repeatedly sparked accusations of "liquidation hunting." In response to this destructive impact, the industry gradually evolved progressive liquidation: when liquidation is triggered, the position is not closed all at once but reduced in batches. The proportion cut each

time is calculated dynamically by the liquidation engine based on the severity of the margin shortfall and the position's tier—the larger the shortfall and the higher the tier, the larger the proportion cut in a single step. The liquidation orders are submitted as limit orders, with the target execution price set between the bankruptcy price and the mark price, rather than impacting the order book with market orders. After each partial close, the system re-assesses the remaining position: if the price recovers to a safe level, liquidation stops; if it continues to deteriorate, the cutting continues. Notably, liquidation limit orders that are not immediately filled remain on the order book as resting orders, forming a dense layer of sell orders that constitutes a resistance level to any price rebound and is gradually absorbed as sentiment deteriorates further—smoothing the liquidation impact over time while fixing it in place in price space. This approach markedly reduces the immediate impact of a single liquidation but lengthens the total liquidation window, and when the price is falling rapidly the delay can lead to larger bankruptcy losses. Binance was the first to adopt progressive liquidation comprehensively, around 2020, and OKX, Bybit, and others followed, making it the industry standard for centralized exchanges.

Another mode is the vault backstop, exemplified by Hyperliquid's HLP vault (see Chapter 9, which systematically analyzes the operating mechanism, return structure, and risk exposure of HLP as an in-protocol market-making vault). Hyperliquid's liquidation process is in fact a multi-step mechanism: when a position triggers liquidation, the liquidation engine first attempts to place the position on the order book as a limit order at a price near the bankruptcy price. Only when the order book cannot absorb the position (i.e., the position is already "underwater," with the market price worse than the bankruptcy price) do the insurance fund and then the HLP vault step in, in sequence, as successive backstops to absorb it (the full three-tier liquidation waterfall of order book $\rightarrow$ insurance fund $\rightarrow$ HLP vault is detailed in Section 9.4.3 of Chapter 9). After the JELLY manipulation event of March 2025, the protocol introduced major mechanism reforms, including a cap on the size of any single position and improved oracle-price handling logic. This tiered design channels most liquidation pressure to the public order book in normal markets and calls on the vault to absorb positions only in extreme cases, seeking a balance between minimizing market impact and preserving system solvency. In essence, however, this design creates a risk-concentration trade-off: the vault, as a single entity, absorbs liquidation pressure that should have been dispersed across the entire market, and its risk exposure rises monotonically as a one-sided market persists. Once the vault's net asset value is eroded to a critical level, it transforms from a provider of liquidity into a demander of liquidity and even becomes a new node of systemic risk (as the analysis of the JELLY manipulation event in Chapter 9 reveals, this is precisely what happens when the scale of liquidation exceeds the vault's capacity). Unlike the vault backstop, auto-deleveraging serves as the last risk buffer: when the bankruptcy losses produced by liquidation exceed the capacity of the insurance fund (the dedicated risk-reserve pool an exchange accumulates from liquidation residuals, whose capital structure, replenishment mechanism, and stress capacity are detailed in Chapter 12), the system automatically "trims" profits from the most profitable counterparty positions to cover the losses. Auto-deleveraging (ADL) ensures that the system does not incur socialized losses (in which all users share the loss) in

extreme cases, but it does so at the expense of the legitimate interests of profitable traders, provoking serious fairness disputes.

Although the design of the liquidation engine has been continually optimized, its limitations remain fully exposed in extreme conditions. The data from the "10.10 event" provide striking empirical evidence: within the 40 minutes of the cascade's eruption (20:50–21:30 UTC), the liquidation rate surged from an average of $120 million per hour over the preceding 8 hours to $10.39 billion per hour, an acceleration of 86-fold [2]. At the peak moment (21:15 UTC), $3.21 billion of positions were force-closed within a single minute, of which 93.5% were market sell orders produced by long liquidations [2].

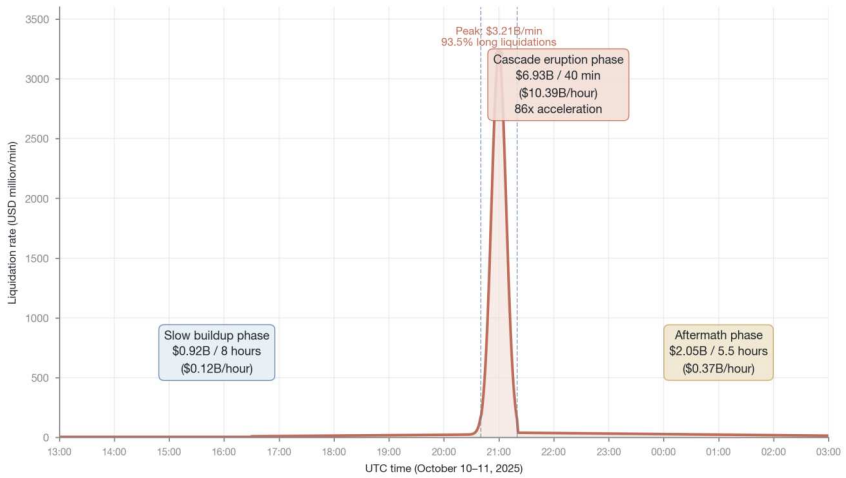

Figure 11-5. Timeline of the liquidation rate during the "10.10 event" (Data source: Amberdata [2], as of October 2025; 93.5% is on a peak-minute basis, while the 24-hour aggregate is about 87%; the roughly $9.9 billion three-phase total is Amberdata's tracked subset and is not the same basis as CoinGlass's market-wide 24-hour figure of about $19 billion—do not conflate the two)

As shown in Figure 11-5, the entire event exhibits three clearly distinguishable phases: slow accumulation, cascade eruption, and aftermath. When such a massive volume of liquidation requests floods in simultaneously, the liquidation engine itself may queue and lag because its processing capacity has reached its ceiling. This infrastructure overload means there is a discrepancy between actual execution time and theoretical trigger time, and while the price is falling rapidly, this delay often leads to larger slippage and more severe bankruptcy losses. The "3.12" event of March 2020 is a classic case of infrastructure overload amplifying risk: on March 13, BitMEX suffered a service outage of about 25 minutes (officially attributed to a DDoS attack on the platform), during which matching and liquidation nearly halted and the price subsequently rebounded, so that many positions were actually executed only at levels far below their theoretical liquidation prices before and after the outage, with bankruptcy losses far exceeding expectations [4].

11.1.4 Margin modes

The way a trader manages margin fundamentally determines the path along which risk is transmitted within the account and across the entire market. The two mainstream margin modes are isolated margin and unified margin (cross-margin). The choice between them is far from a mere tuning of technical parameters; it is an underlying institutional variable that fundamentally shapes the path of systemic-risk transmission.

Under isolated margin, the trader allocates a specific amount of margin to each position, and risk is fully isolated between positions. The maximum loss on one position is limited to the margin allocated to it and does not spill over to other funds or positions in the account. For example, if a trader allocates $5,000 of margin to a BTC long, then even if that position is fully liquidated, the funds used for ETH and SOL trading in the account are unaffected. The advantage of this mode is precise risk control and predictable losses, but its disadvantage is equally clear: low capital efficiency, because the unrealized profit of a winning position cannot be used to support other losing positions, and the trader must set aside an independent margin buffer for each position.

Under unified margin, the entire account is treated as a single liquidity pool. All available balances and the unrealized P&L of all positions serve jointly as margin, and the system decides whether to trigger liquidation based on the account's total net equity. This mode greatly improves capital efficiency: the unrealized profit of a winning position can automatically offset the margin consumption of a losing position, making long-short hedges and cross-asset strategies possible. For this reason, unified margin has been actively promoted by the major exchanges in recent years and has become the mainstream choice for professional traders.

In extreme conditions, however, unified margin exposes a fatal weakness: it creates a cross-asset, cross-position path for risk contagion.

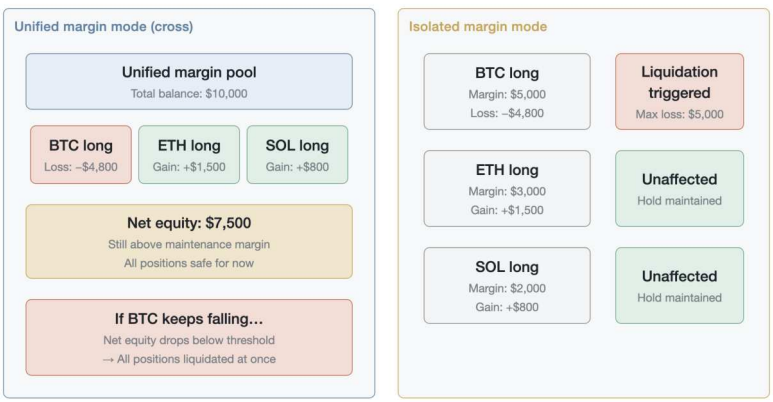

Figure 11-6. Comparison of isolated margin and unified margin under extreme conditions (conceptual illustration, not empirical data)

As shown in Figure 11-6, under the isolated mode the liquidation of the BTC position

does not affect the ETH and SOL positions, whereas under the unified mode a huge loss on BTC erodes the entire margin pool, and if net equity falls below the threshold, all positions face simultaneous liquidation. When the price of one asset in the account moves sharply and adversely, the large loss substantially reduces the net equity of the entire unified margin pool. Once total net equity falls below the total maintenance margin requirement, the system may be forced to liquidate healthy positions in the account that are themselves still profitable and entirely unrelated to the loss-making asset. This cross-asset contagion mechanism was on full display in the "10.10 event."

The most representative contagion path in the "10.10 event" came from the synthetic stablecoin USDe. Many traders used USDe as margin collateral for their unified accounts—regarded as a reasonable choice in normal markets, since it was treated as a "stablecoin-like" asset. When the collateral value of USDe plunged, however, total account net equity shrank instantly, and unified margin transmitted the discount on this single collateral asset directly into the forced liquidation of a large number of BTC and ETH longs that had nothing to do with USDe [3]. A seemingly isolated stablecoin-pricing problem thus evolved into a liquidation cascade that engulfed the entire market (the full dissection of USDe's depegging to \$0.65 on Binance during the "10.10 event"—a discount of about 35%—is given in Section 11.9.3).

Viewed from a network perspective, the unified margin pool is merely one of several contagion channels operating simultaneously. Other key contagion channels include: shared market makers withdrawing liquidity from all trading venues simultaneously once they detect adverse order flow, causing synchronized depth droughts across platforms; the cross-exchange linkage of oracle prices, which transmits a price shock on one exchange to the liquidation decisions of other exchanges via the mark-price mechanism; common collateral assets (such as USDe and USDT) being used simultaneously in the margin pools of multiple protocols, so that a discount on a single asset spreads through the collateral value chain to all protocols using that asset; and the transmission of operational risk—for example, a brief failure in one oracle's price feed for a given asset, or the temporary freeze of a cross-chain bridge, can affect all positions in a unified margin account that depend on that infrastructure. As Acemoglu, Ozdaglar, and Tahbaz-Salehi (2015) [5] argue in the theory of financial networks, network structure determines whether a shock is absorbed and buffered by the connections between nodes or amplified and propagated. When connection density exceeds a critical threshold, the network turns from a stabilizer that "disperses risk" into an amplifier that "propagates risk." In the "10.10 event," the simultaneous activation of these multiple contagion channels produced a superadditive amplification effect: the scale of liquidation and the depth of the collapse actually observed far exceeded the sum of the independent predictions for any single channel, indicating a nonlinear coupling in which the channels reinforced one another.

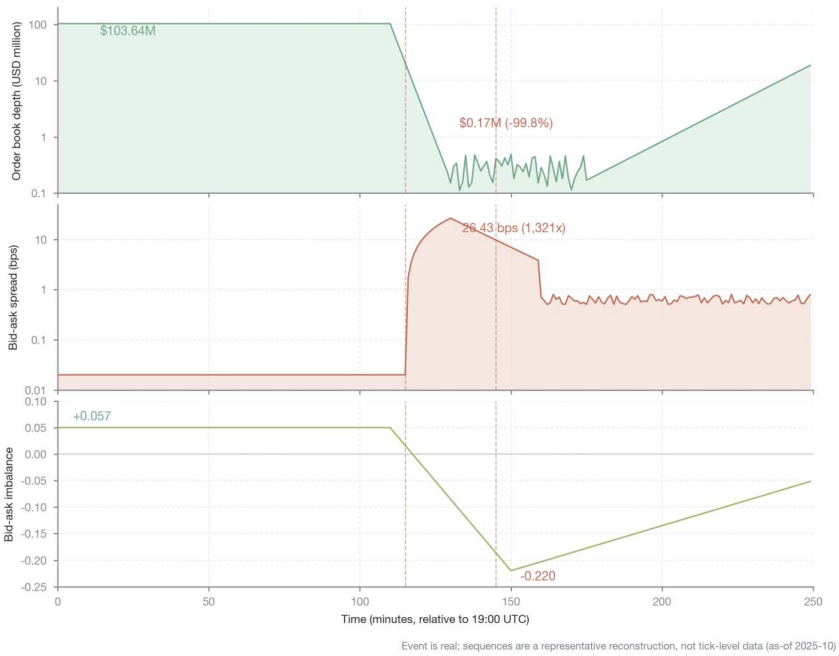

Figure 11-7. The three-dimensional collapse of liquidity during the "10.10 event" (Data source: Amberdata [2], as of October 2025; depth of about $103.6 million → $170,000 and a peak spread of 26.43 basis points are Amberdata's measured top-of-book values for BTC perpetual futures, while the three-dimensional point-by-point series is a representative reconstruction)

The essence of this procyclicality is that unified margin is a fair-weather friend: it improves capital efficiency in calm markets but turns into a dangerous liability in extreme ones. The fundamental reason is that in a true crisis the correlations among crypto assets tend to spike toward 1. As the preliminary discussion of cross-margin procyclicality in Chapter 7 (the endogenous tendency of the unified margin system to amplify risk contagion rather than provide diversification during market downturns) points out, the probability that "all positions lose money at the same time" is far higher than typical risk models assume. As shown in Figure 11-7 (the red shaded region marks the 40-minute window of the cascade's eruption), liquidity underwent a three-dimensional collapse during the "10.10 event" (see Section 11.9.2, Table 11-7 for the specific figures): order-book depth contracted by more than 99% (here depth refers to the aggregate visible limit-order depth within ±2% of the mid-price on major exchanges, with data from Amberdata, excluding iceberg orders and the dynamically refreshed liquidity of algorithmic market makers), bid-ask spreads widened by three orders of magnitude, and the buy-sell imbalance swung sharply toward overwhelming selling. This depth evaporation, spread spike, and buy-sell imbalance are the direct expression, at the order-book microstructure level, of cross-asset contagion. When all assets fall at once, all margin shrinks at once, and all liquidations trigger at once, the unified margin mode not only fails to provide a buffer but becomes a conduit for risk contagion.

The choice of margin mode therefore constitutes a deep design dilemma: the isolated mode sacrifices efficiency for safety, while the unified mode sacrifices safety for effi-

ciency. Under competitive pressure, exchanges tend to promote unified margin to attract professional traders who seek capital efficiency, but this simultaneously plants a larger procyclical risk at the system level. This dilemma receives a deeper theoretical treatment in the "impossible trinity of liquidation design" in Section 11.6.

11.1.5 Differences in cascades across market architectures

Although the underlying dynamic logic of the liquidation cascade is the same in all leveraged markets, the fundamental differences in market architecture between centralized and decentralized exchanges cause the manifestation, propagation speed, and destruction pattern of the cascade to display marked structural divergences.

In the CEX environment, the liquidation engine runs on the exchange's internal matching servers, with execution latency typically on the order of microseconds to milliseconds. CEX order-book depth is maintained continuously by professional market makers through high-frequency API connections, and liquidity supply is relatively ample in normal times. This centralized architecture, however, also means that all liquidation decisions and execution are concentrated in a single entity. When extreme conditions overload the matching engine (as in the March 2020 BitMEX event), the queuing delay in liquidation processing makes actual execution prices deviate far from trigger prices, and bankruptcy losses are sharply amplified. In addition, CEXs hold unilateral authority to adjust margin parameters and liquidation thresholds, and this centralized risk-control power can, in a crisis, act as a stabilizer (for example, by temporarily lowering the leverage ceiling) or become an additional source of uncertainty (for example, by suddenly adjusting collateral factors).

In the DEX environment, the transmission chain of liquidation is fundamentally constrained by the underlying blockchain architecture. The liquidation execution of on-chain DeFi lending protocols on Ethereum and similar chains (such as Aave and Compound) is limited by block confirmation time (typically 12 to 15 seconds), a delay that in the traditional sense constitutes a passive "speed bump." The order-book DEXs at the center of this chapter, however, are not subject to this limitation: dYdX v4 runs on a Cosmos application chain with sub-second block times, and Hyperliquid's block latency is only about 200 milliseconds. Nonetheless, the transparency of the blockchain introduces an additional risk dimension that does not exist on CEXs: the visibility of liquidation transactions in the mempool makes them a target for MEV (see the discussion of MEV and liquidation sniping in Chapter 6). A sandwich attacker can insert a front-running transaction before a liquidation transaction is confirmed, artificially widening the price slippage and thereby aggravating liquidation losses. In periods of extreme congestion, a sharp spike in gas fees further compresses the profit margin of liquidation bots, which can leave small liquidations unexecuted and let them accumulate into a larger systemic risk. The market architecture of DEX perpetual futures is not homogeneous; it comes in at least three distinct types whose liquidation dynamics differ markedly. The first type is the application-chain order-book DEX, exemplified by dYdX v4, which runs on a dedicated Cosmos application chain with block times down to the sub-second level; the execution characteristics of its liquidation engine are relatively close to those of a CEX, though it is still constrained by the blockchain's inherent

finality delay and validators' ordering power. The second type is the self-built-L1 order-book DEX, exemplified by Hyperliquid, whose block latency is about 200 milliseconds and whose execution characteristics have in practice approached CEX levels; Hyperliquid's sequencer architecture, however, is highly centralized, and its classification as a "decentralized exchange" is disputed within the industry. The third type is DEX perpetual futures based on an automated market maker or oracle quotes (such as GMX and Perpetual Protocol); these protocols genuinely lack the discrete depth structure of a traditional order book, their liquidity is distributed continuously along a price curve or an oracle price, and the price impact of a large liquidation order follows a mathematical function different from the order-book model, typically exhibiting smoother but larger total slippage. Both dYdX and Hyperliquid, the focus of this chapter, belong to the first two order-book architectures, whose cascade dynamics are structurally similar to a CEX rather than analogous to the third, automated market maker (AMM), model.

The differences between these two architectures produce distinct fragility patterns at the level of cascade dynamics. A CEX cascade tends toward a "concentrated-eruption" type, releasing a large amount of liquidation energy in an extremely short time (on the order of minutes), but it may also be abruptly cut off by the exchange's manual intervention. A DEX cascade tends toward a "diffuse-penetration" type, in which cross-protocol and cross-chain liquidations propagate gradually through oracle price updates and the delays of cross-chain bridges, with a longer time span (tens of minutes to hours) but more complex and harder-to-trace contagion paths. In the "10.10 event" of 2025, the liquidations between CEXs and on-chain DeFi were not a simple sequential process but formed a concurrent, two-way feedback loop: a price decline on CEXs triggered oracle price updates (whose delay depends on Chainlink's heartbeat interval or Pyth's push frequency), the updated oracle prices drove liquidations in DeFi lending protocols and on-chain perpetual futures, and the selling pressure from on-chain liquidations was transmitted back to the CEX spot market via arbitrageurs, further depressing CEX prices and in turn triggering a new round of oracle updates and on-chain liquidations. This CEX–DeFi two-way feedback loop ran concurrently during the event, and the oracle-update delay acted as a "clock" regulating the speed of the feedback: Chainlink's heartbeat interval and deviation threshold on Ethereum determined the lag in DeFi liquidations' response to CEX price moves, a lag that both prevented, to some degree, the instantaneous transmission of shocks and led to a temporal dispersion of liquidations, so that on-chain aftershocks persisted for hours after the main CEX shock had ended.

We have now fully dissected the micro transmission chain from a price move to forced liquidation: the margin system defines the boundaries of leverage and the measure of fragility, the mark price constructs the "truth" benchmark that triggers liquidation, the liquidation engine executes forced closure in a deterministic manner, and the margin mode determines the path along which risk is transmitted within the account and across assets. Each link in this chain is a carefully designed risk-management tool in normal markets; but when they are activated simultaneously and coupled with one another in extreme conditions, they jointly weave a precise network that converts individual risk into systemic risk. This calls for the two-layer theoretical framework of reflexivity, which provides both a philosophical and an economic lens for understanding how this

network generates self-reinforcing positive feedback.

11.2 The theoretical foundations of reflexivity

Before we can understand the endogenous reflexivity of leverage and liquidation in crypto-asset markets, it is worth tracing its theoretical roots. Most traditional financial theory rests on the efficient market hypothesis (EMH) and the rational-agent assumption, holding that prices passively reflect fundamental information and tend toward some equilibrium. In the highly leveraged and automated crypto derivatives market, however, price movements often no longer merely reflect fundamentals but become the core force driving changes in those fundamentals (such as liquidity and participants' capital), which in turn feed back on prices themselves. This dynamic process is precisely the essence that the theory of reflexivity reveals. This section starts from George Soros's philosophical epistemology and, combining it with the microstructure model of Markus Brunnermeier and Lasse Heje Pedersen, builds a two-layer theoretical framework for understanding liquidation cascades in crypto markets.

11.2.1 Soros's theory of reflexivity

George Soros first systematically advanced the theory of reflexivity in *The Alchemy of Finance* [6]. Unlike traditional economics, which assumes that supply and demand curves are independent and jointly determine price, Soros held that in social systems involving thinking participants there is a two-way feedback mechanism between participants' perceptions and the actual state of affairs. Soros decomposed this feedback mechanism into two basic functions: the cognitive function and the participating function. In the cognitive function, participants try to understand their environment, and information flows from the world to thought; in the participating function, participants act on their understanding in an attempt to change the environment, and information flows from thought to the world [7].

In the traditional equilibrium framework, these two functions are treated as independent: price merely reflects reality passively. Under the reflexivity framework, however, the two functions are intertwined and mutually causal. When the market price changes (reality changes), it affects traders' risk perception and sentiment through the cognitive function (perception changes); traders adjust their positions on the basis of the new perception (for example, by actively selling or adding margin), and this behavior is converted, through the participating function, into actual buying and selling pressure in the market (action changes reality); these trades in turn push the price further in some direction, closing the loop.

In perpetual futures markets, this reflexivity framework can be formalized as a set of coupled difference equations. Let C_t denote the market's collective cognitive state at time t (which can be operationalized as an observable variable such as a market sentiment index, the funding rate, or the long-short ratio), P_t the asset price, and $Q_{\text{liq},t}$ the liquidation order flow at time t. The cognitive function maps price changes into perception updates:

$$C_{t+1} = f(P_t, C_t) = C_t + \gamma \cdot \Delta P_t + \eta_t$$

where $\gamma > 0$ denotes the strength of price changes' influence on perception (in crypto markets, given the immediacy of information diffusion, γ is markedly higher than in traditional markets), and η_t is an exogenous information shock. The participating function maps the cognitive state into price changes, but in perpetual futures markets it must incorporate the mechanical, forced execution of the liquidation engine:

$$P_{t+1} = g(C_t, Q_{\text{liq},t}) = P_t + \lambda \cdot h(C_t) - \beta \cdot \frac{Q_{\text{liq},t}}{D_t}$$

where $h(C_t)$ denotes the influence on price of perception-driven voluntary trading, λ is the market-impact coefficient of the participating function, and $\beta \cdot Q_{\text{liq},t}/D_t$ is the mechanical price impact of the liquidation engine—a rigid participating function specific to crypto markets that does not exist in the traditional Soros framework. A note on dimensional conventions: in this equation P_{t+1} and P_t are price levels (in dollars), so β and λ here carry price dimensions (dollars). They describe the same impact mechanism as the identically named dimensionless coefficients β and λ that act on the dimensionless log return ΔP in Section 11.3.3, and they merely adopt different scalings because the dependent variable is defined differently (price level versus log return); the two should not be equated numerically. When the system is in a steady state ($\Delta P_t \approx 0$, $Q_{\text{liq},t} \approx 0$), the two equations converge to equilibrium; when a price decline triggers liquidation ($Q_{\text{liq},t} > 0$), the liquidation impact depresses the price further, the price decline in turn updates perception and triggers more liquidations, and the coupling of the two equations drives the system along a divergent path.

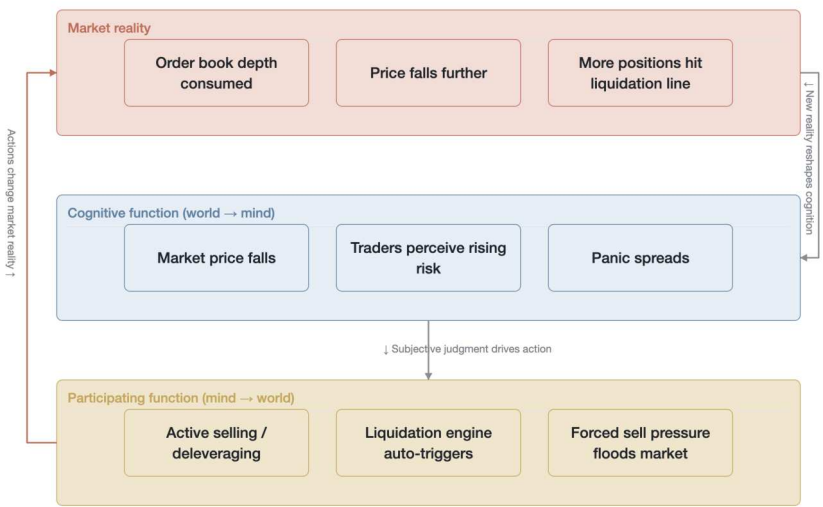

Figure 11-8. The reflexivity feedback loop of leverage and liquidation (based on the Soros framework)

As shown in Figure 11-8, in the crypto derivatives market this reflexivity is greatly amplified by the automated liquidation engine. Acting as a hard-coded "participating function," the liquidation engine forcibly converts under-collateralized positions into market orders, directly consuming order-book depth and depressing the price, shaping a harsher market reality and pushing the system away from equilibrium into a

self-reinforcing divergent state. The core difference the figure reveals is this: the "participating function" of a traditional market must be mediated by human judgment (assessing risk, deciding to cut positions, choosing timing), and these steps introduce time delays and behavioral heterogeneity that constitute a natural damping of positive feedback; in crypto markets, by contrast, the participating function is hard-coded directly into the smart-contract logic of the liquidation engine, and its execution is deterministic, instantaneous, and unconditional, with no buffer space for human intervention. This positive-feedback loop therefore has no natural attenuation mechanism, and each cycle may release greater selling pressure than the last, so that the system, absent external intervention, keeps evolving toward divergence.

11.2.2 The liquidity spiral model

If Soros's theory of reflexivity provides a macro philosophical framework, the model of Brunnermeier and Pedersen lays bare the mutually reinforcing relationship between an asset's market liquidity (how easily the asset can be converted to cash) and a trader's funding liquidity (how easily the trader can obtain funds) [8]. They show that when an external shock hits, these two forms of liquidity form a vicious circle through two mechanisms: the loss spiral and the margin spiral.

The loss spiral describes an equity effect. When an asset's price falls, leveraged traders holding a long position in it suffer a loss of equity. To maintain a given leverage ratio or meet regulatory requirements, they are forced to sell part of the asset. This selling impacts the market price and drives the price down further, triggering fresh equity losses and another round of selling. Consider a concrete transmission process: when a long trader using 10x leverage holds a \$100,000 BTC position, a 5% price decline shrinks their \$10,000 of equity to \$5,000, and their actual leverage jumps from 10x to 20x; to restore leverage to its target level, the trader must sell about \$50,000 of the position, and this forced sale itself exerts downward pressure on the market price, subjecting other leveraged traders to the same predicament.

The margin spiral describes a collateral-constraint effect. When a price decline is accompanied by rising volatility, funding providers (such as brokers and exchanges) raise margin requirements to control risk. This means the trader's existing collateral can borrow less than before. To make up the funding gap, the trader must sell more assets, which not only depresses the price further but may also trigger greater volatility, leading margin requirements to be raised again. In crypto markets this mechanism is especially aggressive: during high-volatility periods, exchanges dynamically raise maintenance margin rates or lower collateral factors, and such adjustments often affect a large number of accounts simultaneously within a very short time, creating collective forced-deleveraging pressure driven by the change in risk-control rules itself.

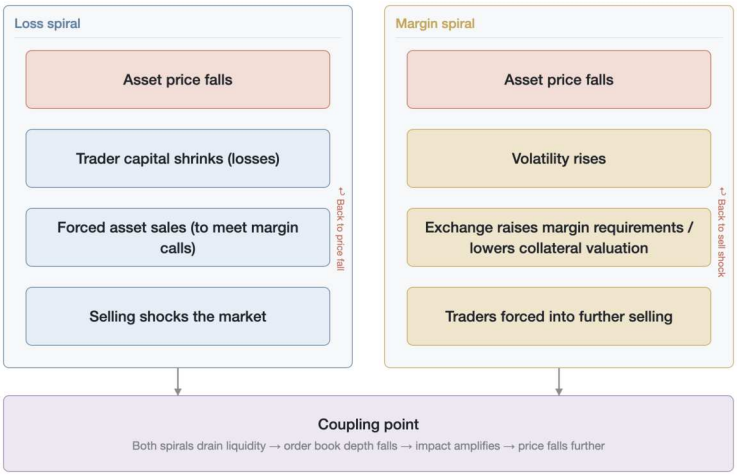

Figure 11-9. The coupling mechanism of the loss spiral and the margin spiral

As shown in Figure 11-9, these two spirals often occur simultaneously and couple with each other during a crisis: a price decline both directly cuts capital (the loss spiral) and raises margin requirements by pushing volatility higher (the margin spiral), and together they generate enormous forced-selling pressure that rapidly consumes order-book depth. The model of Brunnermeier and Pedersen proves mathematically that, under certain conditions, the margin mechanism itself is a source of market instability. The key is this: margin adjustments in traditional markets settle daily and involve manual review, so the two spirals often unfold sequentially and can be separated in time, providing a window for identification and intervention; in crypto markets, margin is computed in real time, so the two are activated synchronously on the same time scale and amplify each other. The mathematical consequence of this synchrony is that the joint effect is not additive but multiplicative—the selling pressure produced by the loss spiral lowers market liquidity, and lower liquidity makes each unit of selling in the margin spiral produce a more violent price impact, and vice versa.

11.2.3 The applicability to perpetual futures

Perpetual futures in crypto-asset markets constitute an extreme testing ground for the two-layer theory above. Compared with traditional financial markets, the crypto derivatives market pushes reflexivity to its limit through its mechanism design.

Table 11-2 compares the core differences in liquidation mechanisms between traditional finance and crypto perpetual futures:

Dimension	Traditional finance (e.g., securities margin trading, traditional futures)	Crypto perpetual futures (e.g., Binance, Bybit)
Margin assessment	Brokers/clearinghouses settle daily (T+0 or T+1), with manual review	Smart contract/liquidation engine monitors in real time (millisecond level)
Grace period	A margin call is usually issued, allowing top-up within T+1 to T+3	Zero grace period; forced closure the instant the maintenance margin line is touched
Liquidation execution	Traders close manually or brokers execute in batches, considering market impact	The engine takes over automatically, typically dumping to market via market orders or better-than-market limit orders
Lender of last resort	The central bank can inject liquidity through the discount window, breaking the spiral	No lender of last resort; reliance only on a limited insurance fund or auto-deleveraging
Spiral evolution speed	Days to weeks (e.g., the 1998 LTCM crisis, the 2008 subprime crisis)	Seconds to minutes (e.g., 3.12 in 2020, 5.19 in 2021, 10.10 in 2025)

Table 11-2. Comparison of liquidation mechanisms between traditional finance and crypto perpetual futures (Data source: compiled by the author)

Notably, the table summarizes the spiral-evolution speed of traditional finance as "days to weeks," which applies mainly to the traditional deleveraging process that relies on human decision-making and daily settlement; when traditional markets likewise introduce highly automated execution, the phenomenon of time compression is not unique to crypto. The U.S. stock market "flash crash" of May 6, 2010, is a case in point: the Dow Jones Industrial Average plunged nearly 1,000 points (about 9%) in roughly 36 minutes and then rebounded over roughly the same span, and its underlying dynamics are highly isomorphic with a crypto liquidation cascade—automated algorithmic execution replacing human judgment, liquidity providers systematically withdrawing quotes as volatility intensified, and positive feedback forming between selling pressure and the liquidity vacuum. The exchange-traded fund (ETF) flash crash of August 24, 2015, further confirmed this pattern, when the prices of hundreds of ETFs deviated from net asset value by 20% to 30% within minutes of the open. The key difference, however, lies in the interruption mechanism: the limit up-limit down (LULD) rule introduced in the United States after the 2010 flash crash, together with earlier circuit-breaker rules such as Rule 48, can halt trading and forcibly break the spiral when a price deviates beyond a threshold, and this external "time wedge" provides a window for liquidity to recover and information to be digested; the crypto perpetual futures market, to this day, lacks any equivalent market-wide circuit breaker, trading proceeds around the clock, the liquidation engine runs continuously, and once positive feedback begins there is no external force to arrest it.

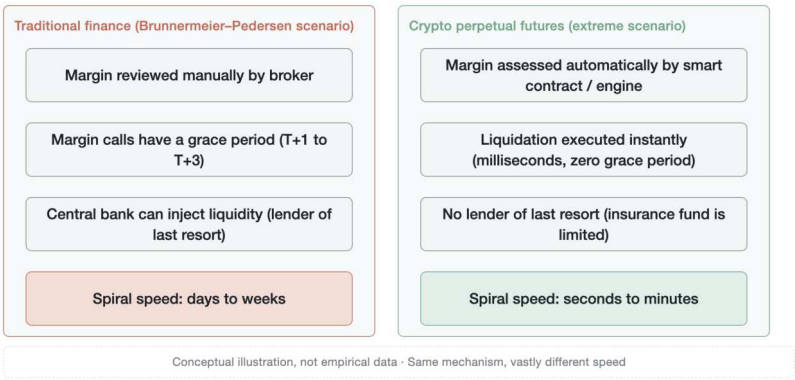

Figure 11-10. Comparison of spiral speed between traditional finance and crypto perpetual futures (conceptual illustration, not empirical data)

As Table 11-2 and Figure 11-10 show, in crypto markets the "loss spiral" and "margin spiral" of the Brunnermeier-Pedersen model are compressed to the millisecond level. Without the buffer of human intervention or the backstop of a lender of last resort, the feedback loop between price declines and liquidation selling has no damping at all. This homogenization and automation of the mechanism make the "participating function" Soros described entirely deterministic and mechanical. When the market is in a highly leveraged state, a tiny price disturbance can topple the first domino and evolve into a systemic liquidation cascade.

Historical data clearly confirm this. Figure 11-11 shows the ten largest liquidation events in crypto history, ranked by total 24-hour liquidations.

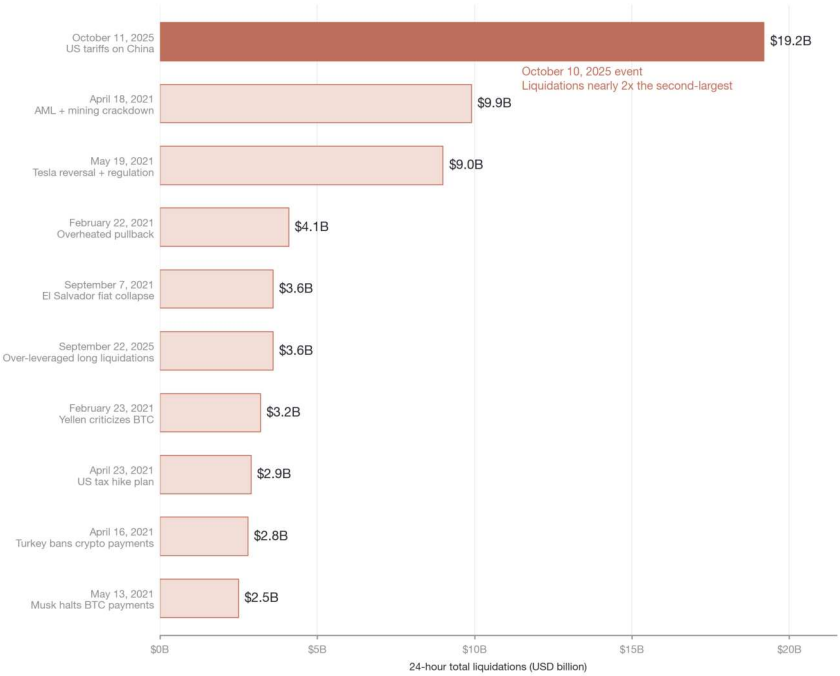

Figure 11-11. Major liquidation events in crypto history (Data source: CoinGlass [9], as of October 2025; the top 10 ranked by 24-hour liquidations; because of exchanges' API reporting caps, the CoinGlass basis historically underestimates and its absolute figures are conservative, so orders of magnitude should be emphasized)

As shown in Figure 11-11, the liquidation event of October 10–11, 2025, set a historical record, with total single-day liquidations of about $19.1 billion (on CoinGlass's exchange basis; constrained by a rate limit that pushes only one liquidation data point per second, this value is a lower bound, and the true notional scale may be higher), nearly double the second-ranked event (April 18, 2021) [9]. In this crash triggered by macro news, the microstructure signatures—Bitcoin's sharp plunge, more than 1.62 million accounts liquidated (about 87% of them long), order-book depth evaporating by more than 99% within minutes, and spreads widening by more than a thousandfold (see the chapter opening and Section 11.9.2 for data) [1]—are precisely the result of reflexivity being amplified to its extreme under the automated liquidation mechanism.

The endogenous reflexivity framework above describes the transmission mechanism of the liquidation cascade, but the system's baseline fragility is modulated to a great extent by macro liquidity conditions. The high open interest and extreme funding rates that constitute the cascade's "fuel" tend to accumulate preferentially in a risk-on macro environment—periods of a weakening dollar index, an accommodative Federal Reserve monetary policy, and narrowing global credit spreads. In such easing cycles, abundant external liquidity not only fuels the swelling of leverage demand but also temporarily sustains higher order-book depth by attracting incremental capital to make markets, thereby suppressing the triggering and propagation of cascades. Conversely, when the macro environment shifts from risk-on to risk-off (for example, a sudden spike in expectations of Fed tightening, or a geopolitical shock that triggers a global flight to

safety), trigger sensitivity rises markedly, because the contraction of external liquidity simultaneously weakens market makers' risk-bearing capacity and arbitrageurs' capital supply. This means that in a macro-easing period, even when market microstructure indicators (such as the OI/market-cap ratio and the funding-rate level) have reached levels comparable to those of historical crash events, the cascades that actually occur tend to be fewer and milder; whereas in a period of macro tightening, even a lower degree of microstructure fragility can brew a severe cascade. A complete cascade-risk assessment model therefore cannot rely on endogenous market-structure indicators alone but must be calibrated conditional on macro state variables. The subsequent analysis in this chapter focuses on the endogenous transmission mechanism, but readers should remain aware throughout of this implicit premise of macro conditionality.

11.3 The liquidation reflexivity equation

The liquidation cascade is not an accidental event. Under specific market microstructure conditions, the occurrence of a cascade is a mathematical inevitability. This section formalizes the positive-feedback process of liquidation into a concise difference equation, revealing the critical condition that drives a cascade out of control.

11.3.1 Liquidation order flow

In market microstructure theory (e.g., Kyle, 1985 [10]), price changes are driven by order flow. Ordinary order flow is random and involves information asymmetry, and its direction is two-sided. Liquidation order flow, however, is a distinctive kind of passive order flow. Its direction is fully determined: when a price decline triggers long liquidations, the liquidation engine necessarily sends sell orders to the market; when a price rise triggers short liquidations, it necessarily sends buy orders. This one-sidedness means that liquidation orders cannot be hedged internally and must be absorbed entirely by market makers or contrarian traders. On top of this, they form a liquidity devourer that is extremely insensitive to price. The liquidation engine's primary task is to close positions as quickly as possible to avoid the systemic risk (socialized losses) caused by bankruptcy. It therefore typically uses market orders or limit orders with an extremely high slippage tolerance. This execution logic means that liquidation orders consume order-book liquidity regardless of cost and constitute a pure demander of liquidity.

11.3.2 The three-step mapping

We can decompose the liquidation-cascade process into three successive mapping steps. The trigger mapping describes how a price change ΔP_t drives the margin balance of some positions below the maintenance margin level and thereby triggers liquidation. Next comes the quantity mapping, in which the triggered positions are converted into actual liquidation order flow Q_{liq}. Building on this, the impact mapping shows how the liquidation order flow Q_{liq} hits the current order-book depth D_t and produces a new price change ΔP_{t+1}.

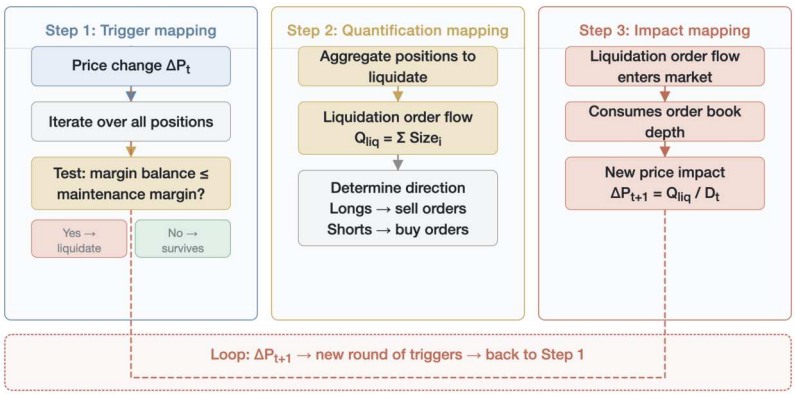

Figure 11-12. The three-step mapping from a price change to the next round's price change

As shown in Figure 11-12, if ΔP_{t+1} has the same direction as ΔP_t and is large enough to trigger new liquidations, this loop continues. The figure decomposes the loop into three mapping steps with clear economic meaning. The first step is the trigger mapping, whose core question is which positions' margin balances will fall below the maintenance margin line under a given price decline and thus be captured by the liquidation engine; the output of this step depends on the distribution density of leverage multiples and the degree of clustering of liquidation prices. The second step is the quantity mapping, which converts the triggered positions into actual market order flow, whose scale is determined jointly by the notional value of the liquidated positions and the liquidation engine's execution strategy. The third step is the impact mapping, which describes the actual effect these liquidation order flows have on the price once they enter the order book—an effect that depends not only on the absolute scale of the order flow but, more importantly, on the effective depth of the order book at the time. The loop arrow in the figure represents precisely the self-reinforcing nature of this process: the new price change ΔP_{t+1} produced in the third step constitutes the input to the first step of the next round, that is, the new trigger condition. As long as the price change output by each round is large enough to activate new liquidation positions, this three-step mapping keeps iterating.

11.3.3 The divergence condition

To formalize this process, we define the following variables. ΔP_t denotes the magnitude of the price change in round t (taken as a dimensionless log return, which for small moves is approximately equal to a percentage). α represents liquidation sensitivity, the proportion of leveraged positions that a unit price change can trigger for liquidation, which depends on the distribution density of leverage in the market. L is the total scale of leveraged positions in the market (such as open interest; note that from this section onward L refers specifically to the leverage stock/notional, distinct from the $P^{\text{liq}}(t)$ that denotes the liquidation price in Section 11.1.1, and the two must not be confused). β is the price-impact coefficient. D_t is the effective order-book depth in round t. Here D_t should be understood as the net effective depth after cross-exchange integration—that

is, the system-level depth net of the friction costs arbitrageurs incur to move liquidity across platforms—rather than the order-book depth of a single exchange. During a cascade, because arbitrageurs cannot redistribute order flow across exchanges quickly enough, the system's overall effective depth is markedly smaller than the simple sum of the individual exchanges' order-book depths. To ensure the dimensionlessness of the feedback gain, the dimensions of the variables are stipulated as follows: ΔP_t is taken as a dimensionless log return; L and D_t are both measured in dollar notional; α is defined as "the proportion of liquidatable notional triggered per unit log-price change, as a share of total notional" (with dimensions of 1/log return); and β is the impact elasticity, "the log-price change produced per unit dimensionless order-flow/depth ratio" (dimensionless). On this basis, $Q_{\text{liq}} = \alpha L \Delta P$ is measured in dollars, Q_{liq}/D_t is dimensionless, and $G = \alpha\beta L/D_t$ is a dimensionless quantity, so that comparison with the critical value of 1 is meaningful.

Based on the three-step mapping above, we can derive the liquidation volume in round t, $Q_{\text{liq},t}$, as:

$$Q_{\text{liq},t} = \alpha \cdot L \cdot \Delta P_t$$

Once this liquidation volume enters the market, the new price impact it produces, ΔP_{t+1}, is:

$$\Delta P_{t+1} = \beta \cdot \frac{Q_{\text{liq},t}}{D_t}$$

Substituting the first equation into the second, we obtain the liquidation reflexivity equation:

$$\Delta P_{t+1} = \left(\alpha \cdot \beta \cdot \frac{L}{D_t}\right) \cdot \Delta P_t$$

Letting the feedback gain be $G = \alpha \cdot \beta \cdot \frac{L}{D_t}$, the equation simplifies to:

$$\Delta P_{t+1} = G \cdot \Delta P_t$$

This concise difference equation reveals that the fate of the cascade depends entirely on the magnitude of the feedback gain G. Under the convergence condition ($G < 1$), the new price impact produced in each round is smaller than the last, the system gradually absorbs the shock, and the price stabilizes after some fluctuation. Under the divergence condition ($G > 1$), the new price impact produced in each round is larger than the last, the shock is continually amplified, and the system enters an out-of-control cascade-collapse state until leverage is fully cleared (L falls sharply) or external liquidity intervenes (D_t rises sharply).

The reflexivity equation above with a constant G, however, produces unbounded exponential divergence, which is physically unrealistic, since a price cannot fall below zero and the leverage pool L is continually depleted as liquidation proceeds. A more complete model must endogenize G: $G_t = \alpha \cdot \beta \cdot L_t/D_t$, where L_t decreases with each round of liquidation, that is, $L_{t+1} = L_t - Q_{\text{liq},t}$. This correction transforms the system from a linear divergence process into a nonlinear difference equation: in the initial phase, because L_t is still ample relative to $Q_{\text{liq},t}$, $G_t > 1$ and the system exhibits divergence; but as liquidation continually consumes the leverage stock, G_t declines round by round, eventually crossing the critical line $G_t = 1$ and decaying into the conver-

gence range. In other words, a liquidation cascade is essentially an initially divergent but conditionally self-terminating dynamic process. The recursion $L_{t+1} = L_t - Q_{\text{liq},t}$ above characterizes only the decay of the numerator (the leverage stock), whereas the denominator D_t also plunges endogenously during a cascade (see Section 11.3.4); only when the depletion rate of the leverage stock ultimately exceeds the deterioration rate of the effective depth does G_t decline monotonically, cross 1, and self-terminate. If depth collapses very fast, G_t may rise before it falls, and the system experiences a more violent overshoot before self-terminating. The total overshoot of the price depends on how many rounds of iteration the system passes through before G_t crosses 1, and this number of iterations is determined jointly by the initial leverage concentration and the depth-to-liquidation-volume ratio. The larger the initial G_0 and the more concentrated the leverage distribution within a narrow price range, the more divergent iterations the system passes through before self-terminating, and the more severe the cumulative destruction. This self-termination mechanism connects directly to the systematic analysis of cascade-termination conditions in Section 11.5.4.

In addition, it should be noted that the linear price-impact model $\beta \cdot Q/D$ in the impact mapping above is itself a first-order approximation. The empirical market microstructure literature shows that the price impact of normal order flow follows a square-root law (Bouchaud et al., 2009), that is, price impact is proportional to the square root of order-flow size. But liquidation flow is not normal order flow: it is concentrated, one-sided, and price-insensitive, and it often penetrates multiple order-book price levels at once, so its actual impact may exhibit superlinear (convex) characteristics. This means that in a liquidation-dense range, the leverage density required to reach the divergence threshold $G > 1$ may be lower than the linear model predicts, so the system's actual fragility is underestimated by the linear framework.

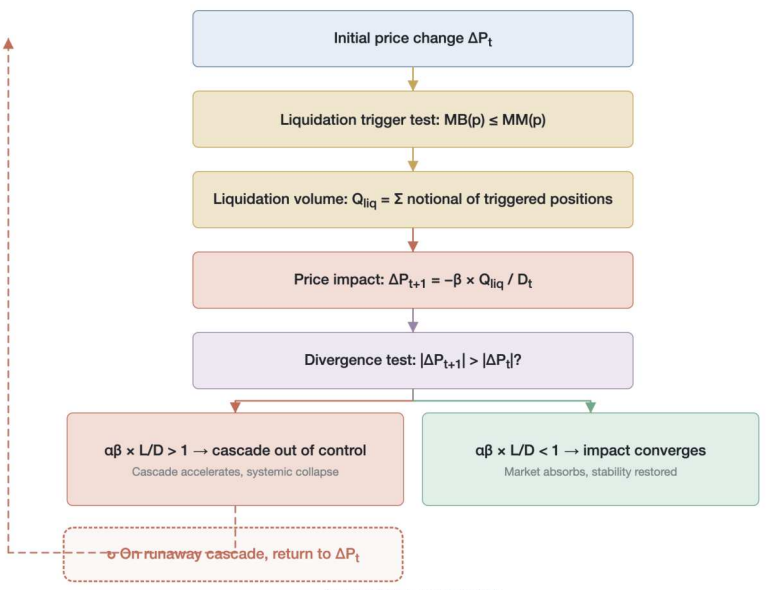

Figure 11-13. The positive-feedback loop and divergence condition of the reflexivity equation (conceptual illustration, not empirical data)

As shown in Figure 11-13, the figure's core is to reveal a key bifurcation structure: when $G < 1$, the price impact of each round of liquidation attenuates round by round, the initial disturbance is absorbed after a finite number of iterations, and the system behaves as a stable negative-feedback equilibrium; when $G > 1$, each round's shock is larger than the last, the price sequence diverges exponentially, and the system enters a self-reinforcing cascade-amplification path (irreversible by a small disturbance before leverage is cleared, but not never-terminating; see the conditional self-termination analysis in Section 11.3.3). Every component of $G = \alpha \cdot \beta \cdot L/D_t$ is a function of market conditions: in a bull market the continual accumulation of leveraged positions increases L and α together, while rising volatility prompts market makers to withdraw liquidity and causes D_t to contract sharply, so the same market can transition smoothly from the $G < 1$ steady state to the $G > 1$ divergence region as leverage accumulates and liquidity ebbs. This explains why a liquidation cascade always appears to erupt "suddenly" to an outside observer: the system may already have been operating on the edge of danger for a considerable time before crossing $G = 1$, but when G is slightly below 1 it still displays apparent stability, and fragility is almost unobservable before the threshold is breached.

11.3.4 Three sources of nonlinearity

In real crypto markets, the variables in the liquidation reflexivity equation are not linear. The equation above assumes that liquidation sensitivity α and order-book depth D_t are constants, but this simplification is severely distorted in actual markets, because the threshold-clustering effect of liquidation prices, the high homogeneity of trader behavior, and the endogenous withdrawal of liquidity by market makers in times of crisis together create multiple discontinuities and positive-feedback acceleration mechanisms. It is precisely the following three sources of nonlinearity that give liquidation cascades their characteristic sudden eruption and highly destructive nature. The research of Danielsson, Shin, and Zigrand shows that the procyclicality of leverage is itself a core driver of endogenous risk [11].

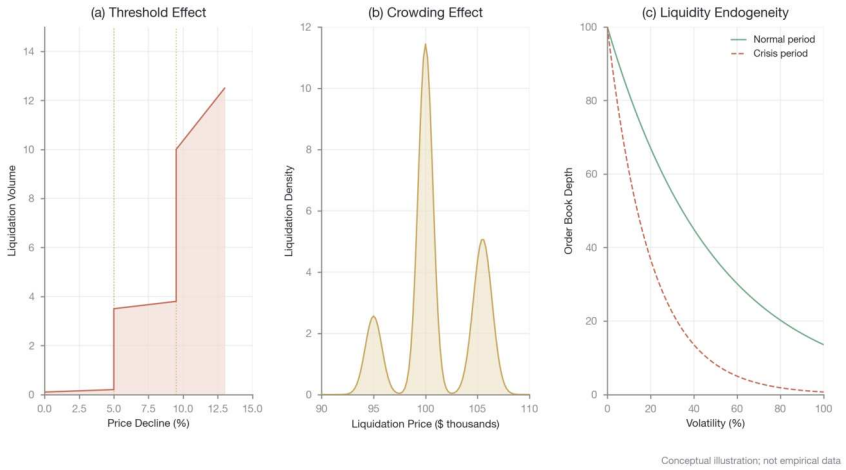

Figure 11-14. The three sources of nonlinearity in a liquidation cascade (conceptual illustration; qualitative axes; not empirical data)

As shown in Figure 11-14, the figure characterizes the three sources of nonlinearity in liquidation reflexivity. The first is the threshold effect: liquidation does not occur smoothly as the price falls; every leveraged position has a precise maintenance margin rate (such as 0.5%), the position exerts no selling pressure on the market before the price reaches the threshold (a latent state), and once the threshold is breached, the entire notional value of the position is instantly converted into a market sell order. This discontinuous jump from "zero" to "a huge amount" can drive the derivative of liquidation volume with respect to price (α) toward infinity in a specific range. The second is the crowding effect: retail traders and quantitative strategies tend to favor integer leverage multiples (such as 10x, 20x, 50x) and to open positions near key round-number price levels or technical support levels, and this has multiple psychological microfoundations—the anchoring effect drives traders to use integer leverage and round-number price levels as reference points; the coordination effect of real-time social media (the "key levels" shared on Crypto Twitter and in Telegram groups) amplifies herd behavior; the informational-cascade mechanism (Bikhchandani, Hirshleifer, and Welch, 1992) [12] leads later entrants to treat peers' opening of positions at the same price as evidence of price support; and the representativeness heuristic ("this support level held in the past, so it will hold again") further entrenches an excessive reliance on historical levels. Because position information in traditional markets is private and social amplification is far less immediate and transparent than in crypto communities, both behavioral homogeneity and the clustering density of liquidation prices are markedly lower there. This clustering forms "liquidation-dense zones," and when the price falls into one, α spikes sharply and generates a massive liquidation order flow instantly. The third is the endogeneity of liquidity: order-book depth D_t is not an exogenous constant; in normal times market makers provide ample liquidity, but when prices swing violently and liquidations occur frequently, market makers face enormous adverse-selection and inventory risk and rationally choose to widen spreads or withdraw their orders outright, so that effective depth D_t falls sharply precisely when the system most needs liquidity to absorb selling pressure, and this "procyclicality" further

amplifies the price-impact coefficient β. The multiplicative superposition of the three nonlinearities (a spike in $\alpha \times$ a plunge in D_t) allows the feedback gain G to jump from below 1 to far above 1 in an extremely short time, driving the market out of control in an instant.

This nonlinear mechanism also answers the paradox posed at the opening of this chapter—why individual prudence produces precisely systemic fragility at the aggregate level. The causal bridge has three parts. First, the stop-loss orders that individuals set out of prudence, like leverage liquidation prices, tend to cluster near round-number levels and technical support levels, and the two superimpose on the price axis, jointly raising α in the liquidation-dense zone. Second, under unified margin and correlations approaching 1 in a crisis, the effective portfolio-level leverage of a "safe" 5x–10x notional leverage is far higher than its notional value (see Section 11.7.5), so that prudent individuals contribute far more liquidation sensitivity at the system level than they realize. Third, the voluntary sell orders triggered by individual stop-losses have exactly the same direction as the forced sell orders of the liquidation engine and are released simultaneously, which in effect further amplifies α. Thus it is precisely the risk-management actions of countless individuals—microscopically "correct"—that, under the structural coupling of unified margin, liquidation-price clustering, and procyclical liquidity withdrawal, aggregate into a macroscopically high α, high liquidation concentration, and low D_t, causing systemic risk to emerge endogenously from individual prudence.

11.3.5 The cascade risk index

To quantify this divergence risk in actual trading and risk control, we can construct an operational indicator based on the reflexivity equation: the cascade risk index (CRI).

$$\mathrm{CRI} = \frac{\text{leverage density} \times \text{liquidation concentration}}{\text{available depth}} \approx \frac{(\text{OI/market cap}) \times \text{liquidation-heatmap density}}{\text{stress depth}}$$

The precise definitions of the sub-components are as follows. Leverage density is measured by the ratio of open interest (OI) to the asset's circulating market capitalization, that is, leverage density = OI/market cap. When this ratio exceeds 0.3, it indicates that the derivatives market's notional exposure is approaching one-third of the underlying asset's market cap and that the leverage level has entered a warning range. Liquidation concentration uses the liquidation heatmap to quantify the share of liquidatable notional value clustered within a specific range below the current price (usually taken as 5%) as a proportion of total open interest, that is, liquidation concentration = $\sum_i N_i \cdot \mathbf{1}[P_i^{\mathrm{liq}} \in (P \times 0.95,\ P)]/\mathrm{OI}$ (where N_i is the notional value of position i, P_i^{liq} is its liquidation price, P is the current mark price, and $\mathbf{1}[\cdot]$ is the indicator function). This indicator reflects the relative scale of the liquidation order flow that might be triggered by a 5% price decline. Available depth cannot be read from the current static snapshot of the order book alone; it should instead be assessed as the "stress depth" that market makers can maintain under a specific volatility-stress scenario—that is, the effective bid depth the order book can still provide within 2% below the price when volatility spikes to its historical 99th-percentile level.

Based on the definitions above, we can retrospectively calibrate the CRI for four major liquidation events in crypto history, providing an empirical calibration benchmark for

the indicator's warning thresholds.

Event	OI/market cap	Liquidation concentration (5%)	Stress depth ($100 million)	Estimated CRI	Actual cascade severity
March 12, 2020, "Black Thursday"	0.18	0.12	0.8	0.027	Severe (~$6 billion liquidated)
May 19, 2021, "5.19 crash"	0.25	0.15	1.2	0.031	Severe (~$8.6 billion liquidated)
August 5, 2024, "yen carry-trade unwind"	0.28	0.18	1.5	0.034	Moderate (~$10.2 billion liquidated, rapid recovery)
October 10, 2025, "10.10 event"	0.35	0.22	0.4	0.193	Extreme (~$19 billion liquidated)

Table 11-3. Retrospective CRI calibration for major historical liquidation events (Data source: author's estimates, derived from public data)

The table above reveals two key patterns. First, the estimated CRI of the "10.10 event" is an order of magnitude higher than in the three preceding events, and its core driver was not a proportionate rise in leverage density or liquidation concentration but a sharp contraction of stress depth, from $150 million in August 2024 to just $40 million—meaning the market lacked sufficient liquidity buffer to absorb selling pressure under the same liquidation shock. Second, the absolute value of the CRI must be read in light of the historical evolution of market size: as the total volume of the crypto derivatives market grows, absolute liquidation volume is markedly amplified even when the change in a relative indicator (such as OI/market cap) is limited. The CRI's warning thresholds should therefore be dynamically calibrated to market size.

As a risk indicator, however, the CRI has several limitations that warrant caution. First, on dimensional consistency: the numerator of the CRI is the product of two dimensionless ratios, while the denominator is stress depth priced in absolute dollars, which means the CRI's value changes mechanically as market volume grows and lacks an intrinsic standardization mechanism comparable across periods. Second, Table 11-3 contains only four data points spanning five years, a sample too small for robust statistical inference or for constructing warning thresholds with confidence intervals; this is essentially a retrospectively calibrated descriptive analysis, not a cross-validated predictive model. Third, the event of August 5, 2024, constitutes an anomaly worth examining closely: its estimated CRI (0.034) is higher than that of May 19, 2021 (0.031), yet its actual cascade severity was clearly lower and the market recovered markedly faster. This discrepancy suggests that the differences in the speed of external intervention and in the macro transmission path that the CRI fails to capture (the yen carry-trade unwind had a clear exogenous source and was self-limiting) may be more decisive than

microstructure fragility itself in determining a cascade's ultimate destructiveness. On balance, the CRI should be improved in the direction of a conditional indicator—that is, by introducing macro state variables (such as the dollar index and credit spreads discussed in Section 11.2.3) as modulating factors on top of the microstructure variables, so that the same CRI value maps to different risk probabilities under different macro environments.

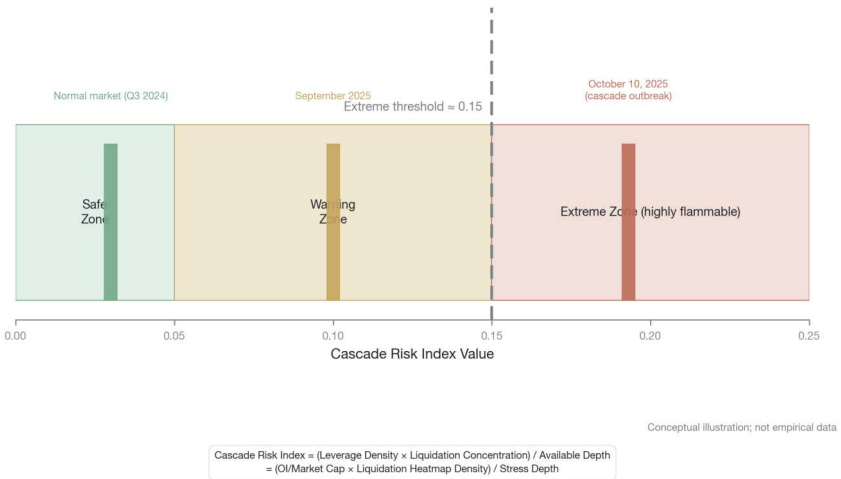

Figure 11-15. Visualization of the cascade risk index (the CRI is an exploratory indicator constructed by the author, based only on retrospective calibration of four historical events and not dimensionally standardized; the threshold bands in the figure are a conceptual illustration, not cross-validated, operational risk-control thresholds)

As shown in Figure 11-15, the CRI can serve as an exploratory, descriptive indicator for monitoring market fragility—though it must be stressed that it is a crowding proxy inspired by the feedback gain G, not yet dimensionally standardized, not the same construct as G, and not sharing the same critical value. Based on the retrospective calibration of four historical events in Table 11-3 (with estimated CRI values falling in the range of about 0.027–0.193), an empirical relative banding can be offered: in the safe range (about < 0.05) the market has enough resilience to absorb local shocks; the warning range (about 0.05–0.15) indicates that leverage is overcrowded and the market is in a subhealthy state, as when the funding rate became extreme in September 2025; and in the extreme range (about > 0.15, into which the October 10, 2025, event's calibration of about 0.193 falls), the system is highly flammable, and any minor negative catalyst can ignite a systemic cascade. Note that this banding is based only on the retrospective, descriptive calibration of four data points, that its warning thresholds and predictive power await large-sample validation, and that it should not be treated as a cross-validated, operational risk-control threshold.

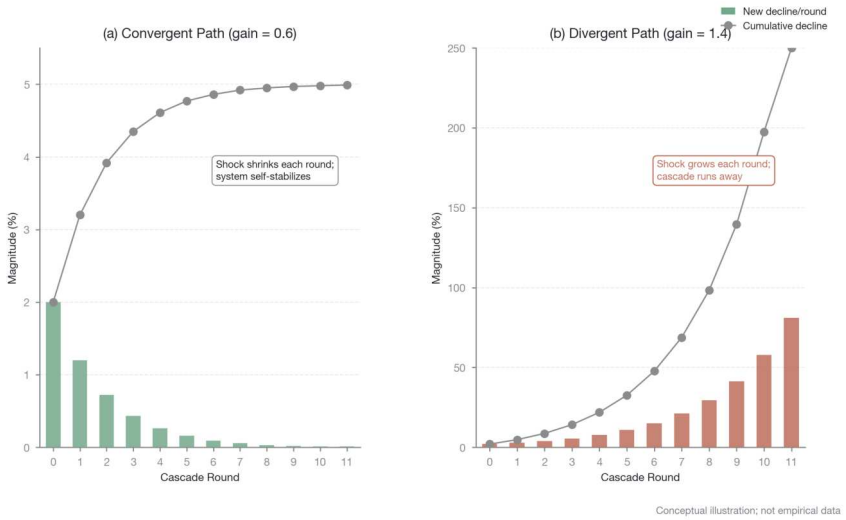

Figure 11-16. Simulation of cascade dynamics—convergent versus divergent paths (dynamic simulation; conceptual illustration; not empirical data)

As shown in Figure 11-16, the dynamic simulation reveals the starkly different evolutionary paths of the feedback gain G on either side of the critical value of 1: on the convergent path ($G = 0.6$), although the initial shock triggers liquidations, the incremental decline in each round attenuates rapidly, and the system recovers on its own after a few iterations with a limited cumulative decline; on the divergent path ($G = 1.4$), a tiny initial shock is continually amplified, the incremental decline in each round grows exponentially, and the result is ultimately a cliff-edge drop and the complete destruction of leverage. This shows that in a highly leveraged crypto market, the core of risk management lies not in predicting when the initial shock will arrive but in monitoring the system's fragility (the CRI is qualitatively positively correlated with G and can serve as an approximate cue to fragility, but $G > 1$ is the strict divergence criterion derived from the difference equation) and avoiding exposure to the market when the conditions for divergence are in place.

11.4 The coupling of the funding rate and leverage

In the market microstructure of perpetual futures, liquidation is the most direct and most violent manifestation of reflexivity, reshaping the price directly through an instantaneous "hard shock." This hard shock, however, does not occur out of nowhere; behind it lies a second reflexivity loop, subtler and slower but no less consequential: the chronic coupling of the funding rate, the basis, and leverage demand. The previous section's liquidation reflexivity equation described the instantaneous transmission of a liquidation cascade, whereas this section analyzes how system fragility is gradually accumulated before a liquidation erupts. The funding-rate mechanism does not directly create forced order flow, but by continuously affecting holding costs and leverage demand, it fundamentally alters the market's "flammability" and prepares the necessary soil for a liquidation cascade.

11.4.1 The margin-erosion effect

The funding rate was originally designed as a stabilizer that anchors the price to spot, but in a high-leverage environment it inevitably reveals its other face as a "chronic cash flow." For the paying side, the funding rate constitutes a continuous margin-consumption mechanism that steadily erodes the account's margin balance. This consumption is hard to notice in everyday trading, because it does not depend on violent swings in the market price but occurs mechanically with the passage of time. The direct consequence of this chronic erosion is that it dynamically raises the effective liquidation price, so that a position originally in the safe range imperceptibly moves close to the edge of liquidation. This process can be understood through a quantitative example. Amid extreme bull-market sentiment, the funding rate reaches 0.1% every 8 hours (about 109% simple annualized, about 198% compound annualized), a level recorded both at the peak of the 2021 bull market and on the eve of the October 2025 event [13]. A trader opens a 1 BTC long at the $100,000 price level with 10x leverage. The initial margin is $10,000, with a maintenance margin rate of 0.5% (i.e., $500).

Even if the market price stays exactly at $100,000, the position's margin balance is rapidly consumed within a short time simply because of funding payments. At this extreme rate, $300 of funding must be paid each day ($100 every 8 hours). At around day 31, the margin balance is fully depleted to the maintenance margin level, triggering liquidation. More dangerously, as margin decreases, its effective liquidation price moves up gradually from an initial level of about $90,500, eventually approaching the entry price. From the perspective of behavioral finance, this gradual erosion has a distinctive psychological stealth. The mental-accounting theory of Thaler (1999) [14] points out that traders tend to record funding-rate expenditures and position P&L in separate mental accounts, thereby underestimating the combined consumption effect of the two on the same margin pool. Prospect theory, meanwhile, predicts that small, high-frequency repeated losses are qualitatively different in psychological perception from a one-time loss of the same total amount; the funding rate deducted every 8 hours acts as a "small incision" whose cumulative effect is far below the trader's perception threshold, forming a "boiling frog" cognitive trap in which the continuous erosion of margin has pushed the position to the edge of liquidation before it is even perceived.

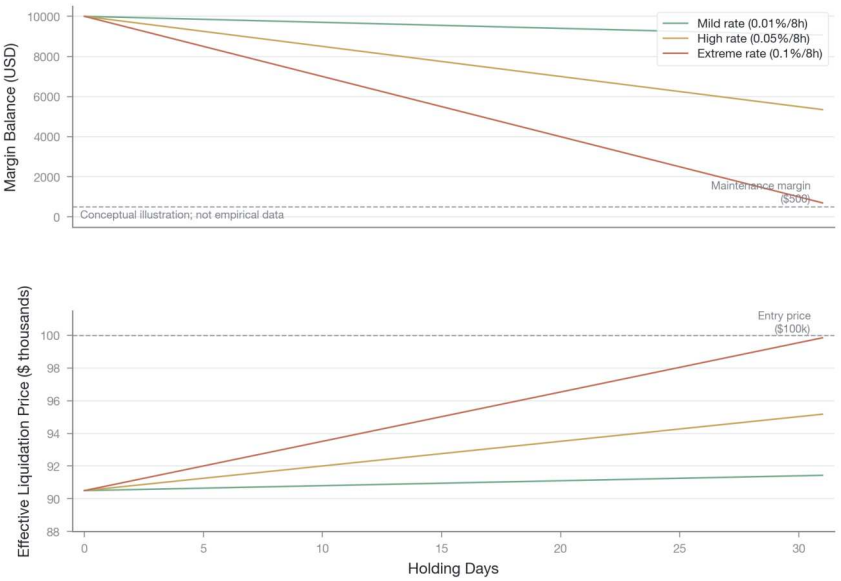

Figure 11-17. The erosion effect of the funding rate on the margin balance and the liquidation price (a numerical example based on an assumed rate; conceptual illustration; not empirical data)

The amplifying effect of the leverage multiple on this erosion process is nonlinear. Figure 11-18 shows the number of days required for positions at different leverage multiples to have their liquidation buffer fully depleted at the same funding rate (0.05% per 8 hours, i.e., about 55% simple annualized, about 73% compound annualized). A position at 100x leverage faces liquidation risk from rate erosion in only about 4 days, whereas a position at 5x leverage can withstand more than 60 days of rate consumption.

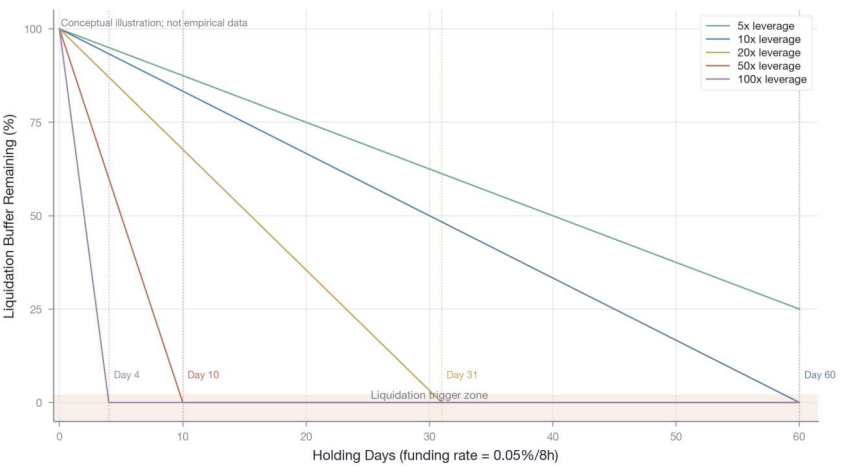

Figure 11-18. The cumulative erosion effect of the funding rate at different leverage multiples (a numerical example based on an assumed rate; conceptual illustration; not empirical data)

This constitutes a gradual process of risk accumulation. The funding rate is not only a pricing of the use of leverage but also a countdown on the account's survival time.

Moreover, the funding-rate mechanism itself contains a negative-feedback regulatory function: a high holding cost theoretically forces some leveraged longs to close voluntarily and simultaneously attracts arbitrageurs to enter through a "buy spot, short perpetual" strategy. This economic incentive is meant to push the market back toward equilibrium. This self-correcting design, however, relies on a key assumption: that arbitrageurs are both able and willing to carry out basis arbitrage. When this assumption is broken under extreme market conditions, the funding-rate mechanism degenerates from a "stabilizer" into an "accelerator."

11.4.2 The failure of basis arbitrage

In the normal market state, there is a healthy negative-feedback loop between the funding rate and basis arbitrage. When bullish sentiment runs high and drives the perpetual price above the spot price, the funding rate turns positive and keeps climbing. This attracts arbitrageurs: they short perpetual futures and go long spot, thereby depressing the perpetual price, narrowing the basis, and eventually returning the funding rate to a normal level. This loop is the core of the perpetual price's anchoring mechanism. During the transition from a normal period to a stress period, however, this negative-feedback mechanism can face three serious failure conditions that render the "stabilizer" ineffective.

Funding constraints are the primary factor in arbitrage failure. In an environment of extreme panic or credit tightening, arbitrageurs' funding costs rise sharply, and they may even face an inability to obtain funding at all. As the liquidity spiral model of Brunnermeier and Pedersen points out [8], when "funding liquidity" dries up, arbitrage is not only unprofitable but arbitrageurs themselves may even be forced to join the selling as they deleverage. At such times, far from acting as a force that stabilizes the market, they become drivers of greater volatility. During the "Black Thursday" event of March 12, 2020, even though the perpetual basis briefly fell to an extreme level below -30%, arbitrageurs were unable to enter because the funding market had frozen completely [4]. The crypto market, moreover, has no central-bank lender of last resort of the kind the traditional financial system provides. Once funding constraints tighten, no external mitigation mechanism exists, and the binding force of a liquidity drought is correspondingly far stronger than in traditional markets.

Inventory risk is the second constraint. When market volatility is extremely high, the cost of managing the price-fluctuation risk of a spot position becomes extremely expensive. Even if the basis between perpetual futures and spot appears to offer ample profit, arbitrageurs may choose to stay on the sidelines because they cannot effectively hedge the risk of a plunge on the spot leg. This arbitrage opportunity—present in theory but unobtainable in practice—allows the basis to remain anomalous for a long time. Shleifer and Vishny (1997) call this the "limits of arbitrage" [15]: even when there is an obvious pricing deviation, risk aversion and capital constraints prevent arbitrageurs from correcting it. At the same time, the cost of delta hedging also rises sharply, because in extreme conditions the implied volatility of the options market spikes in tandem, making the cost of hedging tail risk through options prohibitive.

Infrastructure-level constraints are especially prominent in the decentralized-exchange

environment. Extreme conditions are often accompanied by network congestion and spiking gas fees, which sharply compress the profit margin of arbitrage. At the same time, MEV activities such as sandwich attacks and transaction-ordering manipulation increase execution risk. The delays and security hazards of cross-chain bridges also limit cross-platform arbitrage efficiency. During the "yen carry-trade unwind" of August 5, 2024, API latency at multiple exchanges exceeded several seconds, making cross-platform arbitrage strategies nearly impossible to execute [16]. On the Ethereum network in particular, gas fees can spike 10- to 50-fold during extreme events, directly eroding the arbitrage profit margin and turning an otherwise profitable basis trade into a net loss after execution costs.

Beyond these three failure conditions, there are two further failure mechanisms that are equally critical in practice but less systematically analyzed. The first is funding-rate-reversal risk. Spot-perpetual basis arbitrage (long spot, short perpetual futures) earns a profit in normal markets by collecting a positive funding rate, but when a market crash triggers large-scale long liquidations, the funding rate can flip sharply from positive to deeply negative. At that point, the short position turns from a rate collector into a rate payer, and the arbitrageur faces a double penalty: the mark-to-market loss on the perpetual short (a temporary paper loss from price fluctuation, or margin pressure from an extreme widening of the basis) compounded by the continuous consumption of a negative funding rate. This double pressure may force the arbitrageur to close the short position that had been playing a stabilizing role, and closing a short is a buy operation, which reduces the hedging force against selling pressure on the perpetual side; at the same time, to rebalance delta, the arbitrageur may simultaneously sell the long position on the spot leg, thereby transmitting a shock originally confined to the perpetual futures market directly into the spot market. This mechanism reveals the direct link between Section 11.4.2 and Section 11.4.3: the failure of arbitrage means not only the passive absence of a stabilizing force but potentially the active transformation of a stabilizing force into a destabilizing one. The second is cross-exchange capital fragmentation. Executing basis arbitrage requires capital to be pre-distributed across multiple exchanges so that hedged positions can be established simultaneously on different platforms. During extreme events, however, exchanges may freeze or delay withdrawals, blockchain confirmation times may stretch from a normal few minutes to 10 to 60 minutes, and fiat deposit-and-withdrawal channels may close in tandem. Even if an arbitrageur has ample capital in aggregate, they cannot redeploy funds across platforms within a cascade window on the order of 40 minutes. This geographic and infrastructure-level capital fragmentation means that the system's effective arbitrage capital is far smaller than the nominal available capital, and the actual ceiling on arbitrage-absorption capacity is determined by the weakest link rather than by total capital.

When these constraints all take effect at once, the basis can widen sharply into deeply negative (or extremely positive) territory while arbitrageurs' absorption capacity rapidly decays. At this point, a high funding rate can no longer effectively suppress overheated leverage demand and instead becomes the critical factor that drives high-leverage positions into liquidation (Figure 11-19 contrasts two states: the effective operation of negative feedback in a normal period and the runaway of positive

feedback in a stress period).

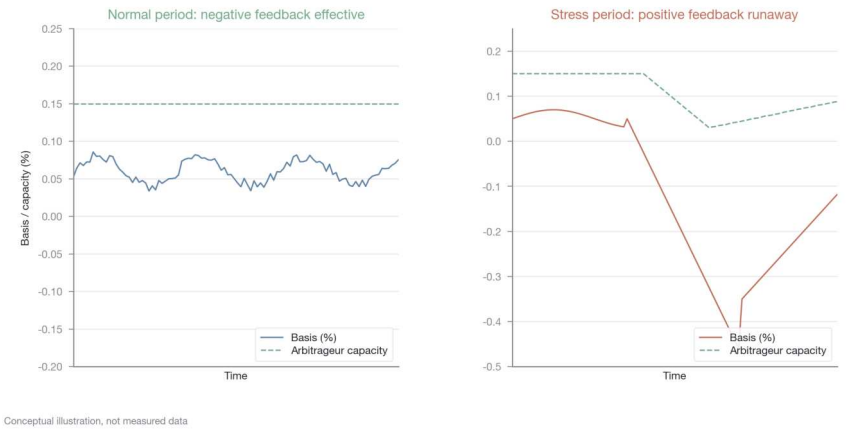

Figure 11-19. Comparison of the basis-arbitrage mechanism in normal and stress periods (conceptual illustration, not empirical data)

Figure 11-20 uses a flowchart to contrast how the arbitrage mechanism operates in normal versus stress periods.

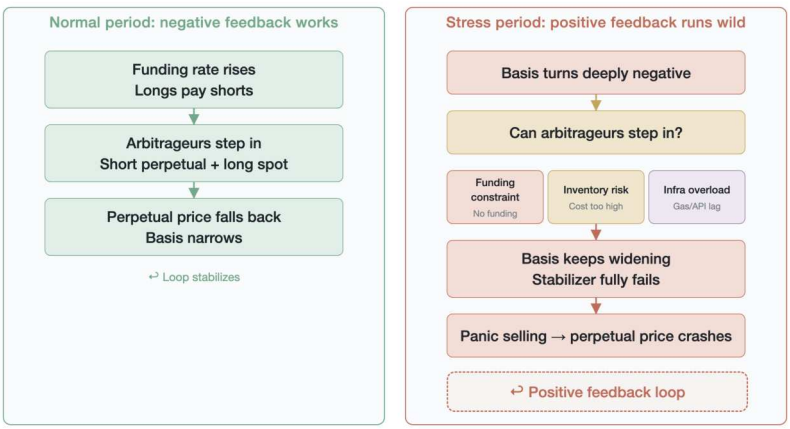

Figure 11-20. The process mechanism of basis-arbitrage failure

The core insight the flowchart conveys is that under normal market conditions arbitrageurs play the role of a negative-feedback stabilizer: when the basis deviates from a reasonable range, arbitrageurs' entry trades push it back toward equilibrium, closing the feedback loop and maintaining the anchoring relationship between the perpetual price and the spot price. Under stress conditions, however, three constraints activate simultaneously—funding constraints (arbitrageurs cannot obtain enough margin or borrowed funds), inventory risk (holding a spot hedge position faces violent mark-to-market losses), and infrastructure overload (exchange delays, API failures, on-chain congestion)—forcing arbitrageurs to withdraw or preventing them from entering at all.

When the executor of negative feedback is absent, the basis deviation is no longer corrected but instead keeps widening through panic contagion and a liquidity-siphoning effect, and the entire feedback loop turns from negative to positive. This shift in mechanism provides the direct precondition for the compound rate-liquidation positive feedback discussed in the next section: it is precisely because of arbitrageurs' systemic failure during a stress period that an extreme deviation in the funding rate can keep accumulating without being corrected by market forces.

11.4.3 The compound rate-liquidation positive feedback

The chronic erosion of the funding rate and the instantaneous shock of the liquidation mechanism do not operate in isolation; they are tightly coupled through their shared core variable, margin, forming a compound positive-feedback chain that weaves indirect pressure together with direct shock. This loop constitutes the most dangerous systemic-dynamics feature of perpetual futures markets.

This loop usually begins with a rate-extremization phase: in a strong one-sided trend, the funding rate stays at an extreme level. This high rate is deducted from the position holder every 8 hours (or, at some exchanges, every hour), continuously consuming their margin balance. This process systematically narrows the liquidation distance of all positions in the same direction, quietly "accumulating fragility" for the coming liquidation cascade. Because the system has been continuously consumed by the rate and has become extremely fragile, a tiny price reversal that would not otherwise be enough to spark a crisis (for example, a normal 2% pullback) is now sufficient to touch the liquidation line of positions that the rate has pushed to the edge, triggering the first batch of forced closures. The selling pressure from the first batch of liquidations drives the price down further and triggers more liquidations, and the liquidation reflexivity equation begins to diverge. As large-scale liquidation is executed, the market's position imbalance changes drastically, causing the funding rate to flip sharply—for example, from an extreme positive value to an extreme negative one in an instant. This sharp flip is not only a mechanical reaction of the market structure but also sends a strong signal to the entire market that "the trend has changed." This prompts the remaining longs to close voluntarily in a panic, joining forces with the liquidation engine's forced selling. In the end, high leverage is thoroughly cleared out, open interest plunges, and the system resets violently.

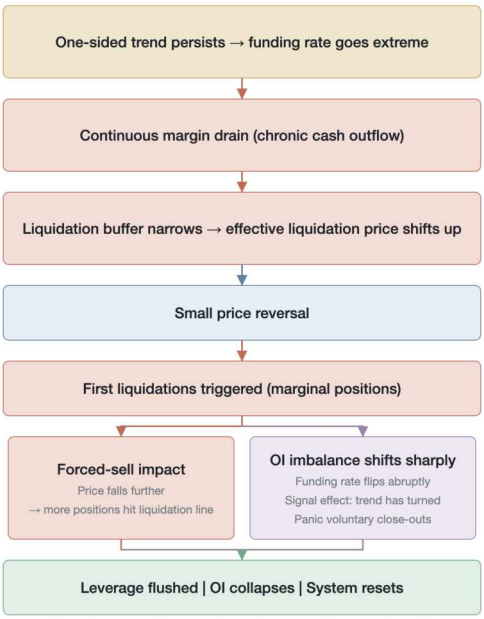

Figure 11-21. The compound rate-liquidation positive-feedback loop

In this nested loop, the "extreme termination path" is far more common than the "mild path." The mild path requires the price to stop moving in one direction before liquidations are triggered on a large scale, which is an extremely narrow condition in a system that has long been eroded by a high rate. By contrast, rate extremization itself accumulates potential energy for the liquidation cascade, and once the price reverses, this potential energy is released all at once. As the "10.10 event" of October 2025 demonstrated, the fundamental cause of a systemic collapse is often not the macro signal that triggers it but the extreme rate consumption of the preceding weeks, which is precisely what degrades the system from a robust metastable state into an extremely fragile, flammable one [17].

A counterfactual exercise helps quantify the contribution of rate erosion to the scale of the cascade. On the eve of the "10.10 event," the funding rate on BTC perpetual futures was about 30% annualized, which means the margin of a 10x-leverage long was eroded by about 1.2 percentage points over two weeks, compressing the liquidation distance of many positions from more than 5% to less than 3%. Had the rate been at a mild 10% annualized (the normal state for most of 2024), the margin erosion over the same holding period would have been only about 0.4 percentage points, and the vast majority of positions eroded to the edge would still have retained an ample liquidation buffer. On this basis, in the counterfactual 10%-rate scenario, the scale of positions liquidated in the initial trigger phase would have been reduced by about 40% to 50%. This range estimate is sensitive to the assumptions about the shape of the leverage distribution and the holding period; if leverage concentration were higher or the average

holding time longer, the actual reduction could deviate from this range. Because of the nonlinear amplification of the liquidation reflexivity equation (each round's liquidation volume determines the next round's trigger scale), the total liquidation scale of the cascade might have shrunk by about 35% to 45%, that is, to about \$10.5 billion to \$12.5 billion. This counterfactual exercise is a partial-equilibrium analysis: a lower funding rate would itself change the equilibrium open interest and market makers' willingness to supply liquidity, placing the entire market microstructure in a different initial state. Moreover, the mapping from initial trigger scale to total cascade scale is highly nonlinear, and its amplification factor depends on the specific shape of the liquidation density function (that is, whether the distribution of liquidated positions on the price axis is a concentrated "fat tail" or a dispersed "thin layer"), a distributional feature that directly determines the cascade's acceleration and duration. This estimate shows that the long-run accumulation effect of the funding rate has an influence on the cascade's ultimate destructiveness of the same order of magnitude as the trigger shock itself, and that rate governance should be regarded as a core element of systemic-risk management rather than merely an auxiliary tool for anchoring the market price.

The funding rate and the liquidation mechanism—one slow and one fast, one hidden and one visible—together forge the endogenous systemic risk of perpetual futures markets.

11.5 The four phases of a liquidation cascade

A liquidation cascade is not a crash achieved in one step but a dynamic process with a clear evolutionary path. It typically passes through four logically progressive phases: trigger, propagation, amplification, and termination. In each phase a different mechanism dominates the market's direction, and identifying the key signals of these phase transitions not only provides observable clues for understanding extreme events but also offers a theoretical basis for risk warning and intervention. This section integrates the liquidation reflexivity equation (Section 11.3) and the rate-coupling effect (Section 11.4) discussed earlier into a complete dynamic narrative, using the "10.10 event" of 2025 as the primary reference case.

Table 11-4 summarizes the key decision indicators and thresholds for the four phases, providing an operational reference framework for identifying in real time which phase a cascade is in.

Phase	CRI range	LIAR range	Feedback gain G	OI change	Depth change	Dominant mechanism
Trigger	0.8–1.2	> 1.0	< 1.0	$< -5\%$	$< -30\%$	Exogenous shock + marginal liquidations
Propagation	1.2–2.0	0.5–1.0	≈ 1.0	-5% to -15%	-30% to -70%	Liquidation reflexivity loop activates
Amplification	> 2.0	< 0.5	1.0	-15% to -35%	$> -90\%$	Multi-mechanism resonance; depth goes to zero
Termination	Falls back to < 1.0	Recovers to > 1.0	< 1.0	Stabilizes	Slow recovery	Leverage cleared + external buying

Table 11-4. CRI/LIAR decision thresholds and key indicators for the four phases of a liquidation cascade (Note: LIAR, the liquidation-impact absorption rate, $\approx$ available depth / liquidation volume per unit time, which is approximately inversely proportional to the feedback gain $G = \alpha\beta L/D$; the two are based on different measures—LIAR uses instantaneous visible depth and G uses cross-exchange effective depth—so they are placed side by side as independent diagnostic columns. The CRI column in this table is an illustrative standardized scale, on a different basis from the unstandardized raw estimates in Table 11-3, so the empirical banding of Section 11.3.5 cannot be applied to it directly. The indicators in this table are contemporaneous phase diagnostics, not forward-looking warnings.) (Data source: constructed by the author)

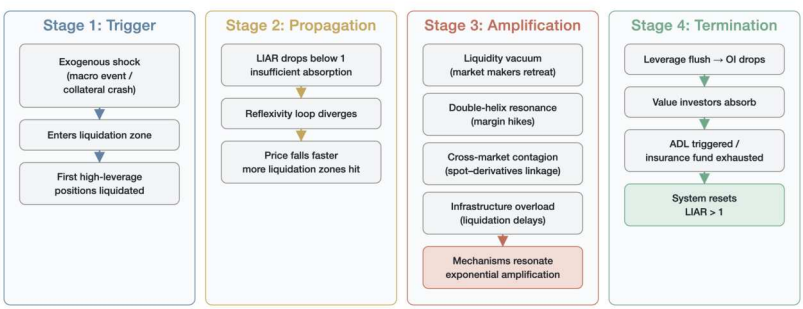

Figure 11-22. Overview of the four-phase liquidation-cascade process

11.5.1 The trigger phase

The starting point of a liquidation cascade is usually an exogenous market shock. This shock need not be large in itself; its key role is to break the system's prior metastable state and push the market price precisely toward the first significant liquidation-dense zone. Here the relationship between the trigger factor and the underlying fragility must be clearly distinguished: the trigger factor is a necessary but by no means sufficient condition, and what really determines whether a shock is absorbed or amplified is the degree of structural fragility the system has already accumulated before the shock arrives—including leverage density, the concentration of liquidation prices, and the thickness of the liquidity buffer.

The sources of trigger factors are highly diverse. A trigger may be a piece of macroeconomic news (such as the unexpected report about the trade dispute in the "10.10 event"), a violent move in the price of a related asset (such as a plunge in an important collateral asset or a brief stablecoin depeg), or even a malicious attack on a weak point in market liquidity (such as "oracle manipulation"). Table 11-5 summarizes the trigger factors and key characteristics of several major liquidation-cascade events in recent years.

Event	Trigger factor	24-hour liquidations	BTC max drawdown	Main cascade duration
March 12, 2020, "Black Thursday"	COVID-19 panic + global sell-off of risk assets	~$6 billion	~39%	~48 hours
May 19, 2021, "5.19 crash"	China's regulatory policy + Musk's remarks	~$8.6 billion	~30%	~12 hours
June 13, 2022, "Luna aftershock"	Chain liquidations of Three Arrows Capital/Celsius	~$4.8 billion	~17%	~24 hours
August 5, 2024, "yen carry-trade unwind"	Bank of Japan rate hike + global unwinding of carry trades	~$10.2 billion	~15%	~8 hours
October 10, 2025, "10.10 event"	Unexpected escalation of the trade dispute	~$19 billion	~14.5% (spot; perpetual wicks of about 16%–17%)	~1.5 hours

Table 11-5. Comparison of major liquidation-cascade events in recent years (Data source: CoinGlass [9], CoinGecko [3], Amberdata [2]). Note: the 24-hour total liquidations for each event use different sources and statistical bases (single-exchange versus market-wide, single-day versus multi-day, and notional versus actual liquidations differ substantially), and the 2020/2021 figures are aggregate estimates with high range uncertainty, so cross-event comparisons should emphasize orders of magnitude rather than precise values

A thought-provoking trend can be observed in the table above: as the crypto derivatives market has grown, the visible forced-liquidation notional of liquidation cascades has kept climbing while the duration of the cascades has shortened markedly. The "10.10

event" of 2025 set a new record for single-day liquidations in only about 1.5 hours (see the chapter opening), indicating that both the leverage density and the liquidation efficiency of the market are rising sharply and that the reaction window left to traders and risk-control systems is narrowing.

In the trigger phase, the market's reaction is usually local. Only the traders with the highest leverage and the most extreme risk appetite are liquidated. At this point, overall market liquidity is still ample, and the forced-closure orders produced by the liquidation engine can be absorbed smoothly by the market. The price decline is relatively linear, and the system has not yet entered an out-of-control state. Whether the trigger phase evolves into the more serious propagation phase depends on one key dynamic balance: whether the selling pressure from the first wave of liquidations exceeds the market's normal absorption capacity. If market depth is sufficient to take on this selling, the shock is dissolved in this phase; if the selling pressure is too great, the system inevitably slides into the next phase. In terms of the LIAR indicator introduced in this chapter, the trigger phase corresponds to the range in which LIAR is still greater than 1—that is, market depth can still take on the liquidation selling pressure. What distinguishes an event that dissolves on its own in the trigger phase from one that ultimately evolves into a systemic cascade is whether the first round of liquidations pushes LIAR below the critical value. Historical data show that in the "yen carry-trade unwind" of August 2024 LIAR briefly fell below 1 in the trigger phase and then quickly recovered, whereas in the "10.10 event" of 2025 LIAR, once it fell below 1, kept accelerating downward and never turned back.

11.5.2 The propagation phase

To quantitatively assess the critical point of phase transition, we introduce a core decision variable: the liquidation-impact absorption rate (LIAR). The design advantage of LIAR is that it integrates both the demand side (liquidation volume per unit time) and the supply side (available order-book depth) of the liquidity equation, making it a more comprehensive measure of system stress than a bare open-interest/market-cap ratio or a simple depth indicator.

> LIAR = available order-book depth within a specific price range / liquidation volume per unit time

When LIAR > 1, the market has enough liquidity to absorb the current liquidation shock. Although the price may fall, its rate of decline is relatively controllable, and the liquidation cascade tends to converge. When LIAR < 1, however, liquidation volume has overwhelmed the market's immediate absorption capacity. At this critical point, the price begins to accelerate downward, the divergence condition of the liquidation reflexivity equation described in Section 11.3 is satisfied, and the positive-feedback loop is formally activated. The system state undergoes a jump into the highly destructive amplification phase. LIAR is essentially a real-time phase-diagnostic indicator, not a forward-looking warning signal. By the time LIAR falls below 1, the cascade is already under way, and the collapse of order-book depth is itself an endogenous product of the liquidation process rather than an exogenous condition independent of it. LIAR's

denominator (available order-book depth) contracts sharply after liquidation begins as market makers withdraw their orders, which means the indicator reflects the current system state rather than the future trajectory. A truly forward-looking improved version should use estimated depth under a stress scenario (for example, assuming that X% of visible resting orders are withdrawn under the shock of adverse order flow, which is typical market-maker behavior when facing toxic liquidation flow) and compute the ratio of remaining depth to expected liquidation volume under that condition, so as to identify the system's fragility before a cascade actually begins.

The essence of the propagation phase is its contagiousness: the price decline caused by the first wave of liquidations does not stay in place but pushes the market price toward the next liquidation zone—potentially larger and more densely distributed—like the first link of a chain reaction, setting off a second and a third wave of liquidations. In this phase, the reflexivity loop between leverage and liquidation begins to replace fundamental information as the core force dominating the price's trajectory. The market's price movements are no longer driven by fundamental information but dominated by the leverage-clearing process. Figure 11-23 uses four panels to show, respectively, the dynamic evolution of price, open interest, per-minute liquidation volume, and the LIAR indicator across the full trigger-propagation-amplification-termination process (based on the data pattern of the 10.10 event of 2025).

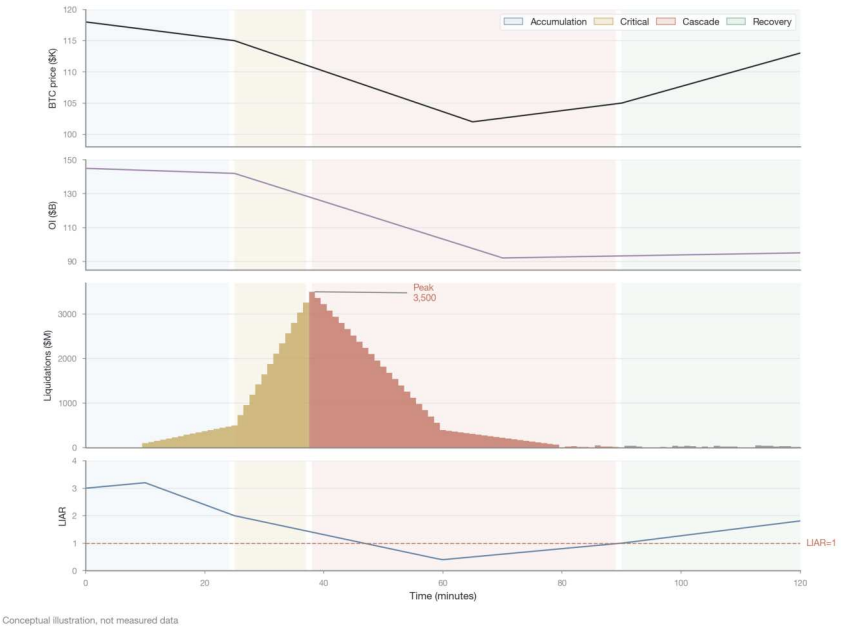

Figure 11-23. A four-phase dynamic model of the liquidation cascade (conceptual illustration: a stylized dynamic model by the author based on the data pattern of the "10.10 event" of 2025, not tick-by-tick empirical data)

11.5.3 The amplification phase

When LIAR stays below 1, the system enters the most destructive phase of the entire cascade: the amplification phase. Now a single loss spiral evolves into a resonant superposition of multiple amplification mechanisms, sharply magnifying what was a controllable risk into a systemic crisis, with multiple amplification mechanisms acting simultaneously and superimposing in resonance.

As liquidation orders continue to consume the buy orders on the order book mechanically, market makers, facing a sharply expanding risk exposure and extremely high uncertainty, choose to withdraw their quotes (i.e., "procyclical liquidity supply"). This causes order-book depth to fall sharply and bid-ask spreads to widen markedly. Subsequent liquidation orders face enormous slippage on execution, with actual fill prices far below the mark price. This slippage itself constitutes an additional huge loss that further erodes traders' margin and may even lead to bankruptcy (i.e., losses exceeding all posted margin). During the "Black Thursday" crash of March 2020, BitMEX's BTC perpetual futures briefly wicked to about $3,600 on March 13 (an instantaneous low at a single venue), a discount of about 12% to the spot price—an extreme manifestation of the liquidity vacuum [4].

The violent price fluctuations simultaneously trigger the "margin spiral" of the Brunnermeier and Pedersen model [8]. To control risk, an exchange's automated risk model may dynamically raise maintenance margin requirements or lower the collateral factor on collateral. This suddenly subjects positions that had been safe to margin-call pressure, forcing traders to close voluntarily. This active selling resonates with the liquidation engine's passive sell orders, jointly intensifying the market's selling pressure. Under a unified margin system this effect is especially pronounced: when the volatility metric rises sharply, the system automatically raises margin requirements for all instruments, subjecting a large number of previously safe positions to margin-call pressure at once.

Under the unified margin system, a plunge in one asset weakens the credit base of the entire account, forcing the liquidation of positions in otherwise unrelated assets. At the same time, arbitrageurs' behavior rapidly transmits the selling pressure of one exchange to the whole market, forming cross-exchange contagion. In addition, the liquidation of perpetual futures depresses the futures price and turns the basis negative, prompting arbitrageurs to sell spot (closing the spot long in their arbitrage position) and thereby transmitting the crisis from the derivatives market to the spot market, forming a cross-market reflexivity loop. This mechanism explains why, during a liquidation cascade, the spot market's decline is often highly synchronized with the derivatives market and can even exhibit the anomaly of spot leading the fall. Determining the causal direction between spot and perpetual futures during a cascade, however, requires rigorous lead-lag analysis methods (such as the Hasbrouck information-share model or the Granger causality test). In the 10.10 event, the causality was most likely two-way: the liquidation selling pressure of perpetual futures and the panic selling of the spot market reinforced each other, forming a closed positive-feedback loop, which makes clear causal attribution methodologically very difficult in the absence of high-frequency data decomposition.

The carrying capacity of infrastructure is far from a secondary technical constraint in

cascade dynamics; it is one of the primary determinants of the cascade's trajectory. During an active cascade, which infrastructure component fails first (the API gateway, the liquidation queue, or the matching engine) determines the cascade's actual evolutionary path. In BitMEX's service outage of March 2020 (March 13), matching and liquidation stalled for about 25 minutes (officially attributed to a DDoS attack), producing an enormous gap between actual execution prices and theoretical trigger prices and thereby sharply amplifying bankruptcy losses [4]. Some exchanges are reported to have deliberately slowed their matching engines in extreme conditions, using this as a de facto circuit breaker. Although this practice may objectively have had a protective effect in curbing the cascade, it raised serious questions of market fairness, because it constituted an implicit intervention that gave some participants (for example, institutions able to trade through over-the-counter channels) an asymmetric advantage over retail traders who depend on the exchange engine. Infrastructure capacity is therefore not merely an engineering problem but a key variable determining whether a cascade is contained within a controllable range or evolves into a catastrophic collapse.

In extreme conditions, an exchange's trading engine may lag, API responses may slow, and the front-end interface may fail to load. Traders cannot add margin, adjust positions, or set stop-losses in time. More seriously, the liquidation engine itself may become congested as requests surge, delaying liquidation execution. During the delay, the price has often already fallen to a lower level, further amplifying the actual loss.

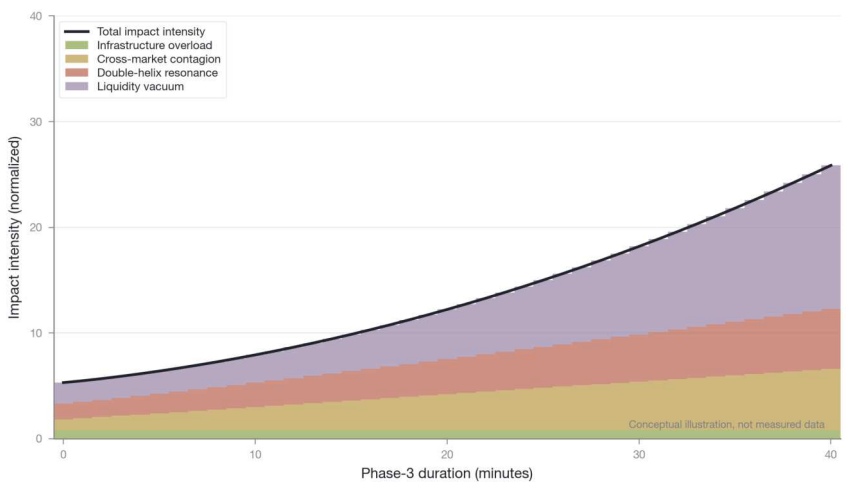

Figure 11-24. The resonant superposition of four mechanisms in the amplification phase (conceptual illustration, not empirical data)

To clearly delineate the risk level the system is in, we can divide the interaction state of the perpetual futures and spot markets into three categories, as shown in Table 11-6. This classification framework helps to assess in real time whether the market is sliding from a normal state toward a dangerous one.

Market state	Basis characteristics	Arbitrage activity	Feedback type	Order-book depth behavior	LIAR indicator
Normal state	Narrow fluctuation ($<$ 0.1%)	Active, full absorption	Negative feedback, self-correcting	Ample, normal level	> 2.0
Stress state	Significant widening (0.1%–0.5%)	Under pressure, partial withdrawal	Positive feedback beginning to appear	Declining, down 30%–60%	0.5–1.0
Extreme state	Violent deviation ($>$ 0.5%)	Withdrawal, near standstill	Positive feedback fully out of control	Evaporation, more than 90% gone	< 0.2

11.5.4 The termination phase

A liquidation cascade does not continue indefinitely. Once the market has passed through this violent phase, it enters the termination phase. A cascade, however, usually ends not because the market has found a new fundamental equilibrium but because the leverage available to be liquidated has already been exhausted. This is a violent but effective forced-deleveraging mechanism.

The termination of a cascade is usually the joint work of several mechanisms. Among them, leverage clearing is the most natural way to terminate. Once the vast majority of high-risk leveraged positions have been force-closed, subsequent price declines can no longer trigger enough new liquidation volume. At this point, selling pressure drops abruptly, the LIAR indicator recovers back above 1, and the loss spiral stops operating. During this process, market-wide open interest falls sharply. In the "10.10 event" of 2025, according to Amberdata, open interest in crypto perpetual futures fell from a peak of about \$146.6 billion to a trough of about \$109.9 billion (a peak-to-trough decline of about -25.03%; this basis is Amberdata's aggregate perpetual OI across the venues it covers, accessed on June 23, 2026), marking a large-scale clearing of leverage [2].

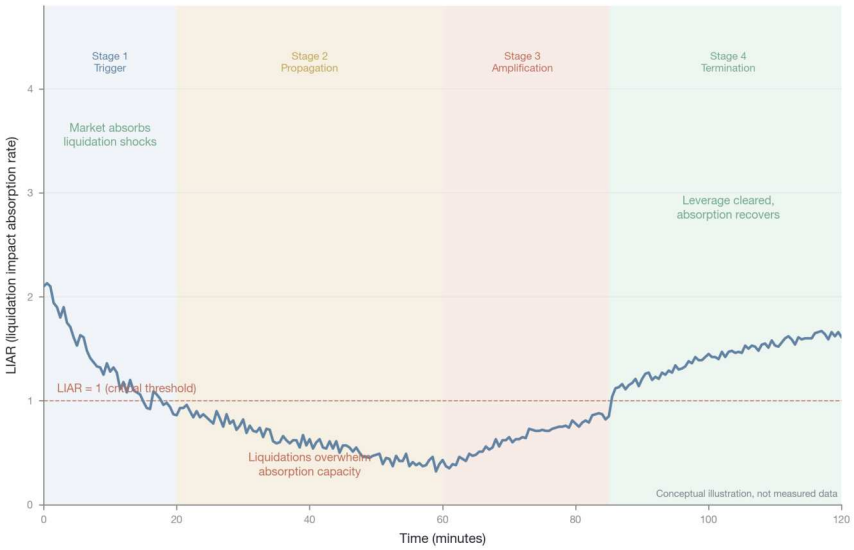

Figure 11-25. The dynamic evolution of LIAR across the four phases of a liquidation cascade (LIAR is an indicator constructed by the author; conceptual illustration, not empirical data)

As the figure shows, LIAR falling below 1 marks the activation of the reflexivity loop (the propagation phase), remaining below 0.2 marks the extreme state of the amplification phase, and recovering back above 1 marks the termination of the cascade.

When the price falls, driven by irrational liquidation selling, far below the fair value recognized by long-term investors, the entry of external buying also helps the market stabilize. These value investors provide deep absorbing liquidity that effectively soaks up the remaining liquidation selling pressure. In on-chain markets, this phenomenon manifests as the on-chain behavior of "whale addresses" buying heavily at the bottom of a crash. On-chain data analysis can track the fund flows of these large addresses in real time, and when a cohort of addresses holding more than 1,000 BTC shows accelerating net inflows during a rapid price decline, it often foreshadows the formation of bottom-absorbing force. This contrarian buying by "smart money" provides a natural price floor for panic selling.

The termination of a cascade also has a behavioral dimension that goes beyond mechanical leverage clearing. Panic selling follows a specific temporal pattern (an initial freeze response, then concentrated selling, and finally the exhaustion of the capacity for emotional selling), a process that runs independently of the mechanical liquidation cycle. Defining all whale-address buying at the bottom of a cascade as the value investing of "smart money" warrants careful critical scrutiny: some large-address activity at a cascade's bottom involves strategic price manipulation (buying to trigger a short squeeze), the release of social-media signals (publicly announcing purchases to influence market sentiment), or the building of reputational capital, rather than a deep judgment about the asset's fundamental value. The actual bottoming process often passes through a vacuum period in which no effective two-sided market exists—neither sufficient buy-side liquidity nor sustained sell-side pressure—and the market gradually finds a temporary equilibrium amid extremely shrunken trading volume.

Moreover, the narrative of orderly value buying at the bottom of a cascade contradicts the actual execution environment in significant ways. During an active cascade, an exchange's API interface frequently becomes unresponsive or imposes strict rate limits, making order submission extremely difficult or even impossible. Deposit and fund-transfer mechanisms may be suspended, preventing new capital from entering the market. Extreme bid-ask spreads (peaking at 26.43 basis points in the 10.10 event) mean that any buy order submitted as a market order will suffer enormous slippage losses. Most critically, professional market makers choose to withdraw rather than enter during a cascade, because the adverse-selection problem of liquidation flow is extremely severe, and any buy order resting on the order book is systematically eaten by the continually declining forced sell orders. A true bottom often forms in a vacuum period in which neither side provides meaningful liquidity, rather than through an orderly handoff from forced sellers to voluntary buyers.

An exchange's manual intervention can likewise arrest a cascade. In extreme cases, an exchange may take various intervention measures, such as temporarily raising maintenance margin requirements to suppress the impulse to open new leverage, or, in some highly contested cases, triggering a brief circuit breaker (suspending trading) to stem the spread of panic. Some exchanges also temporarily lower the maximum leverage multiple or impose trading restrictions on specific contracts.

After bankruptcy losses exhaust the insurance fund, auto-deleveraging is activated as the final resort, force-closing the positions of profitable parties to cover the bankruptcy losses and preserve system solvency (its ranking mechanism and fairness disputes are detailed in Section 11.6.3). The large-scale triggering of ADL usually marks the end of the most dangerous and chaotic phase of a liquidation cascade.

Viewed from the standpoint of system dynamics, the entire four-phase process reveals a clear regularity: the destructiveness of a liquidation cascade depends not primarily on the size of the trigger shock but on the degree of fragility of the system before the shock arrives. A system long eroded by extreme funding rates, with very high leverage density and a highly concentrated liquidation-dense zone, can erupt into a devastating cascade even in the face of a tiny exogenous disturbance. Conversely, a system with moderate leverage, a dispersed liquidation distribution, and ample liquidity can smoothly absorb even a large exogenous shock. This is precisely the core proposition this chapter has repeatedly stressed: the reflexivity of leverage and liquidation is the most important source of endogenous risk in the crypto derivatives market.

11.6 The impossible trinity of liquidation design

In on-chain derivatives and crypto-asset perpetual futures markets, the liquidation mechanism is the last line of defense for maintaining system solvency. Unlike traditional financial markets, which handle risk through a clearinghouse's default waterfall and manual intervention, liquidation in crypto markets relies entirely on preset algorithms and smart contracts. This algorithmic character means that the design of the liquidation mechanism faces severe trade-offs. Research shows that a strict mathematical boundary exists within automated deleveraging and liquidation mechanisms: the

"impossible trinity of liquidation design" [18].

11.6.1 The three design objectives

In designing a liquidation engine, any exchange or DeFi protocol tries to achieve the following three core objectives simultaneously:

The optimal-execution theory of Almgren and Chriss shows that executing a large order involves a fundamental trade-off between market impact and timing risk [19]. The design of a liquidation engine faces essentially the same dilemma, but under harsher constraints, because liquidation must be completed in an extremely short time and cannot choose its timing. Against this backdrop, the conflict among the three design objectives becomes especially sharp. Certainty means the liquidation mechanism must be able to ensure that the system remains solvent under any extreme market condition—that is, when a trader's account equity falls below the maintenance margin requirement, the system must be absolutely certain of being able to close the position and prevent bad debt (bankruptcy); this is the cornerstone of an exchange's survival, and a lack of certainty leads to systemic insolvency. Impact minimization means the negative effect of liquidation on market price and liquidity should be as small as possible, because large-scale forced closures release enormous selling (or buying) pressure into the market, drive the price further from fundamentals, and can thereby trigger the liquidation of more accounts in a "positive-feedback loop"; impact minimization therefore requires the liquidation engine to digest risk positions smoothly. Fairness means the liquidation process should be fair to all market participants and, in particular, must not deprive innocent traders (such as profitable ones) of their legitimate gains without cause; in an ideal state, risk should be borne by the party that took it on (the liquidated party) or absorbed by a system-established insurance fund, rather than arbitrarily shifted to other participants in the system.

11.6.2 The conflict among objectives

There is a deep structural conflict among these three objectives that makes it impossible to achieve all of them perfectly in a single mechanism at the same time. Recent theoretical research on auto-deleveraging mechanisms has even given a formal proof of an impossibility theorem from the perspectives of game theory and mechanism design [18].

The conflict between certainty and impact minimization is the most intuitive. To guarantee 100% certainty, the system often needs to sell all positions at market immediately when liquidation is triggered. This cost-agnostic selling, however, inevitably causes an enormous market impact. Conversely, if the system chooses to process positions slowly and in batches to minimize impact, then in extreme conditions of violent price fluctuation this delay may cause a position to go bankrupt before it is fully closed, thereby undermining certainty.

At the same time, the conflict between certainty and fairness is especially prominent in extreme conditions. When routine liquidation cannot be executed and the insurance fund is exhausted, the system's only option to preserve its own certainty (avoiding insolvency) is to activate auto-deleveraging, forcibly closing profitable traders' positions

to cover the losing side's bad debt. Although this preserves the system's certainty, it severely harms the fairness owed to profitable traders, forcing them to bear a risk that was never theirs.

Further analysis shows that the conflict between impact minimization and fairness manifests in the process of risk transfer. If, to avoid slamming large positions directly onto the market (impact minimization), the system chooses to transfer these positions to specific liquidity providers or market-making vaults, it is in effect concentrating unknowable tail risk onto that group of participants. When the market keeps deteriorating, these backstops may face a devastating blow, which is essentially also an unfair allocation of risk to a specific group.

Notably, this impossible trinity is not a wholly new discovery of crypto markets. The central counterparty (CCP) clearinghouses of traditional financial markets face the same fundamental tension in their mechanism design among certainty, impact minimization, and fairness (Duffie and Zhu, 2011 [20]; Pirrong, 2011 [21]). A CCP absorbs losses layer by layer through a default-waterfall mechanism and, under the constraints of a legal framework, achieves relatively clear rules for risk allocation (the layered structure of the central counterparty and the default waterfall is discussed in Chapter 1). The crypto derivatives market, however, faces harsher constraints on three dimensions. First, there is no legal-level loss-mutualization framework: a traditional CCP's loss-sharing mechanism relies on legally binding agreements among clearing members and on regulatory authorization, whereas the relationship between a crypto exchange and its users is established only through terms of service, lacking an equivalent legal basis for multilateral risk mutualization. Second, there is no central bank as a lender of last resort providing liquidity support: when a traditional CCP faces systemic pressure, the central bank can inject liquidity through emergency lending facilities to prevent cascading defaults, whereas the crypto market has no equivalent external liquidity-injection mechanism. Third, the time scale of margin calculation is compressed from a traditional CCP's intraday or overnight settlement to real-time, position-by-position updates, so that the entire process from detecting a shortfall to executing liquidation is compressed from hours to milliseconds, largely eliminating any possibility of manual intervention or mediation.

Figure 11-26. The impossible trinity of liquidation design—the positioning of the four liquidation modes (conceptual illustration, not empirical data)

11.6.3 The four liquidation modes

Faced with the impossible trinity, different exchanges and protocols make different trade-offs according to their own positioning and technical architecture, giving rise to four typical liquidation modes:

Cliff-edge liquidation is common at early crypto exchanges and some DeFi protocols (the mechanism is detailed in Section 11.1.3). It strikes a balance between certainty and fairness: it strictly follows the principle that "whoever defaults is liquidated" and executes decisively, but at the cost of abandoning impact minimization entirely, so it readily triggers a deep price cliff and a liquidation cascade when liquidity is scarce. Progressive liquidation is adopted by most modern centralized exchanges, exemplified by Binance and OKX (the mechanism is detailed in Section 11.1.3) [22]. It reduces positions by a fixed proportion or in a stepped fashion, mitigating market impact to some degree and being relatively fairer to the liquidated party, but it also sacrifices some certainty (the price may keep deteriorating and drive the remaining position into bankruptcy). The vault-backstop mode is a new mode that has emerged in recent years at decentralized perpetual futures exchanges such as Hyperliquid (the mechanism is detailed in Section 11.1.3) [23]. It transfers liquidated positions to a market-making vault composed of liquidity providers (such as the HLP vault) to be digested gradually, achieving impact minimization to a great degree but severely sacrificing fairness, because vault investors are forced, without their knowledge, to bear the tail risk of high-leverage traders' high-risk assets. Auto-deleveraging is the extreme mechanism that exists as the last line of defense (the mechanism is detailed in Section 11.1.3): when bankruptcy has already occurred and cannot be covered by routine means, the system forcibly closes the positions of the profitable side, ranked by "most profitable, highest leverage," to hedge the bad debt, pushing certainty to the extreme at the cost of shattering fairness completely. In the extreme conditions of October 10, 2025, research

shows that Hyperliquid triggered the first cross-margin auto-deleveraging in its operating history, of which about $653 million was overshoot beyond the actual bankruptcy shortfall (about $23 million), corresponding to an additional loss of about $45 million to $52 million for profitable traders [18] (this quantitative conclusion comes from Chitra's preprint and awaits cross-validation against on-chain data and peer review). The judgment of "overuse," however, requires further precision. Key questions include: at the moment ADL was triggered, did the insurance fund still have sufficient solvency to cover the bankruptcy losses? Did the ADL ranking algorithm (usually a weighted ranking based on profit percentage and effective leverage) have a bias in actual execution? Were the threshold parameters that trigger ADL adequately calibrated and backtested in advance? The answers to these questions will determine whether the event's nature is an inherent flaw in the system design or a technical error in parameter calibration. From a legal standpoint, in traditional financial markets forcibly closing a position that is correct in its directional judgment and in a profitable state would immediately provoke legal challenges; the losses to the profitable side caused by the overshoot above constitute quantifiable, concrete damages, and affected traders would in principle have the right to claim compensation. The adequacy and legal validity of the risk disclosure about the ADL mechanism in the exchange's terms of service will be the core factor determining the ultimate direction of this dispute.

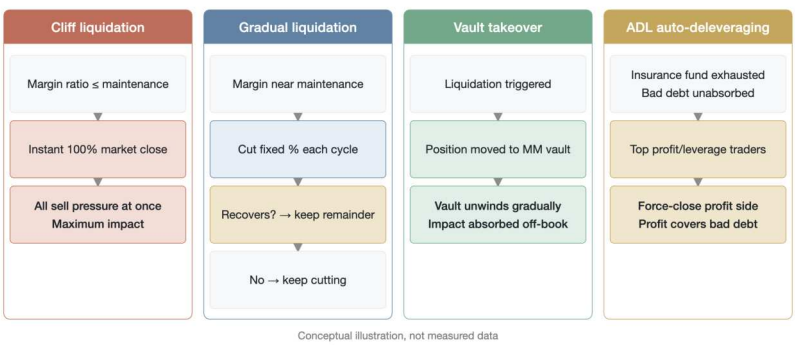

Figure 11-27. Comparison of the execution processes of the four liquidation modes

11.6.4 Strategic liquidation

The inherent design flaws of the liquidation mechanism often give rise to an attack behavior known as "strategic liquidation." Attackers exploit the mechanical nature of the liquidation engine, deliberately manipulating the price to trigger others' liquidations and profiting from it. The feasibility and manifestation of this attack differ across liquidation modes.

Under cliff-edge liquidation, strategic liquidation is most feasible: an attacker need only commit a relatively small amount of capital to push the price to a key support/resistance level, triggering large-scale liquidation orders that then self-reinforce and drive the price far from fair value, so that the attacker can buy at the low and reap a rich profit. By contrast, under progressive liquidation, because positions are released in batches,

an attacker must apply continuous pressure to sustain the liquidation cascade, which markedly raises the cost of the attack and lowers the expected profit potential. The common feature of these two attack modes is that the attacker triggers the mechanical response of the liquidation mechanism through direct price manipulation, differing only in the force required and the duration.

Under the vault-backstop mechanism, the attack vector of strategic liquidation shifts from price manipulation to risk offloading, evolving into "attacking the vault." For example, in the Hyperliquid whale incident of March 12, 2025, a whale trader deliberately built a huge high-risk position and triggered liquidation by withdrawing margin, causing the HLP vault to bear a loss of about $4 million and setting off a subsequent panic withdrawal [24]. The JELLY incident on the 26th of the same month was another, more complex kind of attack: the attacker used the external spot market and oracle transmission to force the HLP vault to take on the short risk of a memecoin, with a peak unrealized loss of about $12 million to $13.5 million, which ultimately turned into a small surplus or a limited loss after validators intervened. Both incidents exploited the structural exposure of the vault to absorbed risk, but their attack paths and profit-and-loss bases differed. Under the ADL mechanism, strategic liquidation manifests as a more insidious distortion of participant behavior: fearing being force-closed by the system, profitable traders may close early or deliberately lower their leverage to avoid the ADL ranking, and this preventive "ADL-avoidance" behavior drains liquidity from the market and instead hastens the market's collapse. Attacks under the vault-backstop and ADL modes both essentially exploit structural loopholes in the risk-redistribution logic of the liquidation mechanism, achieving the attack's aim by distorting the system's incentives; the JELLY-style path additionally layers on external price manipulation and oracle transmission.

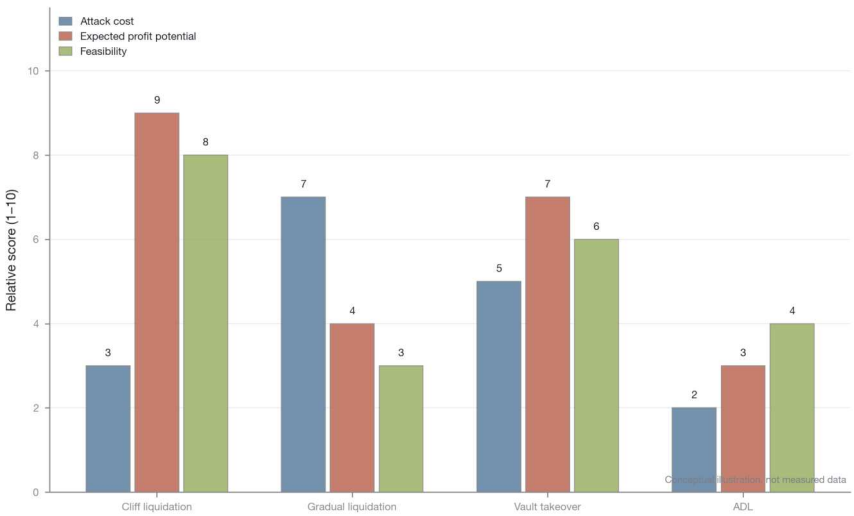

Figure 11-28. Comparison of the cost, profit, and feasibility of strategic liquidation across the four modes (conceptual illustration; qualitative relative values; not empirical data)

The comparison in Figure 11-28 shows that as the liquidation mode evolves from cliff-edge to vault-backstop, the direct feasibility of strategic liquidation declines, but the

attack vector shifts from price manipulation to offloading risk onto the vault. Under the auto-deleveraging mode, the form of strategic liquidation further evolves into a preventive distortion of participant behavior: the profitable side exits the market early to avoid being force-closed, which instead accelerates the contraction of liquidity. This finding shows that the choice of liquidation mode affects not only the system's immediate stability but also the long-run behavioral incentives of participants.

A game-theoretic analysis of strategic liquidation must incorporate the modulating role of legal deterrence as an external constraint. In traditional financial markets, deliberately manipulating the price to trigger others' liquidations falls within the scope of several legal frameworks: U.S. SEC Rule 10b-5 classifies it as a form of securities fraud, the EU Market Abuse Regulation (MAR) expressly lists market manipulation as a criminal offense, and the CFTC has already engaged in enforcement in the crypto space—for example, Avraham Eisenberg's strategic manipulation of Mango Markets in 2022 led to his arrest in December of that year and his conviction by a jury in April 2024 (although this criminal conviction was overturned by the Southern District of New York in May 2025, and only the civil suits by the CFTC and the SEC are currently proceeding—this reversal itself confirms the weakening of legal deterrence by anonymity and cross-jurisdictional arbitrage discussed below). These legal precedents show that legal deterrence markedly alters the game-theoretic equilibrium of strategic liquidation: in a pure game-theoretic model, a rational attacker will choose to attack as long as the expected payoff exceeds the execution cost; legal deterrence, by introducing an expected penalty cost (including fines, imprisonment, and reputational loss), raises the effective cost of the attack and thereby shrinks the parameter space of profitable attacks. This deterrent effect, however, is markedly weakened in crypto markets by anonymity and cross-jurisdictional arbitrage.

In the DEX environment, strategic liquidation faces a distinctive information-structure problem. Because all position data are recorded on a public blockchain, an attacker can precisely compute the liquidation price and maintenance margin level of every account and thus precisely trigger a target liquidation with minimal capital outlay. This "glass box" of complete information transparency contrasts sharply with the privacy of position information at a centralized exchange. On a CEX, an attacker can only roughly infer the location of a liquidation-dense zone through the liquidation heatmap or public aggregate data, whereas the on-chain visibility of a DEX removes this information barrier, making the planning and execution of strategic liquidation more precise and lower-cost.

11.6.5 The nested double trinity

The impossible trinity of liquidation design does not exist in isolation; it is in fact nested within the design trade-offs of the service-provider layer. Chapter 5's service-provider impossible trinity takes "performance, transparency, and decentralization" as its three vertices; for the purpose of characterizing the cross-layer transmission of liquidation and leverage, this section reparameterizes it, from the perspective of systemic risk, into the derived outer triple of "decentralization, capital efficiency, and security" (capital efficiency being expressed as the pursuit of high leverage and high performance, and

security as the guarantee of solvency and verifiability) to constrain the inner liquidation trinity. There is a strong cross-layer tension between these two trinities.

The pursuit of capital efficiency inevitably leads platforms to offer higher leverage. High leverage means traders' safety cushion is extremely thin, which directly makes liquidation events more frequent and larger in scale. This forces the liquidation mechanism to tilt toward certainty in its design, thereby intensifying the conflict within the liquidation trinity. In other words, there is an almost unavoidable causal chain between capital efficiency and system fragility: for every order-of-magnitude increase in leverage, the density of the liquidation-dense zone grows superlinearly, and the squeeze the certainty constraint exerts on fairness and impact minimization intensifies accordingly.

At the same time, the pursuit of decentralization means the system lacks a centralized arbiter with an unlimited balance sheet (such as a traditional clearinghouse) to serve as a backstop. Without the possibility of external capital injection, the system can only resolve bankruptcy through internal rules (such as ADL), which inevitably touches the bottom line of fairness.

These factors point jointly to the conclusion that the pursuit of security requires the system to build a thick insurance fund or market-making vault to safeguard solvency. This inclines the system toward modes such as the vault backstop to achieve impact minimization. As noted above, however, this mode in fact concentrates and transfers risk, and once tail risk exceeds the vault's capacity, the system's overall security instead collapses in an instant. This nested relationship shows that risk management in the crypto derivatives market is an extremely complex systems-engineering problem, in which optimizing any single dimension can trigger unpredictable chain reactions in others.

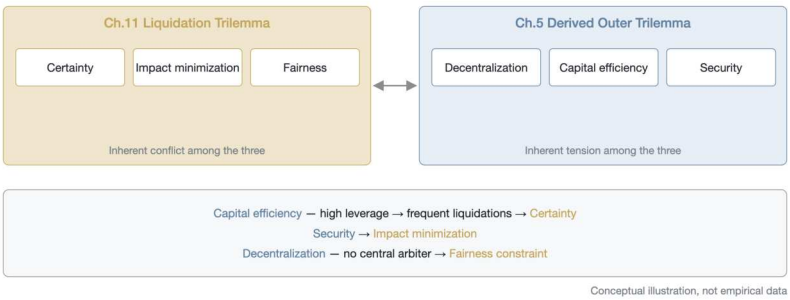

Figure 11-29. The nesting relationship between the impossible trinity of liquidation design and the service-provider impossible trinity (conceptual illustration; the outer trinity's decentralization/capital efficiency/security is a derived reparameterization of Chapter 5's service-provider impossible trinity from the perspective of systemic risk, not Chapter 5's original three vertices of performance/transparency/decentralization)

As shown in Figure 11-29, the parameter choices of the outer trinity (decentralization, capital efficiency, security) directly constrain the feasible region of the inner trinity (certainty, impact minimization, fairness): when the outer trinity tilts toward capital efficiency, the density of high-leverage positions rises, the inner trinity is forced to

tilt toward certainty, and the space for fairness and impact minimization narrows in tandem. This nesting means that risk management in the crypto derivatives market is not a single-dimensional parameter optimization but a systems-engineering problem under multi-layer constraints.

The actual binding boundary of this impossible trinity is being reshaped by external regulatory forces, forming a dynamic process that might be called "regulatory reflexivity." The EU Markets in Crypto-Assets Regulation (MiCA) established the first comprehensive crypto-asset framework, but crypto derivatives themselves are excluded from MiCA and fall under the Markets in Financial Instruments Directive (MiFID II); the European Commission's 2026 review of MiCA is only beginning to examine crypto leveraged contracts and derivatives exposure (as of mid-2026 this remains a regulatory gap rather than an established leverage cap). The UK Financial Conduct Authority (FCA), meanwhile, expressly banned the sale of crypto derivatives to retail investors through PS20/10 (effective January 6, 2021), and Japan and Hong Kong have each set leverage caps. Against this trend, the 125x leverage offered by some exchanges relies to a great extent on regulatory arbitrage—that is, operating in jurisdictions that regulation has not yet reached or where enforcement is weak. Regulatory intervention itself, however, also faces a deep reflexivity paradox: if regulators choose to forcibly lower the maximum leverage or require additional margin during a period of high open interest, this consumer-protection measure may itself become a cascade trigger, as a large stock of positions opened at high leverage is forced to close under the new margin requirements, and the resulting concentrated selling pressure superimposes on the mechanical response of the liquidation engine, an effect dynamically isomorphic with a cascade triggered by an exogenous price shock. There is therefore an inherent conflict in the time dimension between the goal of consumer protection and the goal of preventing systemic risk: in the long run, lowering the leverage cap undoubtedly reduces system fragility; but in the choice of implementation timing, if it falls during a period of high leverage stock, the protective measure may itself create the very systemic crisis it seeks to prevent.

11.7 The time-compression effect

In traditional financial markets, deleveraging is usually a slow process measured in days, weeks, or even months. In the crypto-asset derivatives market, and especially the perpetual futures market, however, this process is extremely compressed to the level of minutes or even seconds. This "time-compression effect" not only fundamentally changes the dynamics of market microstructure but also renders the traditional risk-management paradigm ineffective in the face of crypto markets.

11.7.1 A cross-market comparison

By reviewing the major deleveraging events in financial history, we can clearly see this dramatic change in time scale.

In traditional finance, the 1998 collapse of Long-Term Capital Management (LTCM) took about three months to substantially complete its deleveraging and asset-

liquidation process, with the Federal Reserve's intervention [25]. The financial tsunami triggered by the 2008 bankruptcy of Lehman Brothers took months to years to unwind its complex derivatives positions [26]. Even the high-leverage blowups of recent years, such as the 2021 collapse of Archegos Capital, took about three days to force-close its main positions [27]. In the 2022 UK pension liability-driven investment (LDI) crisis, facing a surge in UK gilt yields, pension funds took about two weeks to top up margin and sell assets [28].

In traditional markets, a standard margin call usually gives a trader T+1 to T+5 business days to replenish funds or close positions on their own. This time-buffer mechanism plays the role of a system stabilizer with a decisive influence on system stability. Take the 1998 LTCM crisis: within a single weekend, the Federal Reserve organized a consortium of 14 banks and, after a full three days of intensive negotiation, ultimately arranged $3.6 billion in rescue financing. This crisis-response process, centered on manual coordination, was extremely slow by the standards of crypto markets, yet it gave the parties ample room for information exchange and negotiation of interests, allowing a coordinated systemic rescue to be formed. This response mode, which relies on human intermediation, however, has no structural basis in a permissionless market: there is no central coordinator to convene the parties, no enforceable negotiation framework, and no legal force to bind the parties to honor rescue commitments.

By contrast, in the crypto derivatives market, during the "3.12" crash of 2020 the market's deleveraging was mostly concentrated within 24 hours. By the extreme liquidation event of October 10, 2025, according to market-data analytics firms, nearly $20 billion in leveraged positions were liquidated within a single day, as described at the opening of this chapter (see Section 11.9.2 for the complete microstructure data), while the most central destruction was concentrated within a 40-minute window, and the peak liquidation rate accelerated 86-fold above the normal level [2]. In this same crisis, according to Chitra's preprint, Hyperliquid's auto-deleveraging mechanism force-closed about $2.1 billion of positions within about 12 minutes (this was the first cross-margin ADL trigger in its operating history) [18].

From the months and weeks of traditional finance to the minutes and tens of seconds of crypto markets, the time scale of deleveraging has been compressed by roughly 10^4 to 10^5 times (this is a mid-range estimate based on a traditional typical of T+3 to a few weeks and a crypto typical on the order of minutes; taking the extreme endpoints of months $\rightarrow$ seconds yields about 10^6 times, and days $\rightarrow$ minutes about 10^3 times).

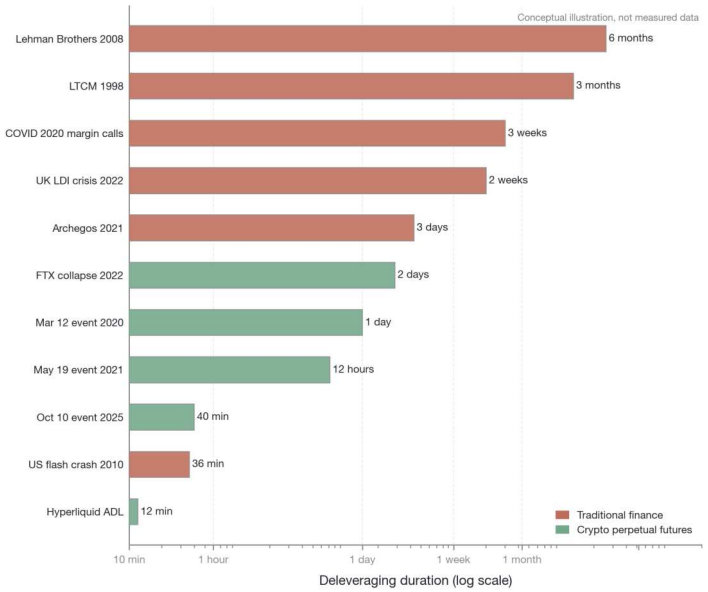

Figure 11-30. Comparison of the deleveraging timeline between traditional finance and perpetual futures (logarithmic scale; deleveraging durations are an illustrative comparison of typical orders of magnitude, not precise measurements)

11.7.2 Four driving forces

This extreme time compression is no accident but is jointly determined by the underlying architecture and rule design of the crypto derivatives market. Specifically, four core driving forces produce this phenomenon:

Around-the-clock operation with no buffer mechanism means the crypto market trades continuously, 24/7/365, with no close, no weekend break, and no official price limits or circuit breakers. There is also a fundamental difference between the price-anchoring mechanisms of perpetual futures and traditional futures: traditional futures have a hard, discrete anchor (delivery at expiry forces futures and spot to converge), whereas perpetual futures rely only on the funding rate as a soft, continuous anchor that can fail or even reverse under extreme stress (such as the funding-rate-reversal risk analyzed in Section 11.4), allowing a basis deviation to persist indefinitely in the absence of a hard delivery constraint, so that panic and liquidation selling pressure in a crisis cannot be cooled by a market close. Automated liquidation hard-codes the liquidation logic into the matching engine or an on-chain smart contract, and once the oracle price feed reaches the maintenance margin threshold, it triggers closure unconditionally within milliseconds, with none of the traditional market's room for manual notification, negotiation, and grace. The contagiousness of cross-margin arises because a unified account allows the paper profit of one asset to collateralize the loss of another, raising capital efficiency in calm times but, in extreme conditions, making portfolio risk determined by the highest-risk constituent asset—as in the October 2025 event, when the plunge of long-tail assets such as WLFI dragged down the account's overall margin ratio and triggered the forced sale of core assets such as Bitcoin and Ethereum [27], greatly accel-

erating the liquidation process. The transparent order book and the liquidity vacuum arise because liquidation lines can be precisely anticipated by professional market makers: foreseeing the arrival of large-scale liquidations, rational market makers instantly withdraw their buy orders to avoid "toxic orders," so that on October 10 the liquidity of key trading pairs evaporated by more than 99% within minutes and spreads widened by three orders of magnitude (see Section 11.9.2, Table 11-7) [2], and a small number of liquidation orders could cut through the remaining depth and trigger deeper liquidations.

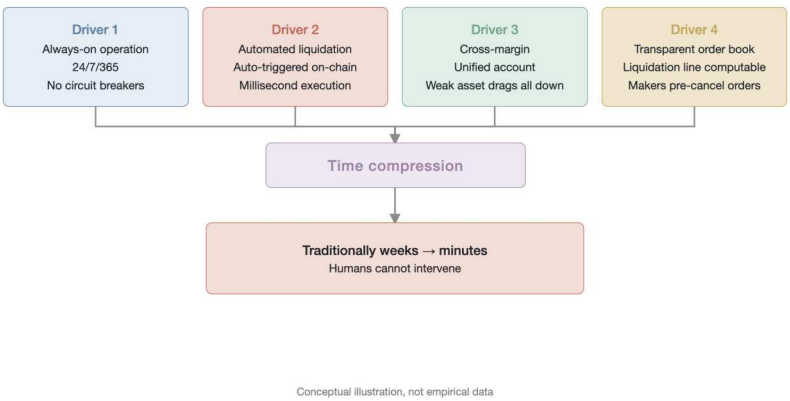

Figure 11-31. The four driving forces of time compression and their transmission mechanisms

11.7.3 The mismatch between decision-making and execution

The time-compression effect brings a serious consequence: a fundamental mismatch between the latency of human decision-making and the speed of machine execution.

In the traditional risk-control framework, after receiving an alert of abnormal market movement, a risk-management team must go through a series of steps—data verification, risk assessment, decision-making, fund allocation, and order issuance. Even for a top-tier, well-trained institution, this process takes at least tens of minutes to hours. Even an algorithmic trading firm that has deployed pre-programmed risk-control thresholds usually needs 30 to 60 seconds in extreme conditions to judge whether an abnormal move is a data error, a local exchange anomaly, or a genuine market event—and this delay already exceeds the entire duration of the most destructive phase of the 10.10 cascade crisis. We roughly estimate that a human risk-control team's ceiling for effective response and fund deployment in an emergency is about $50 million per hour.

As the October 10, 2025, event demonstrated, however, during the eruption of the liquidation cascade the system's equivalent liquidation rate reached $10.39 billion per hour; and within the peak 60 seconds it reached the extreme equivalent rate of about $192.6 billion per hour (this is the equivalent rate obtained by linearly extrapolating the peak-minute liquidation volume to an hourly basis; it lasted only about one minute and is not a sustainable rate). This means the speed of machine liquidation was hundreds or even thousands of times faster than the fastest human response.

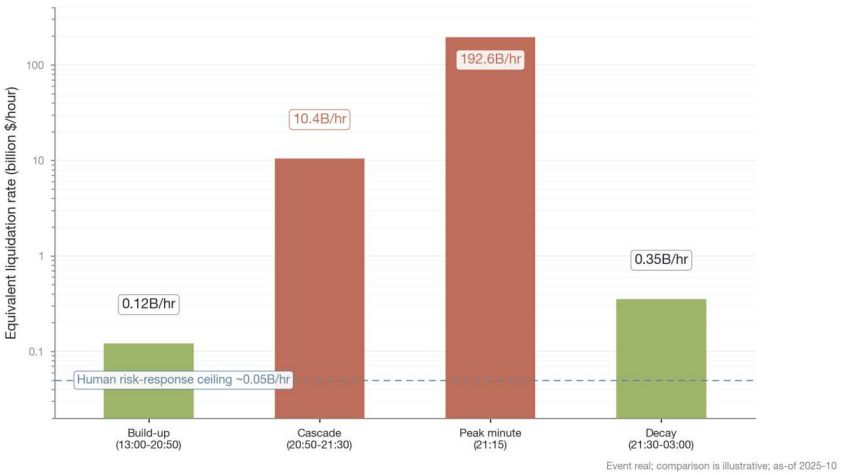

Figure 11-32. Comparison of the liquidation rate and the decision-response speed in the "10.10 event" (Data source: Amberdata [2], as of October 2025; the liquidation rate has multiple bases that should not be conflated: about $3.21 billion per minute at the peak minute, about $10.39 billion per hour averaged over the 40-minute cascade, and about $192.6 billion per hour from the linear extrapolation of the peak minute, which lasted only about 1 minute and is not a sustainable rate; the human response latency is an illustrative representative value)

11.7.4 Implications for risk control and regulation

The time-compression effect is not only a technical feature of market microstructure; it poses far-reaching challenges to the risk-control methodology and future regulatory path of the crypto derivatives market.

The definition of "effective leverage" must be reconstructed. Traditional risk-control models often calculate the safety cushion on the basis of static margin rates and historical volatility. In an environment of time compression and instantaneous liquidity evaporation, however, nominal leverage is meaningless. The real risk depends not only on directional exposure but, more importantly, on the liquidity depth of the collateral basket under extreme conditions. As research points out, "the market trades at the margin, not at the mean" [27]. Risk-control models must introduce dynamic, nonlinear liquidity-penalty factors to simulate whether a position is still safe in a scenario where order-book depth has shrunk by more than 90%.

At the same time, guarding against single points of failure directly determines the system's survivability. When infrastructure becomes unreliable in extreme conditions, concentrating all positions, collateral, and oracle price feeds at a single exchange (even a decentralized one) becomes a fatal single point of failure. For example, when an exchange's internal stablecoin price depegs because of a local liquidity drought, a liquidation engine based on that local price will mercilessly liquidate a cross-market hedge portfolio that would be entirely healthy from a global perspective [27]. Multi-centered oracle price feeds, redundant allocation of funds across exchanges, and automated programmatic hedging therefore become must-haves for the survival of professional institutions.

From the standpoint of systemic risk and regulation, the time-compression effect requires us to rethink the applicability of circuit breakers in crypto markets. Although the pure spirit of decentralization rejects any human intervention in trading, when the execution speed of the liquidation engine far exceeds the market's capacity for self-repair, some form of algorithm-level circuit breaker or volatility-based dynamic liquidation-delay mechanism may be a necessary compromise to prevent a "flash crash" from evolving into a systemic crisis. The actual effect of circuit breakers in traditional markets, however, is far from uncontested. The research of Goldstein and Kavajecz (2004) [29] reveals the "magnet effect" of circuit breakers: when the price approaches the circuit-breaker threshold, traders expect trading to be suspended and therefore accelerate their selling to avoid being locked into an unfavorable position, and this behavior instead pushes the price toward the circuit-breaker line faster, making the circuit breaker itself an amplifier of volatility rather than a damper. The theoretical root of this "magnet effect" can be traced to Subrahmanyam's (1994) [30] early analysis of how a circuit-breaker threshold distorts traders' intertemporal order placement. In the crypto market's fragmented exchange environment, this problem is further complicated: if a single exchange unilaterally suspends trading, its immediate effect is to drive order flow to competing platforms that are still trading, rather than genuinely arresting the cascade, and the selling pressure does not disappear because one exchange has suspended trading but is merely released in concentration on other platforms. A market-wide coordinated suspension could in theory solve this problem, but it is in deep conflict with the decentralized nature and permissionless operating principle of crypto markets. A more feasible alternative is therefore a dynamic liquidation-throttling mechanism: rather than suspending trading itself, it lowers the execution rate of the liquidation engine when cascade conditions are detected (for example, limiting the volume of liquidation orders processed per unit time to a certain proportion of the available order-book depth), thereby slowing the acceleration of the positive-feedback loop while keeping the market open. This design provides a time window for liquidity to recover and market makers to re-enter, without interrupting the price-discovery function.

11.7.5 The structural protections of traditional margin markets

The extremity of the time-compression effect in the crypto derivatives market becomes even sharper when contrasted with the structural protection mechanisms of traditional margin markets. Through decades of institutional evolution, traditional financial markets have built multi-layered braking mechanisms that jointly constitute a structural buffer preventing the deleveraging process from running out of control.

On liquidity depth, the order-book depth of traditional futures markets is usually tens or even hundreds of times that of crypto markets. Take the S&P 500 index futures of the Chicago Mercantile Exchange (CME): their visible order-book depth in normal times can reach the level of billions of dollars, and even in the extreme conditions of March 2020 they maintained a minimum depth of hundreds of millions of dollars. A liquidity pool of this magnitude means that the price impact produced by one or a few large liquidation orders on execution is effectively diluted, and a self-reinforcing cascade feedback is hard to form. A cross-market comparison of absolute depth should be standardized by open interest or average daily volume to yield a meaningful relative-

liquidity measure. Although the absolute depth of the crypto perpetual futures market is far lower than that of S&P 500 futures, its depth ratio relative to OI may reveal a more precise measure of fragility. An especially analytically valuable comparison case is CME Bitcoin futures: they trade the same underlying asset as crypto perpetual futures but run on traditional market infrastructure, with well-developed circuit breakers, regulated market-maker obligations, margin grace periods, and a clearinghouse's multi-layer default waterfall. Comparing the price behavior of CME Bitcoin futures with that of crypto perpetual futures in the same macro-shock event therefore makes it possible to isolate the net contribution of market microstructure differences to cascade dynamics while effectively controlling for the underlying asset's risk factors.

Circuit breakers are the most direct means by which traditional markets arrest time compression. When a price falls by a preset threshold within a short time (such as 5%, 7%, or 13%), the exchange forcibly suspends trading for 5 to 15 minutes. This pause gives market participants a time window to reassess information, add margin, and adjust strategies, effectively interrupting the positive-feedback loop between panic selling and mechanical liquidation.

In traditional markets, the prime broker acts as a credit-intermediary layer between traders and the clearinghouse. When a client faces margin-call pressure, the prime broker can provide short-term financing grace based on the client's overall credit standing and long-term relationship, allowing the client to adjust positions in an orderly way over hours or even days rather than being forced to close immediately in the worst market conditions. This elastic layer, constituted by interpersonal relationships and credit judgment, is entirely absent from the purely algorithm-driven crypto market.

In addition, the asset diversification of a traditional-market portfolio is far greater than in crypto markets. The correlations among equities, bonds, commodities, and foreign exchange are low in normal times, and even when correlations rise in a crisis, they are unlikely to reach close to 1 simultaneously. By contrast, the correlations of the vast majority of crypto assets with Bitcoin show an empirical tendency to converge rapidly toward 1.0 during a crisis. Although the precise correlation values vary by event, time window, and asset class, this high directional synchrony recurs across successive major cascade events. Correlation, however, measures consistency in the direction of price movements, not symmetry in their magnitude: in the 10.10 event, BTC's maximum drawdown was 14.5%, while the drawdown depth of some DeFi tokens reached more than 70%. The apparent contradiction between high correlation and starkly different drawdown magnitudes can be reconciled by the following mechanism: all assets fell in the same direction (hence the high correlation), but the less liquid assets bore a disproportionate price impact because of their shallower order-book depth, higher leverage concentration, and the faster withdrawal of market makers. This means that under the cross-margin system there is almost no effective risk diversification: the entire portfolio behaves, in direction, like a single high-leverage position in one asset, while in magnitude it is dominated by the least liquid constituent asset.

11.8 The information paradox and mechanism-induced volatility

A liquidation event carries both information and noise in the order book, and market makers cannot separate the two; the systemic overreaction that results constitutes an efficiency constraint peculiar to perpetual futures markets. This section first defines the information paradox of liquidation, then analyzes the adverse-selection dilemma of market makers, and finally proposes the concept of mechanism-induced volatility and its differences across modes.

11.8.1 The information paradox of liquidation

In the market microstructure of perpetual futures, a liquidation event constitutes a distinctive cognitive puzzle, which we call the information paradox of liquidation. This paradox is not only an extension of microstructure theory but also a core key to understanding the extreme volatility of crypto-asset markets. When we observe a liquidation order in the order book, it in fact carries two starkly different attributes at once: an information attribute and a noise attribute. The research of Bouchaud, Farmer, and Lillo shows that order flow's impact on price has a long-memory character, and the influence of large one-sided order flow accumulates over time [31]. The information attribute originates in the liquidated trader's misjudgment, but this statement requires a more precise classification. Liquidated positions can in fact be distinguished, by their information content, into three starkly different cases. The first is a genuine fundamental misjudgment: the trader was indeed wrong about the direction of the asset's value, the price movement reflects a negative update to fundamentals, and in this case the liquidation order carries valid information about the asset's true value, on which market makers should adjust their expectation of fair value. The second is a correct fundamental judgment but excessive leverage: the trader's medium-to-long-term judgment about price direction may be entirely correct, but because they used too high a leverage multiple, even a normal 2% market fluctuation is enough to trigger their maintenance margin line; this liquidation is pure leverage noise and carries no fundamental information. The third is an unrelated liquidation caused by cross-margin contagion: under the unified margin system, a trader's loss on some unrelated asset erodes the account's overall margin balance, causing forced closure of a position in another instrument on which the trader's directional judgment was correct and whose fundamentals have not deteriorated. This third case constitutes pure structural noise; the liquidation is entirely unrelated to any fundamental information about the asset and is merely a by-product of the margin system's design. In the actual operation of the crypto derivatives market, the latter two cases (leverage noise and structural noise) very likely dominate in number, which means the signal-to-noise ratio in liquidation order flow is far lower than in the informed-trading-driven order flow of traditional markets. The core difficulty is that these two attributes manifest identically in the order book. Whether it is a desperate sale caused by deteriorating fundamentals or a mechanical close triggered by excessive leverage, both appear in the matching engine only as ruthless market sell orders. At centralized exchanges, liquidation orders are in fact technically identifiable: Binance's forceOrder WebSocket stream, for example,

lets market participants distinguish liquidation orders from voluntary orders in real time. The real paradox market makers face, therefore, is not the inability to identify a liquidation order itself but the inability, even knowing that an order is a liquidation, to decompose it into signal and noise: which of the three cases above does it belong to? Does it reflect valid fundamental information, is it the mechanical consequence of excessive leverage, or is it a structural by-product of cross-asset contagion? This deep information asymmetry places market makers in a dilemma.

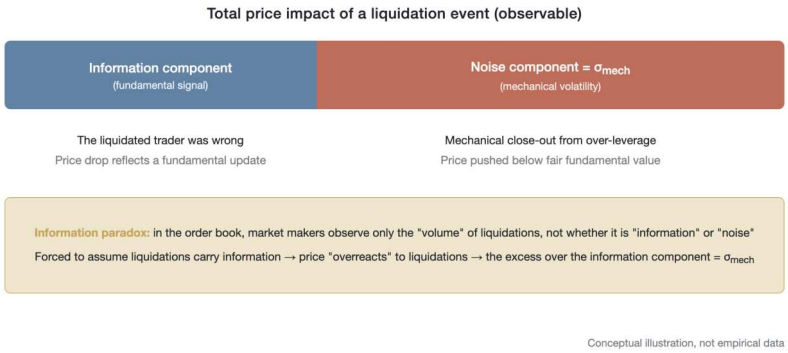

Figure 11-33. Decomposition of the information and noise superimposed in a liquidation order (conceptual illustration, not empirical data)

11.8.2 The adverse-selection dilemma of market makers

Under the microstructure framework proposed by Kyle (1985) [10], when facing informed traders, market makers can infer the information content in order flow from its characteristics and adjust their quotes accordingly. In the Kyle model, market makers gradually adjust the price to the level that reflects the asset's expected value by observing the size and timing characteristics of orders, and the premise of this inference process is that there is a strategic information motive behind the orders. Liquidation orders, however, carry no such strategic information; they are mechanically triggered by the exchange's risk engine at preset price levels and lack the tentative or strategic character of an informed trader, so the standard information-inference framework loses its basis for application. Faced with this massive volume of orders that cannot be distinguished as information or noise, market makers are forced to adopt an extremely conservative strategy. To protect themselves from potential adverse-selection risk, market makers must assume that at least some of these liquidation orders contain unknown negative information.

This forced conservative assumption leads to a systemic consequence: the overreaction of prices to liquidation events. To avoid risk, market makers widen bid-ask spreads substantially and withdraw liquidity, so that liquidation orders, in cutting through the order book, cause a decline far greater than their information content warrants. This rational self-protection by market makers manifests at the macro level as an irrational market plunge. When the dust settles and we look back afterward, we find that the

portion of the price decline beyond the information component was purely manufactured by the liquidation mechanism itself, and we define this as mechanism-induced volatility.

11.8.3 Mechanism-induced volatility

Mechanism-induced volatility is price volatility produced by the liquidation mechanism that reflects no change in fundamental information; it is the core indicator of the degree to which the liquidation system interferes with the market's price-discovery efficiency. This concept is logically similar to the excess volatility Shiller (1981) [32] identified in the stock market, but with one key distinction: the excess volatility Shiller described originates in investors' behavioral biases during valuation, whereas mechanism-induced volatility in the crypto derivatives market is produced by the structural interaction between leverage and automated liquidation, which makes it a predictable and, in principle, measurable component of total price variance. The sources of mechanism-induced volatility can be further decomposed into two components that are conceptually distinguishable but closely intertwined in practice: (a) mechanical-liquidation overshoot, the nonlinear price impact produced by the liquidation engine's forced sell orders when liquidity is thin, a purely algorithm-driven, information-free price deviation; and (b) behavioral-panic overshoot, the panic selling that traders who have not been liquidated undertake voluntarily out of fear after observing a sharp price drop and large-scale liquidations. Take the 10.10 event: at the peak moment 93.5% of sell orders were market orders produced by forced liquidation, which means about 6.5% of the selling pressure came from voluntary panic selling. Although 6.5% seems small, when order-book depth has already collapsed to below 1% of its normal level, even this small portion of voluntary selling produces a significant additional price impact. In the strict sense, "mechanism-induced volatility" should cover only component (a), the price deviation directly manufactured by the liquidation engine; component (b) belongs to the behavioral chain reaction and is essentially a second-order response to mechanical liquidation. As a preliminary measure, we can compare price volatility during liquidation-intensive periods with that during non-liquidation periods and, after controlling for other factors such as macro news, attribute the additional volatility difference to mechanism-induced volatility.

The magnitude of mechanism-induced volatility is closely related to the liquidation mode an exchange adopts. Because cliff-edge liquidation dumps the entire position onto the market at market price in an instant, it injects the most noise and produces the most violent mechanism-induced volatility. Progressive liquidation, by reducing positions in batches, injects the noise dispersed over a longer time window, so its mechanism-induced volatility is at a moderate level. Although the auto-deleveraging mechanism is extremely unfriendly to the profitable counterparty, its precise, targeted closing has limited impact on the public market price, so its mechanism-induced volatility is small. And vault-backstop liquidation internalizes the risk position so that the noise does not enter the public order book at all, producing the least mechanism-induced volatility.

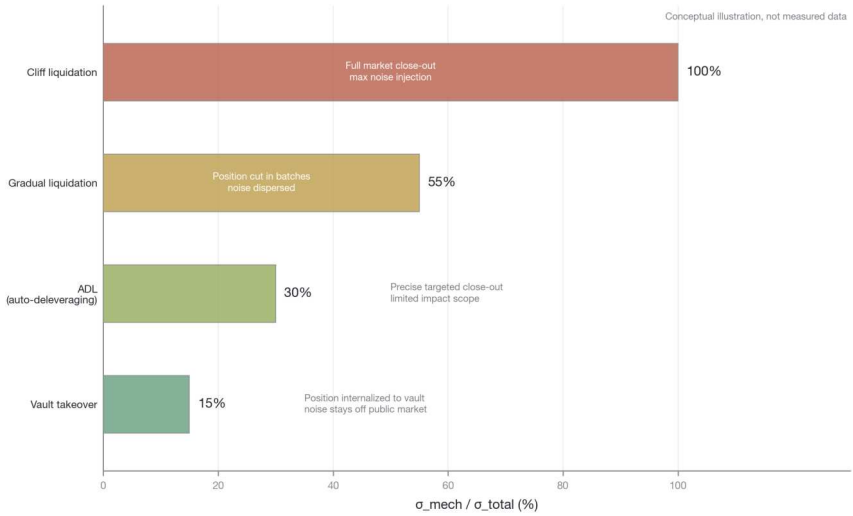

Figure 11-34. The relative magnitude of mechanism-induced volatility under different liquidation modes (conceptual illustration; qualitative relative values; not empirical data)

The information paradox and mechanism-induced volatility have important implications for the price-discovery efficiency and market quality of perpetual futures markets. It shows that during liquidation-intensive periods, the price of perpetual futures systematically deviates from the asset's fundamental value. Mechanism-induced volatility in fact constitutes a hard ceiling on the informational efficiency of perpetual futures. However precise the oracle, as long as high leverage and forced-liquidation mechanisms exist, this endogenous mechanism-induced volatility cannot be eliminated. When assessing the quality of crypto-asset markets, therefore, we must incorporate mechanism-induced volatility into our analytical framework as an efficiency constraint peculiar to perpetual futures. It reminds us that the price seen in extreme conditions often reflects the fragility of the market structure more than the asset's true intrinsic value.

11.9 A reflexivity dissection of the "10.10 event"

The "10.10 event" is a complete empirical test of this chapter's theoretical framework. This section reconstructs, in turn, the system's pre-crisis fragility, the micro process of the trigger and cascade, the cross-asset contagion path, and the empirical validation of the four-phase model and mechanism-induced volatility.

11.9.1 The system's pre-crisis fragility

The crypto-asset market crash that erupted on October 10, 2025—the "10.10 event"—provides a perfect empirical test scenario for all the theoretical tools discussed in this chapter. It was the largest single-day liquidation event in the history of crypto derivatives, with total 24-hour liquidations estimated by institutions at more than three times those of "Black Thursday" in March 2020 [17] [3] (note: sources differ substantially in how they measure the total liquidations of the March 2020 event; the complete microstructure data appear in Section 11.9.2). Many market commentators simply

blamed it on the shock of macro geopolitical news, but a close dissection of the event's microstructure reveals a more fundamental truth. The macro news was merely the exogenous catalyst that triggered the cascade; the fragile leverage structure inside the crypto-asset market, the cross-contagion of the unified margin system, and the mechanical execution of the liquidation engine were the fundamental causes that amplified a controllable price pullback into a systemic implosion.

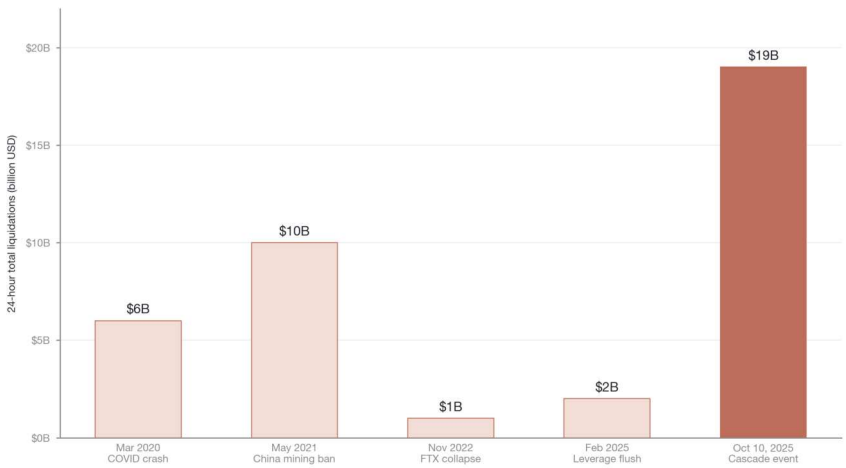

Figure 11-35. Comparison of the scale of historical liquidation events (Data source: CoinGlass [9], as of October 2025; the values are representative rounded milestones—China's mining ban of May 2021 was about $8 billion to $10 billion, with CoinGlass's canonical figure about $8.6 billion; because of API reporting caps, the CoinGlass basis historically underestimates and its absolute figures are conservative, so orders-of-magnitude comparison should be emphasized)

On the eve of the crisis, the crypto-asset market was already in a highly taut metastable state. Total open interest in perpetual futures at major venues had reached a record of about $146.6 billion (on Amberdata's basis, not a full market-wide basis) and displayed an extreme long-dominated character [2]. Because of the market's preceding sustained rise, one-sided crowding was extremely high, the ratio of open interest to market cap had climbed to a historical high, and positions using high leverage above 25x accounted for a significant share. More dangerously, the funding rate had already completed the process of “accumulating fragility.” Before October 6, according to FTI Consulting's post-crash analysis, the funding rate on Bitcoin and Ethereum perpetual futures (driven mainly by the Ethereum market) rose from about 10% annualized to nearly 30% (corresponding to about 0.027% per 8 hours; the figure does not specify whether it is a market-wide weighted or a single-exchange basis) [27]. This extreme positive rate meant that longs had to keep paying shorts a high holding cost, which imperceptibly kept consuming longs' maintenance margin and systematically pulled their liquidation prices upward, making the entire market extremely sensitive to downside risk. The liquidation heatmap showed that a massive number of liquidation trigger points had clustered in the narrow band 5% to 10% below the price at the time, and the cascade risk index had entered a dangerous divergence range.

The macro event that triggered this cascade (the announcement of a 100% tariff on Chi-

nese imports) did not act on the crypto-asset market alone; it simultaneously struck traditional risk assets such as equities, foreign exchange, and commodities. During the six-hour window in which Bitcoin fell 6.8% before the cascade erupted, macro hedge funds rebalanced their portfolios by treating crypto-asset exposure as part of a broader risk-reduction strategy, and this cross-market outflow very likely contributed significantly to the initial selling pressure. Analyzing the co-movement of S&P 500 index futures, the USD/CNY exchange rate, and the gold price over the same time window would help decompose the initial trigger factor into a crypto-market-endogenous component and a cross-market capital-flow component, though such an analysis is beyond the scope of this chapter.

11.9.2 The trigger and the cascade

The crisis was triggered at 14:57 UTC on October 10, when U.S. President Trump announced on social media that a 100% tariff would be imposed on Chinese imports [3]. This macro catalyst immediately set off a global sell-off in risk assets. The price of Bitcoin began to slide slowly from a high of $121,500 and fell to around $114,000 over the following six hours, a decline of about 6.8% [2]. Although painful, the decline in this phase was still within the range of normal price discovery, and the market showed no sign of systemic collapse. This six-hour decline, however, gradually eroded the margin buffer of high-leverage positions and pushed the price toward the liquidation-dense zone.

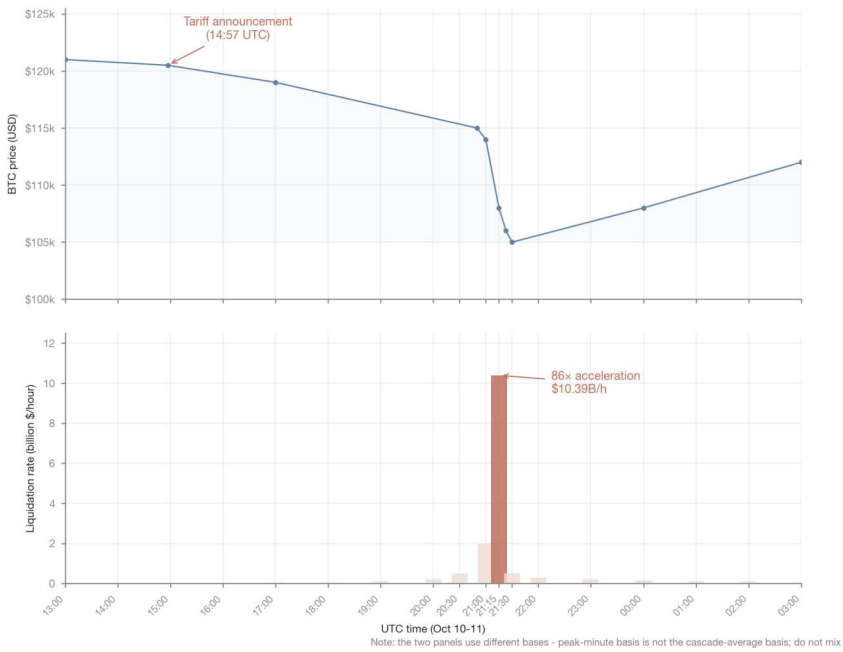

Figure 11-36. Timeline of price and the liquidation rate in the "10.10 event" (Data source: Amberdata [2], as of October 2025)

The cascade crisis began at 20:50 UTC, when the price hit a key liquidity-vacuum zone and the liquidation cascade was formally triggered. Over the following 40 minutes,

the market experienced the fastest mechanical deleveraging in the history of crypto derivatives. The liquidation rate surged instantly from a mild $120 million per hour before the cascade to $10.39 billion per hour, an acceleration of a full 86-fold [2]. In the peak minute at 21:15, as much as $3.21 billion of positions were liquidated within 60 seconds, of which 93.5% were forced closures of longs [2]. This purely algorithmic execution speed completely deprived human traders of any time window to intervene or add margin.

Table 11-7 summarizes the changes in four key microstructure indicators before and after the cascade, showing the comprehensive deterioration of the market infrastructure within 40 minutes.

Indicator	Before cascade (8-hour average)	During cascade (40-minute average)	Magnitude of change
Liquidation rate	$120 million/hour	$10.39 billion/hour	Accelerated 86x
Order-book depth	$103.6 million	$170,000	Contracted 99.8%
Bid-ask spread	0.02 bps	26.43 bps (peak)	Widened 1,321x
Open interest	$146.6 billion	$109.9 billion	Evaporated 25%

Table 11-7. Comparison of key microstructure indicators before and after the cascade in the “10.10 event” (Data source: Amberdata [2])

In this 40-minute liquidity black hole, the microstructure data reveal the complete collapse of the market infrastructure. According to Amberdata, the visible order-book depth of major exchanges fell off a cliff from $103.64 million to a mere $170,000, and more than 99.8% of liquidity contracted sharply precisely when it was most needed [2]. The pre-cascade depth figure of $103.64 million here reflects visible resting limit orders. In practice, the effective liquidity of the crypto market also includes substantial hidden depth (iceberg orders and algorithmic market makers quoting with high-frequency placements and cancellations), and under normal market conditions this hidden liquidity is typically 3 to 5 times the visible depth. During a cascade, this hidden liquidity disappears even faster than visible orders, because algorithmic market makers pause their quoting algorithms within milliseconds once they detect adverse-selection flow. Therefore, from total liquidity including hidden and refresh components down to the residual $170,000, the collapse in actual effective depth was very likely close to 99.95%, which makes the cascade dynamics more extreme than the visible order-book data alone would present. At the same time, the bid-ask spread of Bitcoin perpetual futures widened explosively from an extremely tight 0.02 basis points to 26.43 basis points, an increase of 1,321-fold [2]. This deterioration of the microstructure meant that every new liquidation order, in cutting through the order book, produced far greater price slippage than usual, thereby triggering more liquidations at lower prices and forming a classic positive-feedback spiral.

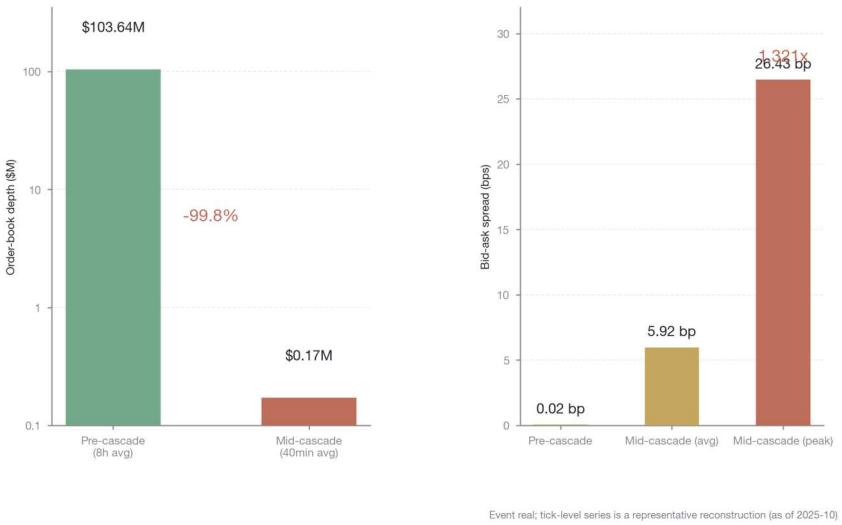

Figure 11-37. Order-book depth and the bid-ask spread in the "10.10 event" (Data source: Amberdata [2], as of October 2025; the endpoints—depth of about $103.6 million → $170,000 and spread of 0.02 → 26.43 basis points—are Amberdata's measured top-of-book values for BTC perpetual futures, while the point-by-point series is a representative reconstruction)

11.9.3 Cross-asset contagion and collateral collapse

The destructiveness of this crisis was reflected not only in the plunge of a single asset but, even more, in its ultra-rapid cross-market, cross-asset contagion. The unified margin system played the role of the key amplification mechanism here. When the fall in Bitcoin's price triggered liquidations, an exchange's risk engine not only closed Bitcoin positions but also indiscriminately sold off the high-risk altcoins in the account to make up the margin shortfall. As a result, although Bitcoin ultimately fell only about 14.5%, Ethereum fell 12.2%, while the maximum drawdown of DeFi blue-chip assets such as UNI and AAVE approached 70% [2]. This asymmetric cross-asset shock carries important structural information. The DeFi tokens' decline far exceeding Bitcoin's was very likely the result of several superimposed factors: compared with Bitcoin perpetual futures, altcoin perpetual futures have markedly thinner order-book depth, which means an equal amount of liquidation selling pressure produces a proportionally amplified price impact; leverage concentration on altcoin perpetual positions is higher; DeFi tokens are disproportionately used as collateral in unified margin accounts, thereby triggering collateral-driven forced selling; and market makers withdraw liquidity from illiquid pairs faster and more completely. A formal quantitative decomposition of these contributing factors would substantially advance our understanding of the structure of cross-asset contagion.

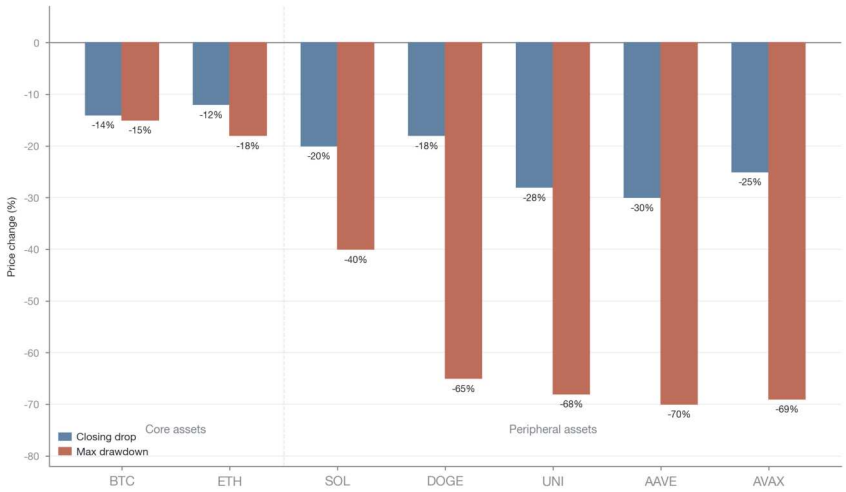

Figure 11-38. Comparison of price declines across multiple assets (as of October 2025; “closing decline” and “maximum drawdown/intraday low” are two different bases that should not be read interchangeably; SOL’s closing decline is a representative rounded figure, with a verified value of about −24% and an intraday low that at one point exceeded −40%; the specific declines for each asset follow the main text of Section 11.9.3)

Collateral collapse was the most striking link in this cross-market contagion. As a high-yield synthetic dollar stablecoin, USDe was used by many traders as margin for contract trading at the time [3]. When the liquidity crisis erupted, USDe encountered severe selling pressure on Binance, and its price briefly depegged and plunged to $0.65, a discount of as much as 35% to its $1 peg [3]. This was mainly a local liquidity event at the single venue of Binance: over the same period, USDe deviated by less than 100 basis points on Curve, fell only to about $0.92 on Bybit, and decentralized venues largely maintained the peg on hundreds of millions of dollars of liquidity; the Ethena protocol maintained about $66 million in excess collateral throughout, its minting and redemption functions operated normally, and it processed more than $2 billion in redemptions within 24 hours, showing that the 35% discount did not reflect the true solvency risk of its delta-neutral strategy but was a pricing distortion in a single low-liquidity trading pair [3]. Because the exchange’s margin system directly used the local internal oracle price feed, the plunge in USDe left countless previously safe accounts instantly insolvent, setting off a fierce secondary liquidation wave. Liquid staking tokens such as BNSOL and WBETH met a similar fate, and this double blow—collateral value and asset price plunging at the same time—constituted two mutually nested positive-feedback loops.

The collapse of USDe exposed the structural risk of using a yield-bearing stablecoin as margin collateral. Unlike traditional stablecoins (such as USDT and USDC) backed by fiat reserves or short-term Treasuries, USDe maintains its peg through a delta-neutral strategy (holding a long position in spot crypto assets—mainly BTC and ETH and their liquid staking derivatives—and shorting an equivalent position in the corresponding perpetual futures, plus some stablecoin and cash reserves). This means that USDe’s stability itself depends on the normal functioning of the perpetual futures market, which is precisely the link that collapsed first in the crisis. When the 10.10 event erupted,

the short hedge positions underlying USDe faced huge funding-rate payments (as the rate turned sharply negative), and its redemption mechanism could not be executed in time when market liquidity dried up, producing a discount of as much as 35% between the secondary-market price and the theoretical net asset value. The exchange failed to lower USDe's margin collateral factor in time during the event, meaning that USDe valued 1:1 was still counted toward margin at face value, and the system responded only passively after the price had collapsed; here a distinction should be drawn between "no haircut applied at all" (treating it as equivalent to USDT) and "a haircut that existed but was insufficient," two cases with fundamentally different implications for the direction of risk-management recommendations. This lag reveals a fundamental flaw in the current margin system's assessment of collateral risk: adjustments to the collateral factor are discrete and lagging, whereas changes in collateral's market value are continuous and instantaneous. As noted, USDe's depeg of as much as 35% was mainly a pricing distortion in a single low-liquidity Binance trading pair rather than Ethena's true solvency risk; if so, then the exchange's internal pricing oracle in fact constituted a single point of failure—using a single low-liquidity trading pair as the collateral-valuation mark for the entire unified margin system—and its failure to adjust the collateral factor in real time when the depeg occurred also raises serious questions about the exchange's duty of prudent care and the legal recourse of harmed users. For any yield-bearing asset ultimately backed by a derivatives strategy, its suitability as margin collateral needs to be re-examined on the basis of liquidity and redemption capacity under extreme stress scenarios, rather than relying only on historical volatility under normal market conditions.

At the deepest point of the crisis, the procyclical effect of the auto-deleveraging mechanism dealt a further blow to the market. When the risk reserve was exhausted and not enough liquidity could be found in the market to take on the liquidated long positions, the exchange activated auto-deleveraging. This mechanism forcibly closed short positions that were correct in their directional judgment and profitable. This not only inflicted serious losses on the professional market makers running delta-neutral strategies but, more alarmingly, eliminated the largest potential buying force in the market—because these shorts would otherwise have bought to close as the price fell to low levels, providing precious bottom liquidity to the market. The intervention of auto-deleveraging further weakened the market's remaining liquidity, causing the price to stall further at the bottom.

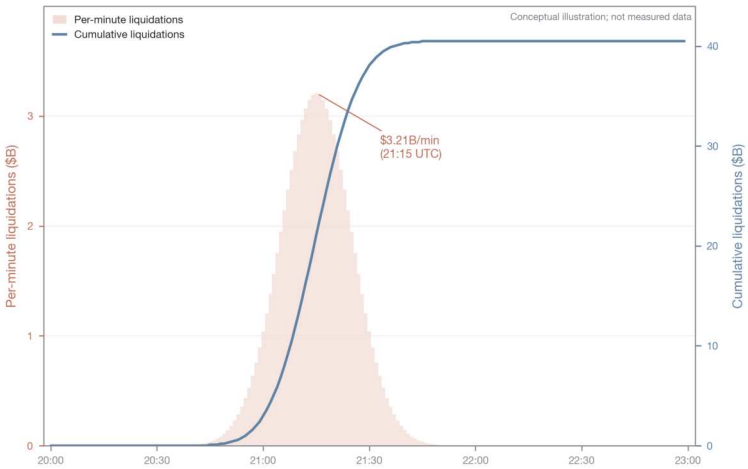

Figure 11-39. The dynamic relationship between the liquidation rate and cumulative liquidation volume (an illustration of the liquidation-cascade model, not tick-by-tick empirical data from the “10.10 event,” and distinct from Figure 11-36)

Figure 11-39 overlays the liquidation rate with cumulative liquidation volume, revealing two key dynamic features of the cascade process: the peak of the liquidation rate occurs at the inflection point of the cumulative-liquidation-volume curve, corresponding to the system’s jump from the propagation phase to the amplification phase; and the sharp fall-back in the liquidation rate is not due to external intervention but to the fact that the liquidatable high-leverage positions have largely been cleared and the system’s own “fuel” is exhausted. This asymmetric pulse shape (slow accumulation, instantaneous eruption, rapid decay) constitutes the typical temporal signature of a crypto-market liquidation cascade.

11.9.4 Empirical validation of the four-phase model

Using the liquidation reflexivity equation and the four-phase model proposed in this chapter, we can systematically reconstruct the entire process of the “10.10 event.” In the trigger phase, macro news caused an initial decline of 6.8%. Entering the propagation phase, the price hit the liquidation-dense zone, the reflexivity engine activated, and the liquidation-impact absorption rate fell below 1. In the amplification phase, the time-compression effect appeared, 70% of the destructiveness was released within a mere 40 minutes [2], and multiple resonances drove depth to zero. Finally, in the termination phase, as open interest plunged 25% and liquidatable leveraged positions decreased sharply, the cascade finally stopped.

The price trajectory after the crisis also provides strong empirical support for the mechanism-induced volatility discussed earlier. After the cascade slammed Bitcoin’s price down to a low of $104,800, as the mechanical selling pressure exhausted itself, the price rebounded quickly over the following day and stabilized near $113,000. This price difference of nearly $8,000 constitutes a direct measure of the overshoot the liquida-

tion mechanism injected into the market. As analyzed in Section 11.8.3, this overshoot comprises two components at once: mechanical-liquidation overshoot (the nonlinear price impact of the liquidation engine's forced sell orders in the liquidity vacuum, corresponding to about 93.5% of the sell orders at the peak moment being forced closures) and behavioral-panic overshoot (the voluntary panic selling of traders who had not been liquidated after they observed the cascade, corresponding to about 6.5% of the voluntary selling pressure, whose marginal price impact was equally significant under the already collapsed depth). Attributing the entire $8,000 price difference wholesale to "pure mechanism-induced noise" is reasonable in order of magnitude, but strictly speaking it requires further distinguishing the respective contributions of these two components.

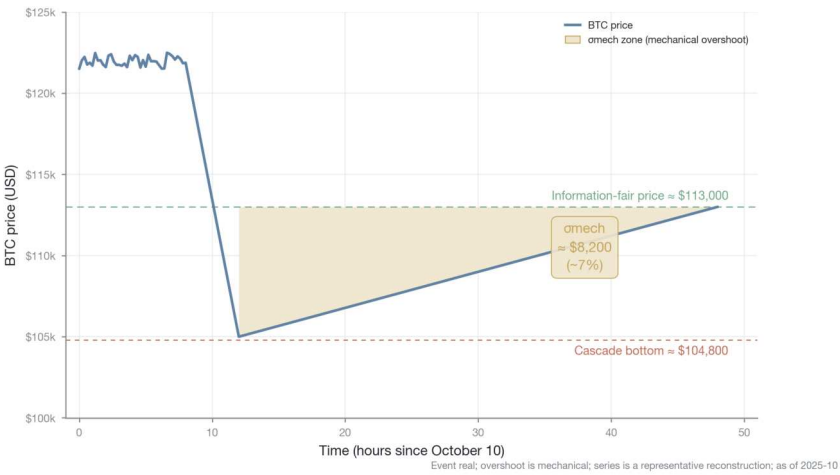

Figure 11-40. Empirical validation of mechanism-induced volatility—price overshoot and rebound (Data source: Amberdata [2], CoinGecko [3], as of October 2025; the endpoints of about $104,800/$113,000 are empirical, while the mechanism-induced overshoot $\sigma \approx$ $8,200, about 7%, is the author's model decomposition and a rough upper bound)

The rapid rebound path of the price after the cascade's termination in Figure 11-40 provides an approximate measure of mechanism-induced volatility: the price difference from the low of $104,800 to the stable range of $113,000 accounts for nearly half of the total decline during the cascade (about 46% based on the intraday high of about $122,500, or about 49% based on the trigger-moment high of about $121,500, the ratio depending on which high is used). Equating this ratio directly with the "share of mechanism-induced volatility," however, requires caution about several methodological limitations. First, using the post-crisis recovery price as a proxy for "fundamental fair value" is itself biased, because the recovery-period price may be affected by short-covering buying pressure, the narrowing of spreads after market makers re-enter, and post-crisis new information (such as signals of a policy response), deviating from the true valuation of the moment just before the crisis. Second, this ratio should be regarded as a rough upper bound on mechanism-induced volatility rather than a precise measure, because the overshoot contains both a mechanical-liquidation-overshoot component and a behavioral-panic-overshoot component (as in Section 11.8.3, with about 93.5% forced

liquidation and 6.5% voluntary panic selling at the peak, the latter still producing a non-negligible price impact under the already collapsed depth). A more robust alternative measure would compare the difference in decline between perpetual futures and spot over the same window (perpetual futures should systematically overshoot because of the liquidation mechanism), or compare the difference in decline between a crypto asset and a traditional asset with similar macro sensitivity but no cascade-liquidation mechanism. Rough as it is, this ratio still provides a valuable order-of-magnitude benchmark for assessing the market-efficiency loss of different liquidation modes.

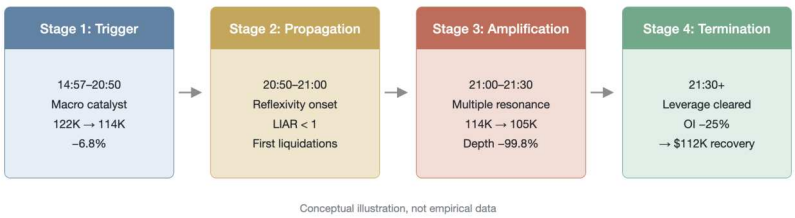

Figure 11-41. Mapping of the four-phase model onto the "10.10 event" (event data as of October 2025; the phase boundaries in the figure are drawn by the model)

As shown in Figure 11-41, superimposing this chapter's four-phase model onto the actual data of the "10.10 event" validates the consistency between theory and empirical observation: the six-hour slow decline of the trigger phase (14:57–20:50 UTC), LIAR falling below 1 in the propagation phase (20:50–21:05), depth going to zero and spreads widening more than a thousandfold in the amplification phase (21:05–21:30; see Table 11-7), and the liquidation rate falling back after OI plunged 25% in the termination phase all closely match the model's phase divisions and transition conditions. This shows that the liquidation reflexivity equation has some explanatory power, while the cascade risk index, as an exploratory proxy for fragility, still requires large-sample testing to establish its warning value.

11.10 Chapter summary

Through a systematic analysis of the liquidation mechanism of perpetual futures, this chapter has revealed the core structural paradox in the microstructure of crypto-asset markets: the liquidation mechanism was designed to eliminate bad debt and maintain system solvency, but under extreme market conditions it turns into the main amplification mechanism of systemic risk. This transformation stems not from a single code flaw but is rooted in the endogenous interaction of leverage, liquidity, and automated execution. This chapter's analytical framework centers on the endogenous microstructure while also revealing the modulating role of macro liquidity conditions on baseline fragility, the amplifying effect of behavioral-finance mechanisms in clustering and panic, and the external constraint that the legal and regulatory dimension imposes on mechanism design.

The five theoretical tools this chapter constructs deconstruct this dynamic process along

different dimensions. The liquidation reflexivity equation formalizes the two-way causal relationship between liquidation and price, showing that when liquidation selling pressure exceeds the order book's absorption capacity, the price decline is no longer driven by fundamentals but dominated by the liquidation mechanism itself. The impossible trinity of liquidation design further indicates that in a decentralized or highly fragmented market, capital efficiency, liquidation smoothness, and system safety cannot be achieved simultaneously, and existing exchanges generally pursue capital efficiency at the expense of liquidation smoothness, creating the structural conditions for cascade collapse. The time-compression effect explains why the deleveraging process in crypto markets is completed on a time scale of minutes: the millisecond execution speed of smart contracts and matching engines deprives traditional risk-management measures of their response window. The theory of the information paradox and mechanism-induced volatility quantifies the degree to which liquidation events distort price-discovery efficiency: unable to distinguish informational selling from mechanical closing in the order book, market makers are forced to adopt overly defensive strategies and, at the macro level, manufacture a price overshoot beyond the change in fundamentals. The compound positive-feedback model of the funding rate and liquidation reveals how extreme funding rates systematically accumulate fragility before a liquidation erupts by continuously consuming longs' maintenance margin.

The "10.10 event" provides a complete empirical validation of this analytical framework. The macro shock was amplified step by step through the weaknesses of the microstructure, the unified margin system turned in the crisis from a capital-efficiency tool into a conduit for cross-asset contagion, and the forced intervention of auto-deleveraging further weakened the market's remaining capacity to supply liquidity.

These findings have practical significance at different levels. Traders' risk management needs to go beyond monitoring individual positions and incorporate systemic liquidity conditions and leverage crowding into its assessment framework. In a highly reflexive market, an individual's leverage not only reflects their own risk appetite but also constitutes a micro-contributing factor to system fragility. Even if an individual adopts a conservative hedging strategy, they may still suffer collateral liquidation under cross-margin and auto-deleveraging mechanisms. Market-infrastructure construction, for its part, needs to place systemic-risk management at the core of product design; specifically, multi-node liquidity-weighted oracles, progressive liquidation curves, and elastic risk-reserve mechanisms are key paths to reducing cascade risk. At the regulatory level, static capital-adequacy requirements or leverage caps are no longer sufficient to cope with dynamic risk, and the regulatory focus needs to shift toward systemic-risk monitoring based on real-time data; an early-warning system that captures order-book depth changes, cross-market funding-rate anomalies, and liquidation-concentration indicators in real time is a precondition for intervening before a crisis takes shape.

The intrinsic paradox of the liquidation mechanism essentially reflects the fundamental tension between efficiency and stability in crypto-asset markets. Having understood how liquidation turns from a risk-management tool into a risk-amplification mechanism, we arrive at the next core question: when the liquidation engine has exhausted market liquidity and auto-deleveraging can no longer cover the margin shortfall, where is the system's final line of defense? This leads to the subject of the next chapter: the insur-

ance fund. The capital structure of the insurance fund, its replenishment mechanism, and its capacity to bear stress under extreme conditions will determine the systemic resilience of the crypto-asset derivatives market.

The Political Economy of Insurance Funds

On October 10, 2025, the cryptocurrency market experienced an unprecedented mass liquidation event. Within just 24 hours, visible liquidation notional exceeded $19 billion (roughly $19.1–19.4 billion on CoinGlass's basis; because some platforms' liquidation feeds are rate-limited to a single record per second, this visible liquidation notional is likely systematically underestimated, and CoinGlass estimates that the true scale of deleveraging may have reached $30–40 billion), affecting roughly 1.62 million traders and erasing about $350 billion in total cryptocurrency market capitalization. This catastrophe, later dubbed the "10/10" event, laid bare for every market participant a problem long buried in the mechanics of perpetual futures: when a chain of forced liquidations finally breaks through a trader's margin floor and drives account equity below zero (a *shortfall*), who ultimately bears that loss, and how?

In the previous chapter, we analyzed in detail how risk evolves from the failure of an individual trader—through the chain reaction of a liquidation cascade—into systemic risk that sweeps across the entire market. If the previous chapter answered the question of how risk spreads, this chapter takes up that logic to examine a more fundamental proposition: how the system absorbs and allocates that risk. The deficit created by a shortfall does not vanish on its own; it must be filled. If such a deficit is allowed to widen, profitable traders can no longer be certain that their gains will be honored in full, and the market's foundation—the credible management of counterparty risk—loses its essential function. In a market where counterparty credit cannot be guaranteed, market makers will refuse to provide liquidity, institutional investors will exit, and the market as a whole will ultimately shrink amid a collapse of trust.

How losses are borne is, at bottom, a question of risk socialization. Because a shortfall loss cannot be covered by the defaulter, it must be transferred to other participants in the system. In crypto derivatives markets, risk socialization proceeds along two distinct paths: ex ante pooling (establishing an insurance fund) and ex post allocation (auto-deleveraging or socialized loss). The two are not opposing alternatives but tightly linked levels of a single risk-socialization mechanism, together forming a tiered risk-resolution system (its penalty sources, buffer-pool mechanics, and allocation mechanisms are elaborated in Section 12.1.2).

Within this system, an insurance fund is far more than a simple pool of capital; it is an institutional arrangement charged with the tensions of political economy. Where

does the money come from? Is the fund large enough? Who has the authority to decide when it is used? Are the rules for its use transparent? And does the very existence of an insurance fund create new moral hazard? This chapter argues that the insurance fund is the node where technical design and political governance intersect most deeply in the perpetual-futures system. Its technical dimension—size, adequacy ratio, and trigger rules—can be optimized with actuarial models; but its governance dimension—who controls the fund, who decides on its use, whether information is disclosed, and whether users are told the true risks—involves deeper questions of power, trust, and the distribution of interests. These questions cannot be solved by code alone; they can only be constrained by sound institutions. At the same time, the insurance fund and the auto-deleveraging mechanism together constitute a dual institutional arrangement for risk socialization, and this combination of ex ante pooling and ex post allocation ultimately determines the settlement credibility and rule predictability of the perpetual-futures market. The chapter pursues three questions in turn: What is the dual mechanism of risk socialization, and how does it guarantee settlement credibility? Why must this system inevitably involve political economy, and how are its design parameters determined amid the interplay of competing interests? And how can we build a systematic analytical framework to evaluate the risk-mutualization mechanisms of different platforms?

12.1 The inevitability of shortfalls

Before examining how risk is socialized, we must first grasp a core fact: forced liquidation is by no means risk-free liquidation. In theory, a liquidation engine always seems able to close a position precisely before the price reaches the bankruptcy line, containing the loss perfectly within the trader's margin. In reality, however, a vast gulf—created by multiple sources of friction—separates the idealized liquidation model from the chaos of actual markets. It is precisely these frictions that make shortfalls structurally inevitable, and the existence of shortfalls is the fundamental reason the entire risk-socialization mechanism and all of its institutional arrangements come into being. Understanding these frictions is the logical starting point for understanding why insurance funds must exist.

12.1.1 Four frictions in the liquidation process

When markets enter a state of extreme volatility, the liquidation mechanism tends to encounter four core frictions. These frictions do not stem from design flaws in the liquidation engine itself; they are rooted in the intrinsic limitations of market microstructure and infrastructure. They are the direct drivers of shortfalls and a key entry point for understanding why insurance funds are necessary.

The most direct friction arises from insufficient order-book depth. When a large-scale liquidation occurs, enormous market-order closeouts instantly exhaust the liquidity resting on the order book. Market makers, as the suppliers of market liquidity, build their core business model on spread income rather than on bearing directional risk. When the market moves violently in one direction, market makers—seeking to avoid excessive

directional exposure of their own—often widen their bid-ask spreads sharply or withdraw their quotes altogether. This sudden evaporation of liquidity forces liquidation orders to fill at markedly unfavorable prices, and the final execution price is often far worse than the trader's bankruptcy price. This phenomenon was especially pronounced during the 2025 "10/10" event. According to data from the research firm Amberdata, during a mere 40-minute phase of violent cascading (20:50 to 21:30 UTC), positions totaling $6.93 billion were liquidated, and the liquidation rate surged to $10.39 billion per hour—about 866 times the $12 million per hour of the normal period in the eight hours before the event [1]. Under such concentrated selling pressure, the top-of-book depth for Bitcoin shrank by more than 90%, and the bid-ask spread jumped from a normal single-digit number of basis points to double-digit percentages [2]. In such an extreme liquidity vacuum, the liquidation engine simply could not complete closeouts without triggering shortfalls. Figure 12-1 places the 10/10 event in a longitudinal comparison with major liquidation events in the history of crypto derivatives; it shows that the liquidation scale of October 10, 2025 (about $19.37 billion on CoinGlass's basis, exceeding $19 billion) was nearly double the previous record (about $10 billion on April 18, 2021) and almost 20 times that of the 2020 "Black Thursday," reflecting a trend in which liquidation scale accelerates as the market becomes more leveraged.

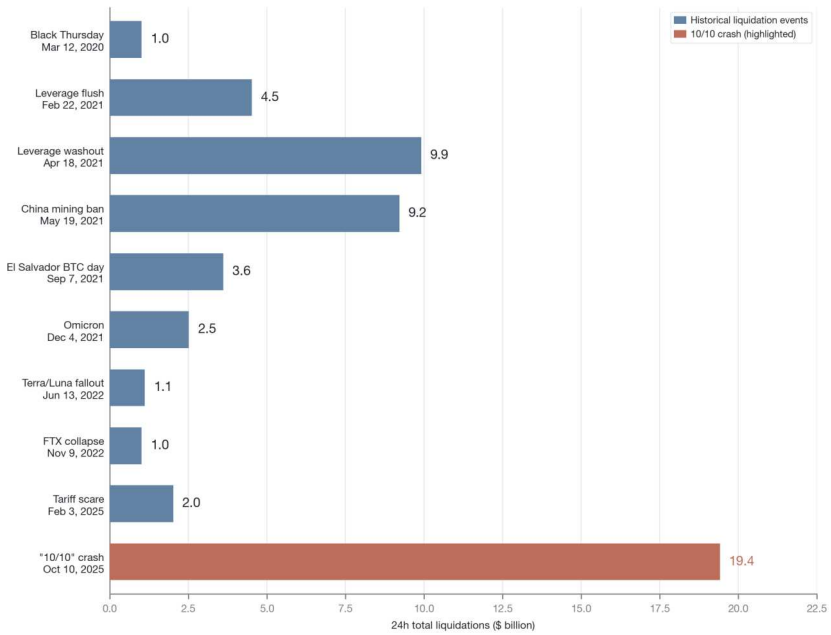

Figure 12-1. Historical comparison of major liquidation events in crypto derivatives (CoinGlass basis, subject to historical underestimation; the April 18, 2021 and May 19, 2021 events were of similar scale, both in the range of roughly $9 billion to $10 billion, with April 18 slightly higher when reconciled at present value)

Comparison across periods based on absolute liquidation volume alone can mislead, because the overall size of the cryptocurrency market has differed enormously across periods. A more analytically useful, standardized metric is the ratio of liquidation volume to the total cryptocurrency market capitalization of the same period. Take

the March 2020 "Black Thursday": about $10 billion in liquidations corresponded to a total crypto market capitalization of roughly $200 billion at the time, a normalized ratio of about 0.5%. By contrast, the roughly $19.37 billion in visible liquidations on October 10, 2025 (CoinGlass basis; note that this visible notional may be systematically underestimated because of platform rate-limiting) corresponded to a total market capitalization of about $3.5 trillion, a normalized ratio of about 0.55%. The closeness of the two events on this standardized metric offers a preliminary hint that the relative severity of extreme liquidation events across different market cycles may follow some regularity worth further verification. This preliminary observation must, however, be treated with caution: two data points are not enough to establish a statistically robust regularity; the normalized ratios of other historical extreme events (such as May 19, 2021, or the liquidation event triggered by the Bank of Japan's rate hike on August 5, 2024) may deviate substantially from this range; and the heterogeneity of macro shocks (global systemic panic versus a regional geopolitical shock may differ fundamentally in transmission path and liquidation severity) means it would be unwise to attribute the consistency of the two ratios simply to an endogenous structural property of the crypto market. Moreover, using total open interest (OI) rather than total market capitalization as the normalization denominator could yield different conclusions. If this preliminary observation holds up under a larger sample and more diverse standardization methods, it would carry important implications for calibrating the actuarial models of insurance funds.

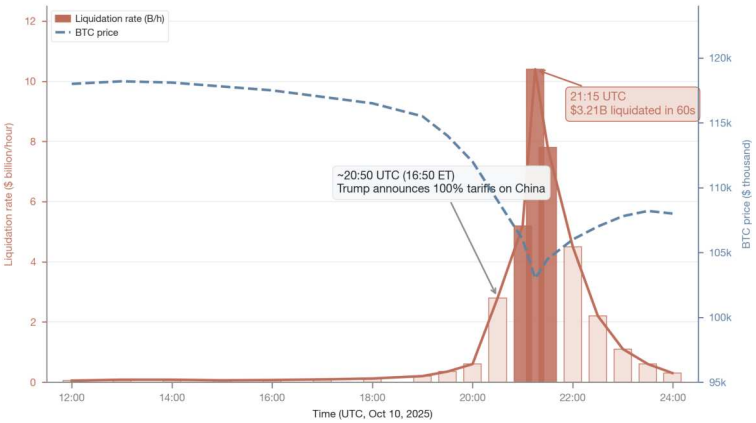

Figure 12-2. Liquidation rate and BTC price timeline for the 10/10 event (the minute-by-minute liquidation-rate and price series is a reconstructed illustration based on characteristic parameters from Amberdata and CoinGecko, not raw tick-by-tick data; endpoints and peaks have been verified)

As shown in Figure 12-2, within the 60 seconds around 21:15 UTC, positions worth $3.21 billion evaporated instantly—a liquidation rate that far exceeded the market's liquidity-bearing capacity. Insufficient order-book depth is a problem not only during extreme events; in day-to-day trading, the distribution of liquidity is itself highly time-varying and non-uniform, and extreme conditions merely amplify this ever-present fragility in its most violent form. The retreat of market makers, though rational risk avoidance at the individual level, constitutes at the system level a *procyclicality of liquidity*: the

moment the market most needs liquidity is precisely the moment when the supply of liquidity is scarcest.

A second class of friction, running parallel to insufficient liquidity, is the price gap. In certain extreme conditions, an asset's price does not move continuously and smoothly but plunges in a cliff-like fashion. The price may instantly leap past a trader's liquidation price or even bankruptcy price, so that the position has no chance to fill at the preset protective level. This phenomenon exists in traditional financial markets as well (the price limits and circuit breakers of stock markets were designed precisely to address such price discontinuities), but in a cryptocurrency market that trades 24/7 without circuit breakers, the losses caused by price gaps are markedly larger. The "Black Thursday" of March 12, 2020, is the most typical case. That day, amid the global panic selling triggered by the COVID-19 pandemic, the price of Bitcoin plunged from about $7,900 to around $3,800 within roughly 24 hours (spanning the two trading days of March 12 and 13), a drop of more than 50% [3]. In such an extreme price gap, large numbers of highly leveraged long positions fell directly into deep shortfall. According to a research report by Ledger Prime, BitMEX alone saw liquidations exceeding $1.4 billion within a roughly 24-hour rolling window; during its downtime it deployed 1,627 deleveraging positions, and its insurance fund fell from about 35,500 BTC to about 33,880 BTC (a decrease of about 1,620 BTC) [4]. The essence of a price gap is that it renders wholly invalid the assumption of price continuity on which the liquidation engine relies. When prices no longer move continuously, any liquidation logic based on step-by-step triggering leads directly to a shortfall because it cannot find an executable intermediate price.

The divergence between mark price and execution price constitutes a third class of friction. To prevent market manipulation and abnormal price swings on a single exchange from triggering unwarranted liquidations, most exchanges use a weighted average of external spot indices as the *mark price* that triggers liquidation. When the exchange's internal derivatives market collapses, however, the internal contract execution price diverges enormously from the external index price. This divergence creates a dangerous *scissors gap*: relying on the relatively stable external mark price, the liquidation engine judges that a position has not yet reached the liquidation line, but when that position must finally be closed in the collapsing internal market, the actual execution price may already be far below the bankruptcy price. Conversely, in other cases abnormal swings in the internal price may trigger liquidations that should never have occurred. During a contract flash crash on OKEx (now OKX) on March 30, 2018, the external spot index price held at about $7,000, but the exchange's internal quarterly contract execution price instantly plunged to about $4,755 (some sources round this to about $4,800). This divergence of more than 25% relative to the index (about 30% to 32% at the prices above) caused large numbers of traders who should not have been liquidated to suffer irrational forced liquidation, producing severe shortfall losses (OKEx subsequently rolled all contracts back to 04:07 that day and introduced price-limit rules). The mark-price mechanism is itself an important protective measure, but it cannot eliminate the risk of the internal and external markets decoupling under extreme stress—and that decoupling is yet another important source of shortfalls.

Infrastructure congestion aggravates shortfall risk along another dimension. Even if the

liquidation mechanism is flawless in its logical design, bottlenecks in the underlying infrastructure on which it runs can likewise lead to serious consequences. This problem is especially acute in decentralized finance, because the execution speed and throughput of on-chain transactions are hard-constrained by the underlying blockchain's performance. During the 2020 "Black Thursday," the Ethereum network became severely congested under a flood of transaction requests, and gas fees surged from about 20 Gwei in normal times to more than 500 Gwei, a 25-fold increase. This left MakerDAO's liquidation bots unable to submit liquidation transactions in time, because the gas fees they bid were insufficient for miners to include them within a reasonable period. As a result, over a window of about 40 minutes, some speculators seized the opportunity to "win" auctions of Ethereum collateral worth millions of dollars at the extremely low cost of 0 DAI; the total value of collateral swept away in these zero-bid auctions reached about $8.32 million (in a normal liquidation auction, collateral should be sold competitively to recover an equivalent amount of DAI to repay the debt, but because the liquidation bots could not participate in the bidding in time, speculators won with bids of 0 DAI for ETH collateral that should have been worth millions). After deducting the collateral taken for nothing, the MakerDAO protocol was ultimately left with about 5.67 million DAI (roughly $4.5 million) in uncollateralized bad debt, a gap eventually covered by an auction that minted new MKR tokens [5]. The success of the 0 DAI auctions was also partly attributable to a design flaw in MakerDAO's auction contract—namely, a starting bid price of 0 with no reserve-price protection—which allowed a speculator to win at an arbitrarily low price when no competitors participated. This event demonstrated that in DeFi, the effectiveness of a liquidation mechanism depends not only on the logical correctness of the smart contract but also on the availability and reliability of the underlying blockchain network under extreme stress. Since 2020, the infrastructure here has changed substantially. Most current decentralized perpetual-futures platforms (such as Hyperliquid and dYdX v4) run on dedicated app-chains or high-performance Layer 2s, and the problem of gas congestion has largely been resolved. The new architecture, however, introduces new forms of infrastructure risk—including the single-point-of-failure risk of the sequencer, app-chain consensus latency, and cross-chain bridge dependencies—and these new bottlenecks can likewise cause liquidation delays and shortfalls in extreme conditions.

These four frictions point to a core fact: no matter how well the mechanism itself is designed, infrastructure bottlenecks, the endogenous limits of market liquidity, and the discontinuity of price discovery can all lead to serious shortfalls. A shortfall is by no means a flaw of system design; it is a structural inevitability under real market frictions. This structural inevitability gives rise directly to the fundamental need for a risk-socialization mechanism.

The four frictions in the liquidation process and their representative cases (panel ① draws on the 2025 "10/10" event; panels ② through ④ draw on the "Black Thursday" of March 12, 2020; the panels are dimensionally heterogeneous, and panel ① approximates order-book depth depletion with the liquidation rate)

12.1.2 Ex ante pooling and ex post allocation

The inevitability of shortfalls means their economic consequences must be handled systematically. A shortfall is, in essence, a default by a debtor (the liquidated trader whose equity is negative) on a creditor (the profitable trader). In traditional financial markets, a broker can pursue a defaulting client for the amount owed through legal channels, because the client's true identity and asset situation are known. In cryptocurrency markets, however, because of the anonymity (or at least pseudonymity) of accounts and the absence of real-world legal recourse, a platform cannot pursue defaulters for the shortfall as a traditional broker would. At the behavioral level, this institutional feature constitutes an implicit moral-hazard incentive: a highly leveraged trader faces an asymmetric payoff structure of "limited liability plus unlimited upside"—profits accrue to the individual, while losses beyond the margin are borne by the insurance fund or by other traders. As Jensen and Meckling (1976) noted in their classic agency-theoretic analysis, limited liability systematically incentivizes an upward shift in risk appetite [6]. As Know Your Customer (KYC) requirements spread and on-chain identity-tracking technologies (such as Chainalysis and Arkham) advance, this "no recourse" constraint is gradually eroding—yet it remains the general reality of crypto derivatives markets at the current stage. This means the loss produced by a shortfall cannot be pushed outside the system; it must be absorbed within it. In other words, the loss must be socialized—borne collectively by some group of participants in the system. To understand this inevitability, one must recognize the (aggregate) zero-sum nature of the perpetual-futures market once funding rates and fees are removed: in the aggregate, a shortfall trader's excess loss corresponds exactly to the receivable, unrealized profit

of the holders on the other side of the contract (typically the profitable side). The shortfall trader's loss exceeds what their margin can cover, and this excess loss corresponds in accounting terms to the profitable side's receivable profit. If the system does not apportion this "bad debt" through some mechanism, the profitable side's profit becomes a paper figure that cannot be honored. Risk socialization is therefore not a subjective choice of the system's designers but a logical consequence of shortfalls under a zero-sum structure. Faced with this challenge, crypto derivatives markets have evolved two distinct paths of risk socialization.

The first path is ex ante pooling, whose core vehicle is the insurance fund. Before a shortfall event occurs, the insurance fund gradually accumulates a common pool of capital by continuously collecting liquidation penalties from the risk-takers who trigger liquidation. Besides liquidation penalties, the fund's revenue sources also include liquidation surplus (the spread that arises when the liquidation execution price is better than the bankruptcy price, which under normal market conditions is typically the main driver of the fund's growth) and, at some platforms, dedicated subsidies drawn from fee income. When a shortfall actually occurs, this pool serves as the first line of defense, collectively covering the deficit. The core advantage of this approach is that it has no direct effect on profitable traders: it does not erode their profits or disrupt the hedging strategies they have carefully constructed. More importantly, because the rules of the insurance fund are set in advance, it provides the market with a high degree of rule predictability. Before entering, traders know clearly that under normal circumstances their profits will not be eroded by others' shortfalls.

The second path is ex post allocation, which appears mainly in two mechanisms: socialized loss and auto-deleveraging. When the insurance fund is exhausted, the system has no choice but to impose the loss on profitable traders. Socialized loss uses a global-apportionment approach, deducting the total loss proportionally from all profitable accounts. Although this makes each person's loss relatively small, the amount is entirely unpredictable, and traders discover only at settlement that part of their profit has been deducted. Auto-deleveraging, by contrast, takes a targeted-selection approach: the system ranks positions by a combined score of return and leverage and forcibly closes the top-ranked profitable positions to offset the defaulter's loss. A trader subject to auto-deleveraging (ADL) is typically force-closed at the shortfall trader's bankruptcy price, which means the selected profitable trader not only loses the position but may be executed at a price far worse than the current market price, so that the actual loss can far exceed a mere give-back of book profit. This mechanism can be highly destructive for the selected trader: a cross-market hedged portfolio carefully constructed across several exchanges can turn instantly from "market-neutral" into naked directional exposure because one of its legs is force-closed by ADL. The execution challenges faced after being ADL'd go well beyond this: the hedging leg on another exchange must be urgently closed in an equally illiquid market; cross-platform capital rebalancing depends on on-chain transfers (which may be delayed by tens of minutes during network congestion); and the compounding of slippage in extreme conditions makes the total loss far exceed the book impact of the ADL itself. The real destructiveness of ADL to cross-platform hedging strategies is far greater than the loss on a single position, and its unpredictability severely undermines the foundation of market trust.

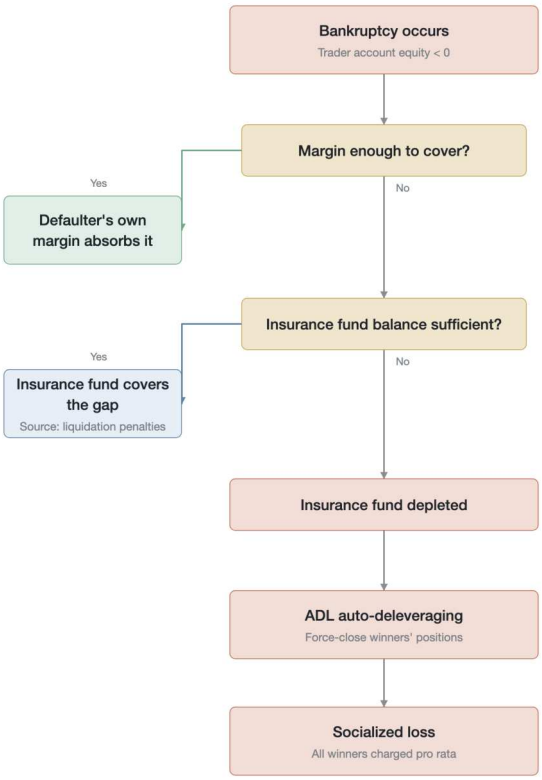

Figure 12-4. The liquidation and risk-socialization waterfall for perpetual futures

The comparison makes clear that both socialized loss and auto-deleveraging resolve the immediate crisis by undermining rule predictability. Socialized loss makes every profitable trader's profit uncertain; auto-deleveraging makes some profitable traders' continued holding uncertain. This uncertainty is a fundamental flaw that any mature financial market strives to avoid, because it directly erodes participants' confidence in the settlement system. For precisely this reason, the ex ante insurance fund is decisive: it is not merely a capital buffer but the ultimate buffer that reduces the probability of ex post allocation being triggered. The more adequate the insurance fund, the lower the probability that ex post allocation is triggered, and the higher the market's settlement credibility and rule predictability.

Ex ante pooling and ex post allocation are not the only conceivable architectures for risk socialization. In traditional finance and the academic literature, there exist at least three alternative or complementary mechanisms. The first is the circuit breaker: when a price falls by more than a preset threshold within a short period, the system halts trading to buy a window of time for liquidity to recover and information to be digested. Traditional stock markets widely adopt this mechanism, but in a crypto market that runs 24/7 and treats censorship resistance as a core principle, "who has the authority to press the pause button" is itself a governance problem. The second

is a market-maker backstop obligation, whereby designated market makers assume an obligation of last resort to absorb order flow in extreme conditions, analogous to the New York Stock Exchange's designated market maker system. Crypto market makers, however, are generally not bound by such obligations and are often the first to withdraw liquidity in extreme conditions. The third is a mandatory hedging requirement, whereby one-sided positions above a certain size must hold an offsetting position in an external market, limiting shortfall risk at its source. This mechanism is conceptually the most thorough, but it lacks a technical basis for enforcement in an anonymized crypto market. The practical limitations of these alternatives argue, by contrast, for the institutional rationality of the current two-tier "insurance fund plus ADL" architecture in crypto derivatives markets. Far from perfect, it is nonetheless the most feasible risk-socialization solution under existing technical and governance constraints.

12.1.3 Internalizing negative externalities and supplying a public good

From a deeper economic perspective, an insurance fund is in essence a mechanism for internalizing negative externalities. In the perpetual-futures market, highly leveraged traders take on great risk in pursuit of high returns. When the market moves against them and they fall into shortfall, that loss—if not handled properly—translates directly into losses for other, profitable traders. This phenomenon, in which the risk-taking of some inflicts losses on others, is what economics calls a classic negative externality. Absent any intervening mechanism, risk-takers need not pay the full social cost of their behavior, which leads to systematic excessive risk-taking: the gains from risk-taking accrue to the individual, while the losses are borne by the collective.

The insurance fund solves this problem by institutional design. It levies a fee—the liquidation penalty—on traders who engage in high-risk behavior and are ultimately liquidated. This fee can be viewed as a "risk tax" that forces risk-takers to pay in advance for the externalities they may cause. The system aggregates these taxes into a common buffer pool dedicated to handling the consequences of shortfalls in extreme situations. In this way, the insurance fund forms, within the system, a closed loop of risk pricing and cost absorption, successfully internalizing the negative externalities of individual speculation. In economic principle, this mechanism closely resembles a Pigouvian tax: by taxing behavior that generates negative externalities, it brings private cost closer to social cost and thereby corrects market failure. The core function of a Pigouvian tax is to change incentives ex ante so as to reduce the volume of negative-externality activity, not to compensate victims ex post. If the current level of liquidation penalties is insufficient to effectively deter excessive leverage (that is, if it falls short of the Pigouvian optimal tax rate), then the insurance fund is closer to a "compulsory risk-mutualization fund" than to a Pigouvian tax in the strict sense.

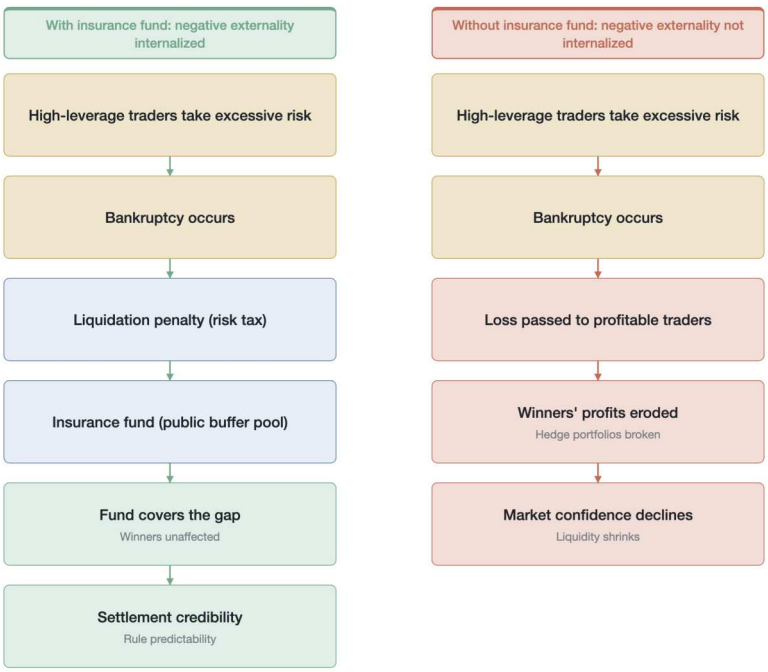

Figure 12-5. How an insurance fund internalizes negative externalities: a mechanism comparison

As shown in Figure 12-5, the presence of an insurance fund corresponds to a virtuous closed loop of cost absorption, whereas the absence of one corresponds to negative externalities spilling outward along the chain of counterparties.

The core output of an insurance fund is not the return earned by investing its capital but two decisive public goods it provides to the entire market. The first public good is settlement credibility. Only when the insurance fund serves as a solid backstop can profitable traders be confident that their book profits will be honored in full and without exception, without having to worry constantly that others' failures will erode their gains. This confidence is especially critical for market makers: the reason they are willing to provide continuous two-sided quotes is that they trust their profits can be reliably settled. If that trust is broken, market makers will withdraw or sharply widen their spreads, and market liquidity will contract dramatically. The second public good is rule predictability. In its Principles for Financial Market Infrastructures, the Bank for International Settlements states explicitly that ensuring the fulfillment of payment obligations to non-defaulting parties is a core function of any financial market infrastructure [7]. In crypto derivatives markets, the insurance fund is precisely the institutional vehicle for this core function. It makes the seemingly self-evident promise that "if you make money, you will surely be able to collect it" possible in a market full of anonymous traders and extreme volatility.

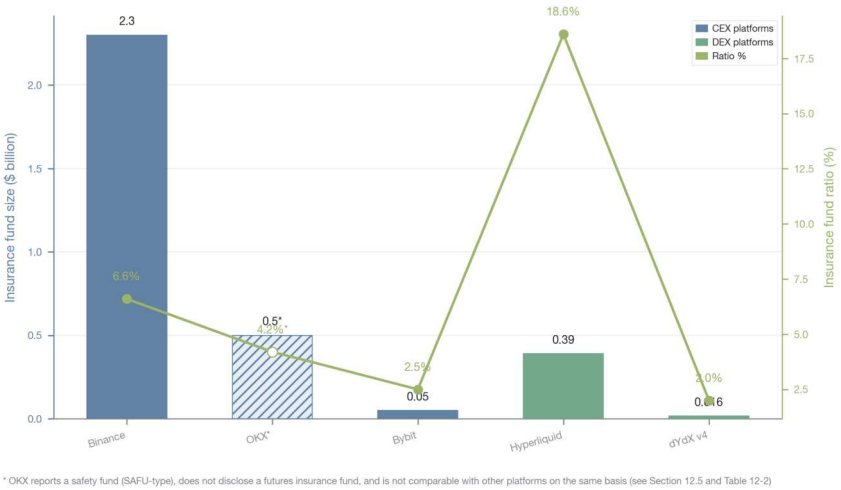

Figure 12-6. Comparison of major exchanges' insurance-fund size and fund-to-open-interest ratio (the fund-to-open-interest ratio is the author's estimate; platforms do not publish this ratio, and the Hyperliquid ratio is an upper-bound estimate based on total HLP TVL; fund sizes are an as-of-2025 snapshot, and present values have since changed and are highly time-sensitive)

Figure 12-6 compares the absolute and relative sizes of major exchanges' insurance funds. It shows that the platform with the largest absolute size (such as Binance, exceeding $2.3 billion) actually has a lower fund-to-open-interest ratio (about 6.6%) than a smaller decentralized platform (such as Hyperliquid, about 18.6%). This difference shows that absolute size alone can be misleading, and that the ratio of the fund to total open interest (here "total open interest" refers to the sum of the notional value of all outstanding contracts across all trading pairs on the platform—that is, the USD-denominated aggregate of open interest) is the effective metric for measuring the buffer thickness per unit of risk exposure. Note that Hyperliquid's roughly $390 million here is the total value locked (TVL) of the HLP vault, which encompasses a shared capital pool for both the market-making strategy and the liquidation-vault strategy. After the 2025 JELLY incident, the liquidation vault was segregated from the HLP main pool, and its standalone size was capped at a "small fraction" of the total HLP balance (the specific proportion has not been publicly disclosed), significantly below the total HLP TVL. Using total HLP TVL directly as the insurance-fund size for cross-platform comparison may therefore overstate Hyperliquid's actual risk-buffer thickness, and the 18.6% ratio should be understood as an upper-bound estimate based on total HLP TVL.

An insurance fund is not, however, a flawless mechanism. In solving the negative-externality problem, it introduces a series of new and complex challenges concerning adequacy of size, transparency of management, and moral hazard. Is the fund large enough to withstand extreme events? Are the rules for its use transparent and verifiable? Does the very existence of the fund instead encourage traders to take on greater risk, because they know a "safety net" underwrites their risk-taking? From a principal-agent perspective, the operation of an insurance fund is nested within two layers of principal-agent relationship. The first layer is between the platform and traders: traders, as principals, delegate the authority for risk management to the insurance fund

operated by the platform, but the platform, as agent, holds an informational advantage regarding the fund's true condition, and this information asymmetry may allow the platform to conceal the fund's true risk exposure or misappropriate its assets (hidden-action moral hazard). The second layer is between the platform and liquidity providers (LPs), who deposit funds into the market-making vault or insurance pool and thereby delegate risk underwriting to the platform, but who lack sufficient observability of the platform's liquidation strategy, risk-parameter adjustments, and discretionary decisions in extreme situations (hidden-information adverse selection). This dual principal-agent structure means that the institutional design of an insurance fund must not only solve the technical question of whether the fund is large enough but also mitigate the moral hazard inherent in each layer of agency through incentive-compatible mechanism design. These challenges test not only a platform's technical design capabilities but, more deeply, its governance wisdom. The sections that follow take up these questions across several dimensions: the institutional architecture of the liquidation waterfall, actuarial adequacy-ratio models, the economic consequences of auto-deleveraging, the political economy at stake, the transmission between confidence and liquidity, dual moral hazard, and the governance spectrum.

12.2 Auto-deleveraging: the final mechanism of risk socialization

When extreme conditions leave the liquidation engine's closeout orders unexecutable for lack of liquidity, and the insurance fund is fully exhausted, the system triggers its last line of defense: auto-deleveraging. As the bottom layer of the liquidation waterfall, ADL is the most contested institutional design in crypto derivatives markets. It no longer attempts to resolve risk through market-based means; instead, through forced intervention, it directly strips some profitable traders of their profits and positions in exchange for the survival of the entire system. ADL is not a simple "risk-bearing switch" but a complex mechanism-design problem, involving the fairness of the ranking algorithm, the differentiated impact on different participants, and an inescapable trilemma among solvency, revenue, and fairness. To understand ADL is not merely to understand a risk-control algorithm; it is an entry point for analyzing the trade-offs among efficiency, fairness, and solvency in crypto markets under extreme conditions.

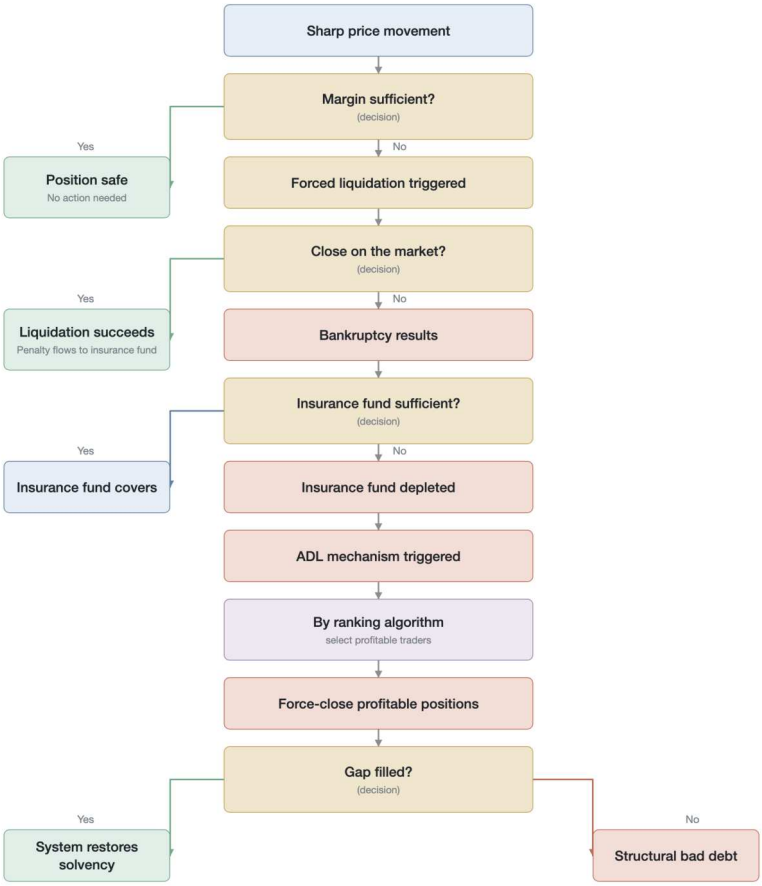

Figure 12-7. The decision process from price movement to an ADL trigger

12.2.1 Ranking algorithms

After shortfall losses break through the three buffers of margin, the liquidation engine, and the insurance fund in turn, the system finally enters the ADL stage (as shown in Figure 12-7). The core of ADL lies in deciding who bears the loss. When a shortfall loss exceeds the insurance fund's current balance, or the fund balance falls below a preset threshold, ADL is triggered. The system first identifies the size of the shortfall gap, then determines a deleveraging priority among the holders of opposing profitable positions according to a ranking algorithm, and force-closes at the bankruptcy price starting from the highest-ranked holder until the gap is completely filled. In mainstream implementations, these "opposing profitable positions" are strictly limited to opposing holdings in the same contract: when a BTC long falls into shortfall, the system selects ADL targets only among the profitable holders of BTC shorts, and never executes across contracts. A direct consequence of this design is that for low-liquidity long-tail assets, if long and short positions are highly imbalanced, the opposing profitable positions available for ADL are extremely limited—which is precisely the root cause

of the structural bad debt in the WLD case discussed in Section 12.2.3. When facing a systemic shortfall gap, an exchange must establish a clear set of rules to select the "sacrifices" from among its many profitable traders. The concrete embodiment of these rules is the ADL ranking algorithm. At present, the market's ADL algorithms have evolved into three main paradigms, each embodying a distinct design philosophy.

The oldest and most widely used is the queue-ranking algorithm based on the "product of profit rate and leverage." This ranking formula was introduced by BitMEX in 2016 (Huobi first introduced the ADL mechanism itself in 2015, but it lacked an estimable ranking), and it has since become the de facto industry standard, adopted by Binance (which adopted the formula in 2019), Bybit, and the decentralized platform Hyperliquid, among others [8]. Its core logic is that those who use the highest leverage and reap the largest unrealized profits are regarded as the group that has benefited most from the current extreme conditions and, simultaneously, contributed most to system risk. The system therefore scores and ranks all profitable accounts by the product of return and effective leverage. When ADL is required, the system force-closes the positions of these "top winners" one by one, strictly from highest to lowest, until the shortfall gap is completely filled. The advantage of this algorithm is its extremely high execution efficiency: it can eliminate the largest risk exposure with the fewest operations. Its core defect, however, is that it excessively concentrates its punishment on the most successful traders, giving rise to strong moral hazard and adverse selection. A selected trader may lose all of their profit or more, while the vast majority of profitable traders are entirely unaffected. More seriously, the queue-ranking algorithm has extremely low Sybil resistance: a sophisticated trader can split one large account into several small accounts to lower each account's ranking score, effectively evading the risk of being selected for ADL, so that those who ultimately bear the ADL impact are often the less sophisticated participants. Sybil-evasion strategies are not, however, costless: on centralized exchanges, operating multiple accounts runs up against the hard constraint of KYC identity verification; on decentralized platforms, spreading positions across sub-accounts requires each to maintain margin independently (forfeiting the capital efficiency of cross-margining), and managing multiple accounts increases the probability of operational error in extreme conditions.

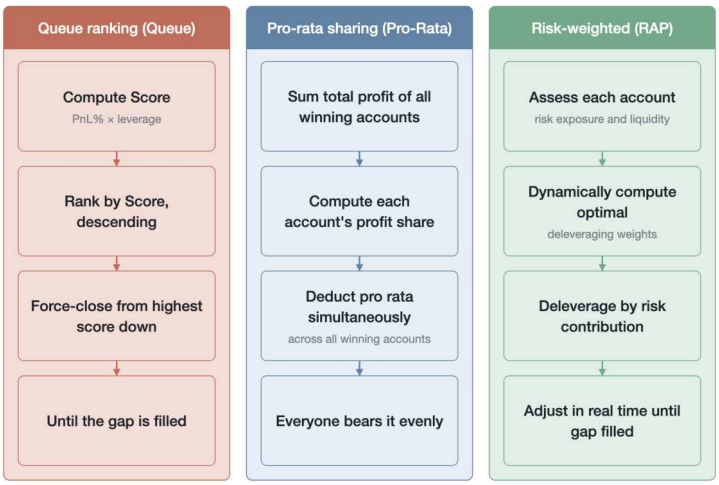

Figure 12-8. A comparison of the execution logic of three classes of ADL ranking algorithms

As shown in Figure 12-8, queue ranking concentrates its blows on the top winners; pro-rata allocation distributes losses evenly; and risk-weighted allocation dynamically allocates losses according to each account's aggregate risk exposure. To mitigate the extreme unfairness of queue ranking, some decentralized exchanges (DEXs, such as Drift and Paradex) have begun to explore pro-rata allocation [9]. This algorithm abandons the precise targeting of the "largest winners" and instead apportions the shortfall gap evenly across all profitable accounts in proportion to their profit. This means that regardless of leverage, any account in profit must pay a "compulsory tax" for the survival of the system. On its face, pro-rata allocation appears more moderate and fair—each person's loss is smaller—and its Sybil resistance is extremely high (splitting accounts does not change the pro-rata outcome). In actual execution, however, because it involves the simultaneous handling of a large number of tiny accounts, its computational complexity and execution latency increase markedly, and it often proves inadequate in the split-second urgency of extreme conditions. A deeper problem is that if pro-rata allocation ignores differences in risk, it causes low-risk traders to provide an implicit subsidy to high-risk traders. When this subsidy cost exceeds the trading utility that low-risk traders derive from the platform, they will rationally choose to exit, raising the platform's average risk level, which in turn forces still more low-risk traders to exit—a self-reinforcing chain of exits.

In recent years, the academic community has proposed a more advanced risk-weighted allocation algorithm. Represented by the research Tarun Chitra published in late 2025 [10], the RAP algorithm seeks a dynamic balance between efficiency and fairness. Rather than relying solely on static profit or leverage metrics, it incorporates an account's aggregate risk exposure, historical volatility, and the current market's liquidity depth, using a complex mathematical model to compute in real time each account's optimal deleveraging share. Its core idea is to align risk with cost: accounts

that contribute more to system risk should bear a larger deleveraging share, rather than being ranked simply by profit or leverage. Chitra's research further proposes the MDIC algorithm, which achieves an $O(\sqrt{T})$ regret bound, whereas any static strategy incurs linear regret $\Omega(T)$ in an adversarial environment. The core distinction here is this: in the face of an adaptive adversary, a static strategy (such as a fixed queue ranking or a fixed pro-rata allocation) accumulates regret that grows linearly with the time step T, meaning the gap between the strategy's performance and the optimal ex post benchmark widens uncontrollably; MDIC, as an online-learning algorithm, dynamically adjusts the allocation weights after each ADL event based on the observed market state, compressing cumulative regret to $O(\sqrt{T})$—that is, sublinear growth. This jump in order from $\Omega(T)$ to $O(\sqrt{T})$ is used in the paper's formal model to establish two propositions (these conclusions come from a preprint and await peer-review verification): first, under the premise of an adversarial market environment, any static ADL rule that does not adjust to the market state cannot achieve sublinear regret and is therefore suboptimal; and second, there exists a computable dynamic strategy that can asymptotically approach optimal performance [10]. Moreover, the asymptotic optimality of the online-learning framework (the advantage of an $O(\sqrt{T})$ regret bound relative to $\Omega(T)$) rests on the premise that T tends to infinity, whereas ADL events are extremely low-frequency (the 12-minute window of the 10/10 event produced only about 1,000 shocks, and most platforms experience only single-digit numbers of ADL events per year); when T is small (for example, $T < 100$), the practical numerical difference between the two is negligible. The engineering value of the MDIC algorithm may therefore lie more in its idea of dynamically adjusting weights than in a strict guarantee of asymptotic optimality. Combined with the computational complexity of the MDIC algorithm (each round requires solving a convex optimization problem) and the challenges of engineering implementation, it remains difficult to deploy at scale in a production environment and remains largely a subject of academic exploration.

12.2.2 The trilemma

A close analysis of the ADL mechanism reveals that it faces an inescapable theoretical dilemma: the ADL trilemma. In designing any ADL strategy, an exchange tries to achieve three core objectives simultaneously: maintaining the system's solvency, protecting the platform's long-term revenue, and ensuring fairness to traders. In his 2025 research, however, Chitra proves within his formal model that—under the objectives and the class of feasible strategies specified in that paper—no ADL algorithm can simultaneously dominate on all three dimensions of solvency, long-term revenue, and fairness (the three constitute a Pareto trade-off), and an exchange must make a difficult trade-off among them [10].

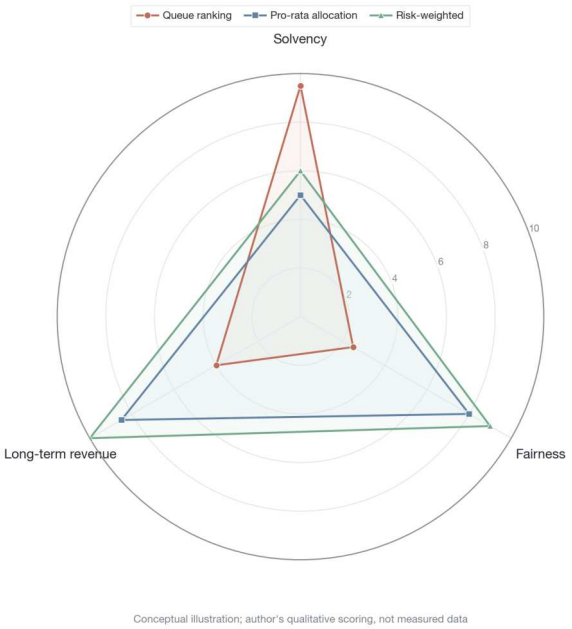

Figure 12-9. The trilemma performance of different ADL strategies (conceptual illustration, qualitative scoring by the author, not measured data)

Figure 12-9 presents, in radar-chart form, the trade-offs of different ADL strategies across the three dimensions: queue ranking has the highest solvency and the lowest fairness, pro-rata allocation is the reverse, and risk-weighted allocation seeks a balance. Solvency is the exchange's core constraint, requiring that ADL rapidly and thoroughly eliminate every shortfall gap. The most effective way to achieve this is to adopt an aggressive queue-ranking algorithm that directly cuts off the largest winners' positions. This approach, however, severely damages fairness, because it makes a tiny minority bear a disproportionate share of the systemic cost. Worse, this crude expropriation markedly reduces the willingness of high-net-worth traders to participate, causing them to leave the platform permanently after suffering ADL (that is, user attrition). The attrition of high-frequency traders and market makers directly drains platform liquidity and sharply reduces long-term fee revenue, thereby damaging the exchange's long-term revenue objective.

If, to protect long-term revenue and preserve fairness, an exchange chooses a gentler pro-rata allocation or sets a deleveraging cap, then in the face of a massive shortfall gap the force of ADL execution may fall far short. This not only fails to restore the system's solvency in a short time but may, through the continued spread of risk, trigger even larger-scale panic and a run. And if the exchange prioritizes protecting whale clients (high-net-worth traders) to preserve revenue, then small and medium traders must bear a larger share of the loss, fairness is further distorted, and systemic risk may keep accumulating because large positions are not disposed of in time. Within this trilemma, the prevailing mainstream queue-ranking algorithm has in effect chosen to preserve solvency at all costs, sacrificing fairness and long-term revenue.

To quantify this unfairness, Chitra introduces the profit-to-solvency ratio (PTSR) [10].

The PTSR measures the relationship between the profit a trader retains after suffering ADL and their contribution to the system's solvency. Mathematical analysis shows that the PTSR is of order $O(b_n/n)$, where b_n is the largest winner's profit and n is the total number of traders. For a light-tailed (thin-tailed) probability distribution, the largest winner's profit is asymptotically negligible relative to the total scale ($b_n = o(n)$), which means that as an exchange grows larger, ADL's "expropriation" of top winners tends toward completeness: in a sufficiently large exchange, the most successful traders tend to lose almost all of their profit. This conclusion is premised on the light-tail assumption: when the loss/profit distribution exhibits the power-law heavy tail described in Section 12.3.5 of this chapter (tail index $\alpha < 2$), b_n may be of the same order as the total scale, in which case this expropriation conclusion is weakened or even reversed—and this is precisely the scenario most likely to arise for long-tail/meme assets. Ideally, the PTSR should be close to 0.5, meaning risk-sharing is relatively balanced (the 0.5 benchmark here implicitly assumes a symmetric fairness criterion, namely that about half of the profit should be retained per unit of solvency contribution; under different theories of fairness—for example, the Rawlsian maximin principle that prioritizes protecting the weakest participant, or a utilitarian framework that maximizes total utility—the ideal PTSR value may differ). Under the traditional queue-ranking algorithm, however, the largest winner's PTSR is often below 0.001, reaching the extreme level of one in a thousand, meaning they are stripped of almost all of their legitimate profit. By contrast, the PTSR of pro-rata and risk-weighted allocation strategies ranges between 0.3 and 0.5, which is markedly fairer.

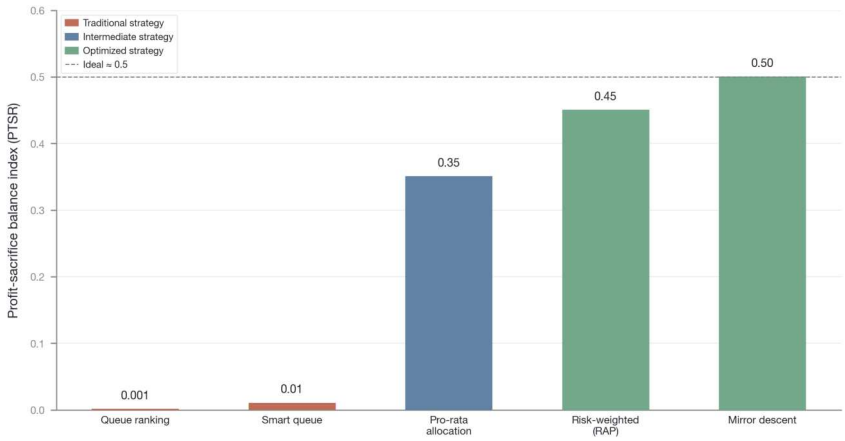

Figure 12-10. PTSR comparison across ADL strategies (PTSR values are constructed or illustrative by the author, based on the ADL research of Chitra and Gauntlet; the primary paper has not been verified; "smart queue" has no independent source, and only the qualitative ranking holds)

Figure 12-10 quantifies this difference in unfairness. From the perspective of a Stackelberg game, this trilemma carries a deeper dynamic implication. The game structure of ADL can be modeled as a sequential game. In a simultaneous game without commitment (Nash), a "bad equilibrium" exists: traders expect the severity of ADL to be high and therefore withdraw or reduce their positions; their withdrawal in turn reduces the total profitable positions available for deleveraging, forcing the system to impose a higher deleveraging intensity on the remaining participants in the next crisis—a vi-

cious cycle. In a Stackelberg setting, by contrast, the exchange can commit in advance to an incentive-compatible strategy (such as RAP or MDIC), sending a credible signal to the market that coordinates participants toward a "good equilibrium," in which traders believe deleveraging will be fair and are therefore willing to stay on the platform, providing the system with a more ample deleveraging buffer [10].

12.2.3 Formal analysis and empirical testing

For a long time, discussion of ADL remained largely at the level of experience and intuition, lacking a rigorous mathematical framework and large-scale empirical testing. Only in late 2025, when Tarun Chitra published the first rigorous formal analysis of the ADL mechanism [10], did the field gain a rigorous scientific footing. Chitra's research not only proved the existence of the ADL trilemma in theory but also, through high-fidelity tick-by-tick replay of a real historical event, revealed the enormous defects of existing mechanisms, providing a solid empirical basis for optimizing ADL algorithms.

The core empirical basis of this research is the extreme market crash that occurred on October 10, 2025 (known in the industry as the "10/10 event"). On that Black Thursday, hit by a sudden shock from macro geopolitical news, the crypto market triggered more than $19 billion in visible liquidation notional within just 24 hours, affecting roughly 1.62 million traders and setting the highest visible liquidation record on record [11]. On decentralized platforms such as Hyperliquid, the ADL mechanism was triggered frequently. Chitra's research focuses on the 12-minute window from 21:16 to 21:27 UTC on October 10, 2025; in that brief but violent period, Hyperliquid saw about $2.1 billion in position liquidations, involving about 160 assets and 19,337 wallets, and producing $T = 1{,}097$ ADL shocks, of which 201 produced a positive shortfall gap (that is, a genuine shortfall) [10].

By replaying tick-by-tick the 1,097 ADL shocks that occurred within these 12 minutes, Chitra's analysis reveals a striking phenomenon: over-deleveraging. The queue-ranking algorithm running in production, lacking dynamic awareness of the global gap, tends to mechanically close far more positions than actually needed. The data show that within these 12 minutes, the cumulative actual loss (that is, the dynamically accumulated value of the shortfall—the liability gap arising after account equity falls below zero across all shortfall events) was about $23.24 million, whereas the total profit available for deleveraging from all profitable traders (that is, the sum of the unrealized profit of the opposing profitable positions within the same time window, i.e., the reducible P&L allowance) was only $6.62 million. Yet the production queue-ranking strategy actually executed cumulative over-deleveraging as high as about $653.6 million (here "over-deleveraging" is measured by the **equity value** of the force-closed positions—that is, margin plus unrealized profit—rather than by a profit measure), with a single largest over-deleveraging of $47.1 million [10]. The seemingly contradictory difference in magnitude among these three figures (millions versus hundreds of millions) stems from two different measurement bases: the shortfall gap and the available profit are measured in "profit and loss (P&L) dollars" (counting only the profit/loss portion), whereas over-deleveraging is measured in "equity dollars" (the full position value, comprising margin principal plus profit). Based on public data, this book estimates that the average

equity-to-profit ratio of the affected traders was about 6.66 times (the paper itself does not directly provide this ratio), meaning that each $1 of reducible profit corresponds to about $6.66 of position equity [10]. The core problem of the queue-ranking algorithm is that it force-closes the **entire position** of the highest-ranked profitable trader in full, rather than reducing only the minimum share of profit needed to fill the gap. To take a simplified numerical example: suppose a BTC short falls into shortfall and produces a $100,000 shortfall gap, while the largest opposing winner holds a long position with $5 million of equity value (of which $4.25 million is margin and $750,000 is unrealized profit). The queue-ranking algorithm force-closes the entire $5 million equity position of that long to fill the $100,000 gap, of which $4.9 million of equity-value closeout is unnecessary over-deleveraging. It is precisely this crude logic of "closing a large position to eliminate a small gap" that leads the system to impose forced closeouts tens of times larger than necessary on profitable traders. All of the optimized alternative strategies (including Smart Queue, Mirror Descent, Vector Optimization, and Hybrid Blend) keep over-deleveraging near zero; measured by the total equity force-closed, this indicates that about 98% was over-deleveraging unnecessary for filling the gap—pure additional harm inflicted on profitable traders by the crude design of the ranking algorithm.

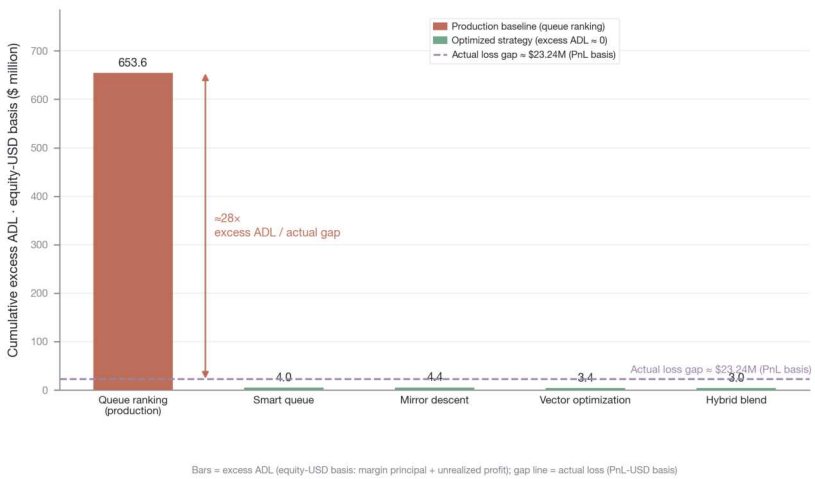

Figure 12-11. Comparison of cumulative over-deleveraging across ADL strategies (bar height is the equity-dollar measure of force-closed positions, including margin principal and unrealized profit, not the P&L actual shortfall gap; the actual loss was about $23.24 million, and over-deleveraging was about 28 times that)

Figure 12-11 compares the cumulative over-deleveraging of different strategies; the enormous gap between the production queue-ranking strategy and the near-zero optimized strategies (Smart Queue, Mirror Descent, and others) confirms the crudeness of static ranking rules. In an on-chain environment, executing 1,097 ADL shocks within 12 minutes involves a large number of state changes and fund transfers, and the operational risk is not to be underestimated: the uncertainty of transaction ordering, partial execution failures, and the challenge of guaranteeing state consistency—risks specific to on-chain systems—make the engineering implementation of ADL far more complex than a database transaction in a centralized environment.

More significant theoretically, Chitra's research identifies the absolute failure boundary of ADL in mathematical terms: the structural bad-debt floor. In the 10/10 event, some small-cap assets encountered a severe liquidity vacuum. The most extreme case appeared in the WLD asset: at one instant, that asset produced a single shortfall gap as high as about $11.56 million, while the maximum deleveraging capacity that all profitable holders of that asset could provide at that moment was only about $2,500 [10]. The gap between the two exceeded 4,600 times, for a coverage ratio of only 0.02%. Under such extreme asymmetry in microstructure, no ADL algorithm, however ingenious (whether queue ranking, pro-rata allocation, or the most advanced risk-weighted allocation), can mathematically fill the loss. This structural bad-debt floor shows that ADL is no panacea. When the market's one-sided tilt reaches an extreme—when a given asset's long and short positions are so severely imbalanced that nearly all participants stand on the same side—the socialization mechanism fails completely, and the system inevitably produces bad debt. Across the entire 12-minute window, at least $16.6 million in losses were structurally uncoverable by any ADL strategy, constituting an irreducible "hard bad-debt floor" [10].

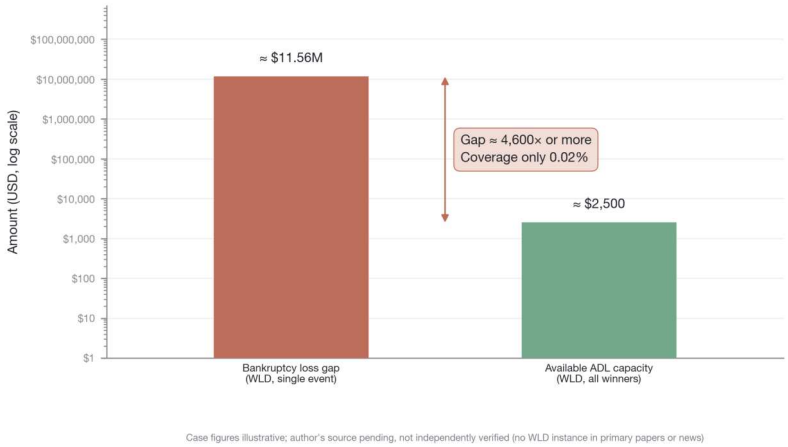

Figure 12-12. WLD's shortfall gap versus available deleveraging capacity (case values are the author's, with sources to be supplemented, or illustrative; neither the primary paper nor news reports contain the WLD instance, which is not publicly measured)

Figure 12-12 presents the stark contrast in this extreme WLD case, illustrating the mathematical failure of the ADL mechanism in the face of a structural liquidity imbalance. This finding carries far-reaching implications for institutional design. It means that even if the ADL algorithm itself is optimized to the extreme, the system's resilience still depends on the upstream mechanisms—including the insurance fund's adequacy ratio, the liquidation engine's efficiency, the prudent setting of risk parameters, and the quality of liquidity management. ADL is only the last resort, not a cure for the underlying condition. As the WLD case reveals, when the underlying liquidity structure itself has a critical flaw, no socialization-allocation mechanism, however ingenious, can avert the loss. This recognition redirects attention from "how to optimize ADL" back to "how to strengthen the upstream defenses," laying an empirical foundation for the later sections' discussion of insurance-fund governance and a re-engineering of the risk

waterfall.

12.2.4 ADL as a contrarian indicator

Although ADL means a passive loss of profit and position for traders, in the eyes of professional quantitative institutions and high-frequency market makers the frequency and scale of ADL triggers are a microstructural market signal with analytical value. From the perspective of market microstructure, ADL is in essence the concentrated eruption, at the liquidation level, of a severe scarcity of liquidity and a high concentration of one-sided positions. It is not only a contrarian indicator of an exchange's risk-management level but also a potential leading signal of turning points in the market sentiment cycle. This dual signaling value makes ADL a unique observational window connecting a platform's microstructural risk controls with the market's macro state: by analyzing the pattern of ADL triggers, one can infer both the mechanistic health of the platform and the sentiment extremes of the market.

ADL trigger frequency and scale are a key contrarian indicator of an exchange's overall risk-management level. When a trading platform begins to trigger ADL frequently, it sends the market several clear signals: the platform's insurance fund is exhausted or severely inadequate; its market-maker cohort has retreated, leaving the liquidation engine unable to find sufficient liquidity in the market to absorb bankruptcy orders; its risk parameters may be too aggressive (for example, allowing excessive leverage or listing illiquid long-tail assets); and the efficiency of its liquidation engine may be in question. Frequent ADL triggers suggest an inadequate insurance fund, an inefficient liquidation engine, overly aggressive risk parameters, or poor liquidity management. Conversely, a platform that has never triggered ADL does not necessarily have a well-designed ADL mechanism; rather, it means that its earlier layers of risk control (the margin system, the liquidation engine, and the insurance fund) are effective enough to have absorbed the risk at a more upstream stage.

The value of ADL as a contrarian indicator, however, goes well beyond assessing platform risk. Astute traders often treat ADL as a strong signal of a reversal in market sentiment. When a market crash is accompanied by large-scale ADL alerts, this usually means that panic selling has been exhausted and the short side's momentum is being forcibly consumed through this destructive process. A profitable short position closed by ADL is not executed by sending a buy order to the order book; it is settled off-book through a matched offset (match-off) between counterparties. ADL therefore does not directly generate buy-side order flow and produces no immediate buy-side price impact on the market. Nonetheless, by forcibly reducing short positions, ADL changes the balance of long and short forces in the market; moreover, if a trader who has been ADL'd loses their position and chooses not to rebuild it, this is tantamount to indirectly removing part of the sell-side force in the market. This indirect rebalancing of forces often produces a supportive effect on price after the peak of an ADL wave, driving a rebound or reversal. Conversely, at a bull-market top, if long positions begin to suffer ADL, it indicates that long leverage has reached a ceiling the system cannot bear, unsupported by real capital. This forced deleveraging, triggered by the collapse of the liquidation mechanism, is often a precursor to the end of the trend and an im-

pending deep correction. In this sense, ADL is not only an exchange's final mechanism for maintaining solvency but also a structural catalyst for the market sentiment cycle to shift from excessive optimism toward mean reversion.

As the WLD case reveals, however, even an optimal ADL algorithm is powerless in the face of a structural shortage of liquidity. The effectiveness of ADL as a contrarian indicator rests on one premise: that sufficient opposing positions still exist in the market to be deleveraged. When this premise breaks down—when a given asset's long and short positions are extremely imbalanced and nearly all participants stand on the same side—ADL can neither save the system nor provide a meaningful reversal signal. In such an extreme case, an ADL trigger marks a structural market failure rather than a cyclical sentiment extreme. Therefore, when using ADL as a trading signal, one must combine it with an in-depth analysis of the underlying liquidity structure, distinguishing a "sentiment-driven extreme" (a high probability of reversal after ADL) from a "structure-driven collapse" (possible further deterioration after ADL). This discriminating ability constitutes a core competitive advantage for professional traders in extreme conditions. The effectiveness of ADL as a contrarian indicator may itself decay as market participants learn—a classic manifestation of Goodhart's law in the domain of trading signals. If the pattern of "the market reverses after an ADL trigger" becomes widely recognized and traded upon, the signal's information content will gradually be replaced by a coordination effect. Worse, an attacker could deliberately trigger ADL to induce herd buying and then take profit in the rebound. The signaling value of ADL must therefore be evaluated dynamically within the framework of Lo's (2004) adaptive markets hypothesis, rather than treated as a static structural regularity [12].

12.3 The confidence-as-liquidity hypothesis

In analyzing systemic risk in derivatives markets, traditional financial models tend to focus on the absolute size of capital and the efficiency of the liquidation algorithm. In a crypto market that lacks a central bank as lender of last resort, however, the effectiveness of an insurance fund depends not merely on its book balance but, more importantly, on the confidence it establishes in the minds of market participants. This section proposes the confidence-as-liquidity hypothesis, which argues that under extreme market conditions the size of the insurance fund is itself a strong market signal: by shaping the confidence of traders and market makers, it directly determines the market's liquidity depth and, in turn, the system's true capacity to withstand shortfall risk. The insurance fund's "signaling function" carries more economic weight than its "absorption function." Confidence management is, in essence, risk management.

12.3.1 The transmission mechanism

As one of the market's few publicly observable indicators of systemic health, the insurance-fund balance transmits complex signals with every fluctuation of its figures. This signal acts directly on the belief layer of market participants, which changes their behavior and ultimately reshapes the entire market's liquidity environment. We can decompose this transmission process into four layers: the signal layer, the belief layer, the behavior layer, and the outcome layer.

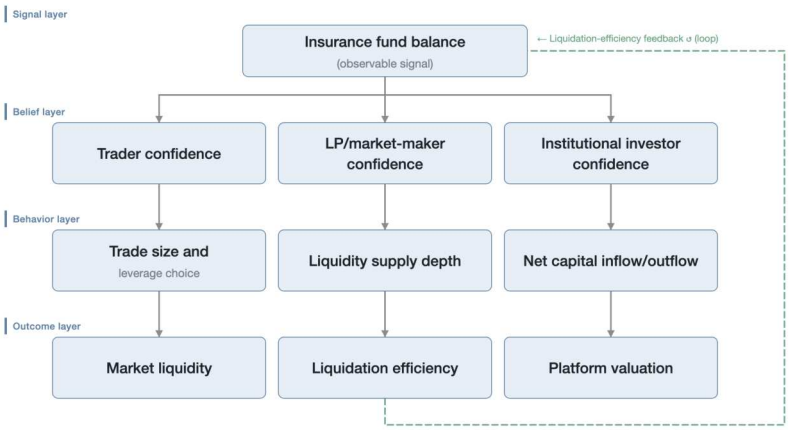

Figure 12-13. The confidence transmission mechanism of the insurance-fund balance

As shown in Figure 12-13, the observable insurance-fund balance signal acts in turn on the belief layer, the behavior layer, and the outcome layer, and forms a closed loop through the feedback of liquidation efficiency on the fund balance.

In the positive transmission chain, when market participants regard the insurance fund as "ample," a series of positive chain reactions unfolds. Users believe the system can withstand extreme events; market makers, facing lower shortfall risk, are willing to quote narrower bid-ask spreads; liquidity providers are willing to keep more capital in the vault (because they believe extreme losses will be absorbed by the fund); and traders are willing to hold larger positions and choose higher leverage. The consolidation of these beliefs translates directly into positive market behavior: trading volume expands, liquidity supply deepens, and capital keeps flowing in on a net basis. Finally, at the outcome layer, the market exhibits abundant liquidity and excellent liquidation efficiency—deeper liquidity, narrower spreads, and higher market quality. Efficient liquidation in turn keeps shortfall losses to a minimum, further protecting the insurance-fund balance and forming a virtuous ecological cycle.

The reverse transmission chain presents the exact opposite picture. When the insurance fund is regarded as "inadequate," or its governance is called into question, fear propagates in reverse along the same chain. Users worry that an extreme event could trigger ADL or a system collapse; market makers quickly widen spreads and cut quoting depth to demand higher risk compensation; liquidity providers withdraw capital from the vault ("I am unwilling to bear a risk I do not understand"); and traders reduce their positions ("I am not sure the platform is safe"). The end result is shrinking liquidity, widening spreads, and a sharp decline in market quality. The deterioration of liquidity in turn further lowers liquidation efficiency, raises shortfall risk, and places even greater pressure on the insurance fund.

12.3.2 The positive feedback loop

When the market suffers a sudden black-swan event that causes the insurance fund to shrink markedly, an extremely dangerous positive feedback loop of confidence collapse can be triggered. In traditional financial markets, such a loop is usually broken forcibly by emergency intervention from regulators or by a central bank's liquidity injection; but in a decentralized or inadequately regulated crypto market, this loop often evolves in free fall until some external force intervenes or the system collapses completely. This process closely parallels the classic mechanism of a bank run. More specifically, Diamond and Dybvig (1983), in their classic bank-run model, revealed the existence of multiple equilibria: in the "good equilibrium," depositors believe the bank is solvent and do not run, so the bank continues to operate; in the "bad equilibrium," depositors expect others to run and therefore rationally choose to withdraw first, so the run becomes a self-fulfilling prophecy [13]. Mapping this framework onto the behavior of insurance-fund LPs: when LPs believe the HLP vault's risk exposure is manageable, keeping capital in place constitutes the "good equilibrium"; but once LPs expect other LPs to withdraw in panic, even if the fund remains fundamentally adequate, a rational LP will choose to exit early to avoid being the last one out—which is precisely the dynamic depicted in the Hyperliquid whale incident of Section 12.3.3.

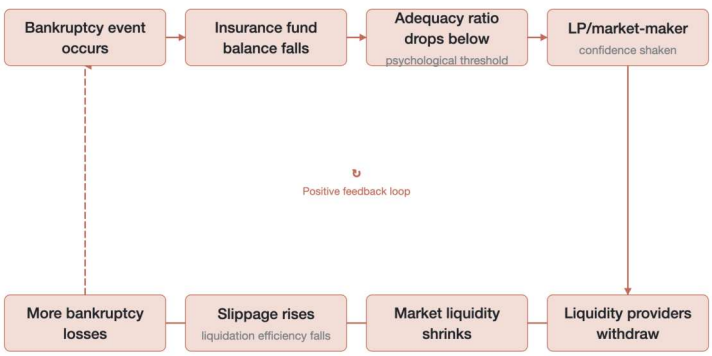

Figure 12-14. The positive feedback loop of confidence collapse and liquidity evaporation

The starting point of the loop is usually a massive liquidation the market fails to absorb smoothly, so that shortfall losses hit the insurance fund directly. When the fund balance falls and drops below participants' psychological expectation threshold, panic begins to spread among liquidity providers. To avoid potential systemic risk, market makers and liquidity providers instinctively choose to cancel orders and withdraw capital. The sudden withdrawal of liquidity further worsens an already fragile market depth. With insufficient buyers to absorb the flow, subsequent liquidation orders can only fill with greater slippage, which not only accelerates the crash in asset prices but also produces more severe shortfall losses. These new shortfall losses are again borne by the insurance fund, causing its balance to plunge further and triggering a new, more intense round of panic and withdrawal.

In this vicious cycle, the loss of confidence is directly equivalent to the evaporation of liquidity. The positive feedback loop keeps running until the vault shrinks to some minimum viable size, or confidence is restored by some external intervention—whether an emergency adjustment of protocol parameters, an injection of external capital, or transparent communication from the core team. Once the spiral begins, however, the cost and difficulty of breaking it rise sharply. This is precisely why preventive confidence management is far more important than after-the-fact crisis rescue.

12.3.3 Empirical evidence of the confidence multiplier

The Hyperliquid whale liquidation incident of March 2025 [14] provides quantitative empirical support for the confidence-as-liquidity hypothesis. The incident showed how a book loss can be amplified dozens of times through the confidence transmission mechanism, ultimately evolving into a severe liquidity crisis.

The incident began when a whale trader, at an address starting with 0xf3F, built a long Ethereum position on the Hyperliquid platform with a notional value exceeding $300 million (Arkham basis; at a liquidation price of about $1,915 and roughly 113,000 ETH, this works out to about $210 million, the difference stemming from different pricing at the position peak versus at the liquidation moment), opening at a notional leverage as high as 50x. When the market price moved unfavorably, the trader did not close out in the usual way but actively triggered the system's forced liquidation by strategically withdrawing collateral. The trader's choice of a "strategic liquidation" path rather than closing directly on the order book had a clear economic rationale: for a massive position with a notional value exceeding $300 million, closing directly at market would have caused a price impact of hundreds of basis points on the liquidity-limited order book, whereas transferring it to HLP through liquidation externalized this slippage cost to the liquidity providers. In essence, this was a form of arbitrage against the liquidation mechanism, using a gap in the rules to convert a private trading cost into a socialized loss borne by the public pool. Ultimately, the position was liquidated at a price of about $1,915, and the trader exited having cashed out a profit of about $1.8 million. Because the position was too large, however, the liquidity of the platform's public order book could not fully absorb this liquidation order, forcing the remaining position to be transferred to Hyperliquid's liquidity provider vault for backstop liquidation.

In handling this massive position, the HLP vault suffered an actual loss of about $4 million due to enormous market slippage, roughly 1% of the vault's total size (about $450 million to $480 million before the event). In a crypto derivatives market with trading volumes routinely in the hundreds of millions, an absolute loss of $4 million hardly seems fatal. Yet this loss triggered a strong psychological shock among liquidity providers. Vault participants suddenly realized that, as passive risk-bearers of an automated market maker, they not only shared in the trading-fee income but could also be forced to absorb this kind of hard-to-handle, high-risk liquidation order flow in extreme situations, bearing enormous socialized losses. Even more unsettling, the scale and frequency of this risk had not been fully understood or anticipated beforehand. The driver of the panic was not that "a $4 million loss is unacceptable," but rather the sudden realization that one's capital was exposed to a risk one did not fully

understand, that even greater losses might occur in the future, and that it would be better to withdraw first.

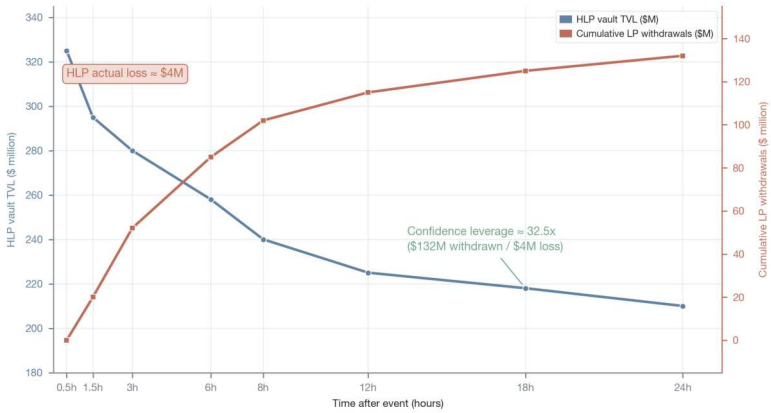

Figure 12-15. The confidence-leverage effect in the Hyperliquid whale incident (the intermediate series of HLP vault TVL and cumulative withdrawals is an on-chain estimate for illustration, with only the endpoints and the 32.5-times figure verified; 32.5 times is a correlational amplification, not strict causation)

The scissors gap between the two curves in Figure 12-15 captures the divergence between the decline in the HLP vault's TVL and the cumulative LP withdrawals.

Panic quickly turned into a run. Within 24 hours, more than $130 million was withdrawn in panic from the liquidity provider vault. A book loss of $4 million was accompanied by a liquidity outflow of $130 million, a ratio of about 32.5 times (this book's estimate, defined as the secondary panic-redemption amount divided by the primary direct vault loss). This striking correlational amplification factor reveals how fragile liquidity providers' confidence is in a decentralized architecture.

> The correlational amplification factor of about 32.5 times (a correlation measure, not a strict causal estimate) far exceeds the amplification of capital leverage: 50x leverage merely magnifies margin by 50 times, whereas confidence-related amplification expands the book loss more than 30-fold—and this "leverage" is not constrained by any margin system.

The 32.5-times confidence multiplier above comes from a single event (the March 2025 whale liquidation) on a single platform (Hyperliquid), and its external validity is subject to several limitations. First, as a newly emerging decentralized platform, Hyperliquid's LP cohort may differ systematically in risk perception and behavior from the LPs of mature centralized-exchange (CEX) platforms, who typically have richer experience with extreme events and higher risk tolerance. Second, the event occurred during Hyperliquid's early growth stage, when the platform had not yet experienced a similar shortfall event, and the LPs' panic stemmed partly from the "cognitive shock of first risk exposure," a factor that may weaken in subsequent similar events. Moreover, the 32.5-times amplification factor must also be treated with caution in causal attribution: LP withdrawal behavior may have been driven simultaneously by a contemporaneous

decline in macro risk appetite (such as the Fed policy-expectation shift of March 2025), the viral spread of panic narratives on social media, changes in competing platforms' yields, and other factors, rather than being a pure confidence response to Hyperliquid's single event. If other DeFi protocols also experienced synchronous TVL declines over the same period, then part of the LP withdrawals can be attributed to a systemic deterioration in risk appetite rather than a platform-specific confidence shock. The 32.5 times should therefore be understood as a "correlational amplification factor" after multiple factors are superimposed, and the multiplier actually attributable to pure confidence transmission may be considerably lower; it should be regarded as an observed value under specific conditions rather than a universal constant. Building a more robust confidence-leverage model would require systematic empirical comparison across platforms (CEX and DEX), across event types (manipulative shortfalls versus market-driven shortfalls), and across market cycles (bull and bear). Even so, even if the true confidence multiplier varies substantially across contexts, the core qualitative conclusion revealed by the Hyperliquid incident—that the amplification effect of a confidence shock far exceeds the book loss itself—remains robust.

The core mechanism revealed by the Hyperliquid whale incident is that the loss of confidence is not a linear response to "losses already incurred" but a fearful amplification of "losses that may occur in the future." The magnitude of the fear is severely disproportionate to the loss already incurred. A tiny crack in the books, once it touches participants' trust in the system's safety boundary, triggers a large-scale flight of capital. This nonlinear amplification effect has a solid theoretical basis in behavioral finance. Kahneman and Tversky's prospect theory holds that the psychological weight of a loss is about twice that of an equivalent gain [15], and in scenarios involving the perception of systemic risk this asymmetry may be amplified further. Liquidity providers' decisions are based not on a precise calculation of realized losses but on a subjective probability estimate of the worst future scenario. When an unexpected loss event updates their cognitive model of the system's fragility, their subjective probability of extreme future losses rises sharply, triggering a withdrawal far exceeding the actual loss. Prospect theory explains the psychological basis of panic from the angle of individual cognitive bias, but it overlooks the key amplifier of panic transmission in crypto markets: the information-cascade effect of social media. The herd-behavior theory of Banerjee (1992) and Bikhchandani et al. (1992) reveals that in an environment of information uncertainty, individuals rationally choose to follow others' behavior while ignoring their own private information [16][17]. Among crypto LP cohorts sharing the same Discord channels and Twitter feeds, the behavior of a few early withdrawers may, through an information cascade, trigger exponentially growing follow-on withdrawals, with an amplification effect far exceeding loss aversion at the individual level. If the temporal distribution of LP withdrawals exhibits the typical features of a cascade (a few early movers triggering exponential growth in followers), then social-media-driven herd behavior may be the dominant amplification mechanism behind the correlational amplification factor. This evidence shows that the "signaling function" of an insurance fund (or market-making vault) carries more economic weight than its "absorption function."

12.3.4 Confidence management as risk management

Faced with the enormous destructive power of the correlational amplification effect of confidence transmission, exchanges and decentralized protocols must elevate "confidence management" to a strategic priority on par with "balance-sheet management." For the operators of insurance funds and market-making vaults, managing confidence may be as important as managing capital—perhaps more so. The core of confidence management lies in stabilizing participants' expectations of the system's risk-absorption capacity through institutional design and transparency-building.

Effective confidence management depends first on a transparent communication mechanism. When a shortfall event occurs, the platform must promptly and accurately inform liquidity providers and users of the scale of the loss, its cause, and the countermeasures. An information vacuum breeds panic. As Shiller's (2019) narrative economics points out, the "viral narratives" that form in an information vacuum (such as "the protocol is about to go bankrupt" or "the team has already absconded") propagate in a dynamic closer to an epidemiological model, with contagiousness correlated with emotional arousal rather than with factual accuracy [18]. When participants cannot obtain authoritative firsthand information, speculation and rumor on social media quickly fill the void and amplify fear. In the Hyperliquid whale incident, the community's misreading of the nature of the event and its excessive worry about the system's safety stemmed in large part from the lag and incompleteness of information dissemination. Equally important as after-the-fact communication is the ex ante setting of expectations: before liquidity providers deposit capital, a platform should clearly convey "the extreme loss scenarios your capital may face," so that LPs make an "informed" decision when depositing rather than "suddenly discovering" in a crisis that they are exposed to unanticipated risk. In the Hyperliquid incident, many LPs panicked precisely because they had not previously understood the tail risk that the HLP vault bears as the backstop liquidator. Had these risks been fully disclosed and quantified in advance, the degree of panic would very likely have been much lower.

Another core issue in confidence management is the selective disclosure of the adequacy ratio. Publishing the insurance fund's actuarial adequacy ratio can enhance transparency, but if the adequacy ratio is poor, publishing it may instead trigger panic. This trade-off between transparency and stability parallels the "constructive ambiguity" strategy of central banks in traditional finance. A central bank does not always publish its full assessment of the banking system's fragility, because excessive transparency can, in some circumstances, become a self-fulfilling prophecy. For crypto-market insurance-fund managers, the key is to find a balance point: providing enough information for market participants to make rational judgments while avoiding the release, at sensitive moments, of signals that could be over-interpreted.

In addition, platforms need to build multi-layered defense in depth. A single insurance-fund pool is easily and quickly exhausted in the face of an extreme shock, triggering panic. By introducing an auto-deleveraging mechanism as a safety valve, establishing tiered and segregated insurance pools, and introducing external insurance capital, a platform can effectively slow the spread of risk and buy a precious window of time for market confidence to recover. The FTX affair, from the opposite direction, confirms

the institutional value of confidence management. According to the court testimony of co-founder Gary Wang [19], the insurance-fund size that FTX displayed to the outside world was entirely fabricated data generated by a formula containing a random number, bearing no relation to the fund's true balance. At one moment, FTX claimed the fund held $5.5 million and 5 million FTT tokens, when in fact the fund held no FTT at all. This fraud reduced the insurance fund from a risk-management tool to a mere instrument of false marketing, and when the truth came out it ultimately dissolved the foundation of user trust in the platform.

12.3.5 The cliff effect

A pronounced nonlinear feature exists between insurance-fund size and market confidence, which can be summarized as the "cliff effect." This effect indicates that market confidence does not decay smoothly and linearly as the insurance fund's adequacy ratio declines; rather, it collapses in cliff-like fashion within a specific threshold range. This nonlinear feature closely parallels the effect of bank capital adequacy on depositor confidence in traditional finance. The reason the minimum capital requirements under the Basel III framework are set at specific levels is precisely that regulators recognized that the impact of a decline in capital adequacy on market confidence is not linearly incremental but exhibits an exponential amplification near a critical point. In crypto derivatives markets, because there is no deposit-insurance system and no lender of last resort, this nonlinear feature manifests even more dramatically.

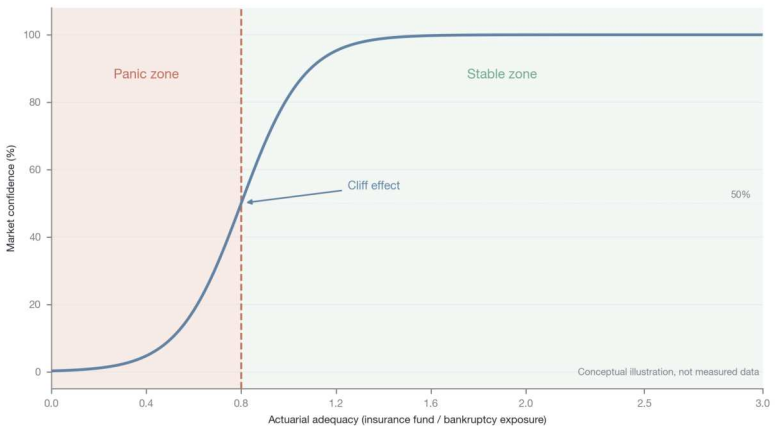

Figure 12-16. The nonlinear relationship between insurance-fund adequacy ratio and market confidence (conceptual illustration, not measured data; the threshold is an illustrative critical band, not a precise critical point, and the text likewise stresses that the threshold cannot be known precisely in advance)

We can define the actuarial adequacy ratio as the ratio of the insurance fund's current size to the maximum shortfall loss that might arise under expected extreme market conditions (measured by value at risk, VaR, or expected shortfall, ES). The academic roots of this definition trace back to the classic Cramér-Lundberg ruin model in actuarial science [20]. In that model, the insurance fund's balance is modeled as a stochastic process: premium income (corresponding to the steady inflow of liquidation penalties)

grows at a constant rate, while claims (corresponding to shortfall losses) arrive as a compound Poisson process. The ruin probability (the probability that the fund balance first falls below zero) depends on the ratio of the premium rate to the claim intensity and on the tail distribution of claim sizes. Applying this framework to a crypto derivatives insurance fund, the key modeling choice lies in the selection of the tail-risk measure: VaR measures the quantile threshold of losses at a given confidence level (the loss level exceeded with only a $1-\alpha$ probability) but ignores the severity of losses beyond that threshold, whereas ES (also known as CVaR) measures the conditional expected loss beyond the VaR threshold and better captures the "tail of the tail" extreme risk. Given the heavy-tailed character of the crypto market's shortfall-loss distribution (for example, WLD's single shortfall gap of about $11.56 million in the 10/10 event far exceeded that asset's VaR estimate of shortfall loss), ES is therefore a more prudent and appropriate choice of measure than VaR. Furthermore, if the shortfall-loss distribution exhibits a power-law tail (tail index $\alpha < 2$), then even ES may face the challenge of unstable estimation, requiring extreme-value-theory methods (such as fitting a generalized Pareto distribution) for more robust tail-risk modeling. The chapter's later adequacy analysis will therefore prioritize ES as the benchmark denominator. In operationalizing this definition, key parameter choices include the confidence level (99.5% or 99.9%, whose estimates may differ severalfold under a heavy-tailed distribution) and the time window of the extreme scenario (the maximum single-day loss or the cumulative loss over several consecutive days). These parameter choices have an enormous impact on the numerical value of the adequacy ratio, so cross-platform comparisons must ensure the use of a consistent parameter baseline. Two core assumptions of the classic Cramér-Lundberg model face significant departures in crypto markets. First, the model assumes that claim arrivals follow a compound Poisson process (that is, claim events are mutually independent), but shortfall events in crypto markets are highly clustered—for example, 1,097 ADL shocks within 12 minutes in the 10/10 event—and this tail clustering severely violates the independence assumption of Poisson arrivals, requiring self-exciting models such as the Hawkes process to more accurately capture the clustering of shortfall losses. Second, the model assumes a constant premium rate (corresponding to liquidation-penalty income), but insurance-fund income is itself procyclical (higher in bull markets, and potentially negative in extreme conditions precisely because liquidation volume surges while payouts explode simultaneously), and this comovement of income and expenditure further weakens the model's applicability. When the adequacy ratio is at a high level (that is, in the stable zone), market participants generally take the system's safety for granted. Within this zone, whether the insurance fund grows or shrinks by tens of millions of dollars has no material effect on market confidence. Traders' and market makers' attention is focused mainly on finding trading opportunities and optimizing market-making strategies, and the fund's existence draws no attention.

When frequent shortfall events cause the insurance fund to be continuously depleted, however, and the adequacy ratio approaches and drops into a certain psychological threshold range, the situation changes dramatically. Within this narrow range, even a tiny further loss is amplified by the market and interpreted as a precursor to the system's imminent bankruptcy. At this point, market sentiment flips instantly from

"absolutely safe" to "extreme panic," and participants' behavior shifts from seeking profit to fleeing at any cost. This sharp collapse of confidence directly triggers the liquidity withdrawal and positive feedback loop described earlier, ultimately leading to a comprehensive collapse of the system. From "no one cares" to "everyone panics," there is almost no smooth transition zone in between.

A key feature of the cliff effect is that the location of the threshold cannot be known precisely in advance. It depends on multiple factors: user psychology, the market environment, the memory effect of recent events, and the emotional amplification of social media. In a bull market, participants' risk tolerance is higher, and the threshold may be pushed to a lower level; in a bear market, or just after a major security incident, the threshold shifts markedly upward, and the system becomes more fragile. This uncertainty means that insurance-fund managers face a challenge that "cannot be precisely optimized": staying above the threshold requires an ample safety margin, but too high a safety margin means a loss of capital efficiency.

As shown in Figure 12-6, different exchanges differ enormously in insurance-fund size and relative adequacy ratio. Binance, with an absolute size exceeding $2.3 billion, far surpasses other platforms, but in terms of the ratio of fund size to total open interest, the picture changes markedly. Hyperliquid's relative ratio of about 18.6% (calculated on total HLP TVL) far exceeds Binance's 6.6% (OKX, because it discloses only a security fund rather than a futures liquidation insurance fund, has a ratio that is not comparable on a like-for-like basis; see Section 12.5), but as noted earlier this ratio may be overstated because of the distinction between total HLP TVL and the liquidation vault's standalone size. Even so, this difference still reflects that decentralized platforms, lacking centralized credit backing, must rely on a thicker capital buffer to sustain community confidence. For a decentralized protocol, the relative size of the insurance fund is the on-chain equivalent of its credit rating.

The significance of understanding the cliff effect lies in its warning to risk managers: one must never wait until the insurance fund is about to be exhausted before taking remedial measures. Once the system falls off the cliff, the cost of rebuilding confidence will be astronomical, far exceeding the capital cost of maintaining an ample safety margin in advance. A platform must therefore set an ample safety buffer at the edge of the cliff and, when the adequacy ratio touches the warning line, decisively initiate capital replenishment or a risk circuit breaker, resolutely defending that fragile yet decisive psychological line. It is thus evident that managing an insurance fund is both an actuarial problem and a problem of confidence governance and institutional constraint.

Synthesizing the foregoing analysis of confidence transmission, the positive feedback loop, and the cliff effect, we can construct a unified theoretical framework to explain how insurance-fund depletion triggers a nonlinear system collapse. This framework comprises two levels of mechanism: a macro-level threshold effect and a micro-level amplification mechanism. At the macro level, the cliff effect implies that the insurance fund's adequacy ratio has a critical threshold, below which market confidence undergoes a phase transition, jumping irreversibly from a "stable equilibrium" to a "panic equilibrium." At the micro level, confidence collapse is transmitted through three amplification channels: market-maker withdrawal leading to liquidity evaporation (price-

impact amplification), LP runs further weakening the insurance buffer (capital-buffer amplification), and trader deleveraging aggravating order-flow imbalance (liquidation-cascade amplification). The coupling of the macro threshold and micro amplification produces the characteristic nonlinear collapse dynamic: once the adequacy ratio breaks below the critical point, the three micro amplification channels activate simultaneously, and the positive-feedback interaction among them makes the system's recovery path far longer than its collapse path—which is precisely why "the cost of rebuilding confidence is dozens of times the cost of maintaining it." This "macro threshold plus micro amplification equals nonlinear collapse" framework provides a unified analytical lens for understanding the failure modes of insurance funds in successive crypto-market crises, and it also furnishes a theoretical anchor for the later sections' discussion of re-engineering the risk waterfall.

12.4 The governance dilemma and the governance spectrum

One of the core contradictions of crypto derivatives markets is that the system must respond to extreme and unpredictable market risk, which often requires granting managers some form of discretion; yet at the same time, the core of the crypto ethos is "code is law," which stresses the elimination of human intervention and trust assumptions. This contradiction is especially prominent in the management of insurance funds and the design of liquidation mechanisms, forming a governance dilemma that is difficult to reconcile. Just as central banks in traditional finance perpetually oscillate between "rules" and "discretion," crypto derivatives platforms likewise face the challenge of finding a balance between certainty and flexibility. Because of the immutability of blockchain technology and the automatic execution of smart contracts, however, the search for this balance becomes more complex and fraught with tension.

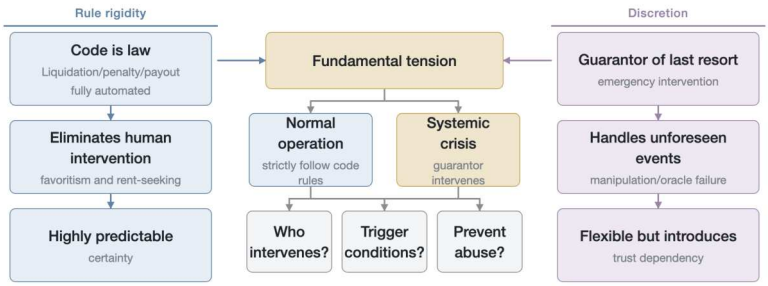

Figure 12-17. The tension between rule rigidity and discretion in insurance-fund governance

12.4.1 The limits of rule rigidity

"Code is law" is the cornerstone of decentralized finance. In an ideal decentralized derivatives platform, the triggering of liquidation, the collection of penalties, insurance-fund payouts, and the execution of auto-deleveraging should all be completed automatically by pre-written smart contracts. This rule rigidity brings a high degree of certainty and transparency, thoroughly eliminating the moral hazards common on centralized platforms—black-box operations, favoritism toward large clients, or internal rent-seeking. Before participating in the market, a trader can know clearly at what price they will be liquidated and how large a penalty they will face, and no one can arbitrarily change these rules.

The complexity of financial markets, however, often exceeds the preset range of code logic. The greatest limitation of rule rigidity is its inability to respond effectively to "unknown unknowns." A smart contract can only execute according to preset parameters and lacks the ability to understand the context of extreme anomalies. When the market encounters an unprecedented liquidity vacuum, when congestion on the underlying blockchain network prevents transactions from being included, or—more commonly—when the oracle price feed is maliciously manipulated, strict execution of the code may instead lead to systemic catastrophe. In these extreme scenarios, if a platform adheres entirely to rule rigidity and lets the liquidation engine blindly dump assets, it will not only aggravate the vicious cycle of prices but may also exhaust the insurance fund in an instant, ultimately triggering large-scale auto-deleveraging that makes innocent profitable traders bear enormous losses.

A further problem of rule rigidity lies in its "predictability" to attackers. When all rules are transparently encoded on-chain, an attacker can precisely calculate the cost and expected return of manipulating the market and thereby design a targeted attack strategy. This predictability does not exist in traditional finance, because regulators and market makers can increase attackers' uncertainty through unpredictable discretionary actions. Therefore, even a platform that touts a high degree of decentralization often has to find some form of emergency intervention mechanism when facing a life-or-death crisis—which brings us to the problem of the "guarantor of last resort."

12.4.2 The guarantor of last resort and discretion

To make up for the deficiencies of rule rigidity, a system often needs to introduce the role of a "guarantor of last resort" or "emergency administrator." On centralized exchanges, this role is naturally played by the platform operator; on decentralized platforms, it may take the form of a core team holding multi-signature authority or a specific governance committee. The guarantor of last resort is granted discretion to suspend trading, modify liquidation parameters, or even roll back transactions in emergencies.

This discretion has an irreplaceable function in responding to a systemic crisis. It endows the system with a kind of "elasticity," allowing the platform to block the spread of risk through human judgment when the code logic fails. Introducing discretion, however, inevitably reintroduces trust assumptions, which directly contravenes the original trustless intent of cryptocurrency. More seriously, once the power to intervene in the system is granted to some person or organization, one inevitably faces a series of thorny

governance problems: who intervenes, what the trigger conditions are, and how to prevent the power from being abused.

The Hyperliquid JELLY incident of March 2025 provides a canonical empirical case of this dilemma. The attacker built two-way positions on the JELLY perpetual futures and actively withdrew margin to trigger self-liquidation, forcing the platform's liquidity provider pool to take over the short side; the attacker then pumped the JELLY spot price on the Raydium exchange on the Solana chain, causing HLP to bear an enormous unrealized loss (the mechanical details—the number of addresses, the size of the two-way positions, the magnitude of the pump, the loss amount, and the rollback price—are elaborated in Section 12.6.2) [21]. Here it is necessary to distinguish precisely between two manipulations of different natures: what the attacker carried out was "manipulation of the underlying asset price" (changing the asset's actual execution price by putting real money into a thin spot market), not "oracle signal injection" (directly tampering with the oracle's data transmission through technical means). In the JELLY incident, the oracle faithfully relayed the manipulated "real" market price, and its own technical integrity was not compromised. This distinction carries important implications for institutional design: defending against manipulation of the underlying asset price requires market-structure measures such as liquidity thresholds and position caps, whereas defending against oracle signal injection requires technical measures such as cryptographic verification and multi-source aggregation. Faced with this crisis, Hyperliquid's validator nodes voted in an emergency to override the oracle price, forcibly rolling back JELLY's settlement price to the level before the attack occurred, thereby avoiding a massive loss to the insurance fund [22].

This incident displays the two-sidedness of the guarantor-of-last-resort role. On the positive side, the validators' emergency intervention did indeed stop a planned market-manipulation attack and protected the interests of the insurance fund and the vast majority of users. On the negative side, however, this forced overwriting of the price triggered widespread doubt in the community: if validators can override the oracle price at any time, then what is the essential difference between Hyperliquid and a centralized exchange? Binance founder Changpeng Zhao went so far as to publicly criticize Hyperliquid's approach, questioning the authenticity of its decentralization. Viewed from a legal perspective, validators forcibly settling users' positions at a non-market price may create legal risk in multiple jurisdictions. At the level of contract law, even if the user agreement contains an "emergency" clause, the enforceability of that clause varies considerably across jurisdictions. At the level of property rights, for non-attackers holding long JELLY positions, the choice of the price benchmark for a "full refund" is itself a point of legal dispute. At the regulatory level, an entity with central counterparty (CCP)–like functions under the EU's Markets in Crypto-Assets (MiCA) framework unilaterally changing a settlement price may trigger scrutiny. The back-and-forth of Eisenberg being charged, convicted, and then having the conviction vacated in the Mango Markets case (see Section 12.4.3) exposes precisely the legal uncertainty of criminal prosecution for crypto-market manipulation on questions of venue and the elements of fraud; at the same time, whether the platform's intervention exceeded the reasonable scope of self-help could also become the focus of future litigation. This legal-dimension uncertainty adds the further complexity of cross-border legal coor-

dination to the "residual control rights" problem discussed in Section 12.4.4. Historical experience shows that unconstrained discretion easily degenerates into an infringement of users' interests. Even with the purest of motives, the boundary of intervention is highly ambiguous. For example, when a large trader's collapse might trigger a chain of liquidations, a platform's choice to suspend liquidation to protect the insurance fund is in effect a disguised bailout of that large trader—and grossly unfair to other users who trade by the rules. This "too big to fail" phenomenon, long criticized in the traditional financial system, now reappears in another form in crypto markets.

12.4.3 Oracle risk

Oracle risk is a central topic in the governance dilemma. The oracle is the bridge connecting off-chain real-world price data with on-chain smart contracts, and it is also the most fragile link in a decentralized derivatives platform. No matter how tightly a platform's internal liquidation logic is designed, once the mark price the oracle feeds in is distorted, the entire system's risk-control mechanism fails in an instant. Take Hyperliquid: it uses a self-built oracle system that feeds prices aggregated from the spot prices of multiple external exchanges. For a low-liquidity asset like JELLY, however, its spot trading may be concentrated in the liquidity pools of just one or two decentralized exchanges, leaving the oracle's data sources severely lacking in diversity, so that the cost of manipulation is correspondingly extremely low. This reveals a key design flaw: for low-liquidity assets, an oracle should set a minimum data-source-diversity threshold, and if the available data sources fall below the threshold, the system should automatically limit the maximum position size on that asset or suspend its derivatives trading. The reason oracle risk occupies a special place in insurance-fund governance is that the shortfall losses it triggers arise not from normal market risk but from malicious manipulation of external inputs, which renders traditional risk-management frameworks almost entirely ineffective against such attacks.

Oracle manipulation attacks take multiple forms in practice. The most direct is spot-price manipulation, in which an attacker artificially pumps or dumps a token's price in a poorly liquid spot market with enormous capital, causing the oracle to capture the abnormal price and transmit it to the derivatives platform. A more covert approach exploits the flash-loan function of DeFi protocols to borrow an enormous sum within a single transaction to manipulate the price, repaying the loan immediately after completing the attack, with the entire process completed within one block. In addition, an attacker can exploit the gap in the oracle's update frequency to conduct arbitrage before the oracle reflects the latest price. According to Chainalysis estimates, in 2022 alone DeFi protocols lost about $403.2 million to oracle manipulation attacks across 41 separate incidents (this figure is explicitly labeled by Chainalysis as an estimate, and its statistical scope covers the entire DeFi ecosystem rather than being specific to perpetual futures) [23]. According to other estimates by security researchers, since 2020 oracle manipulation has accounted for about 15% to 20% of major DeFi security incidents (this proportion lacks a uniform definition of "major incident" and a public methodology, and should be treated with caution) [24]. The statistics above come mainly from publicly disclosed security-incident reports and on-chain data analysis, and the actual loss scale may be underestimated because of undisclosed incidents.

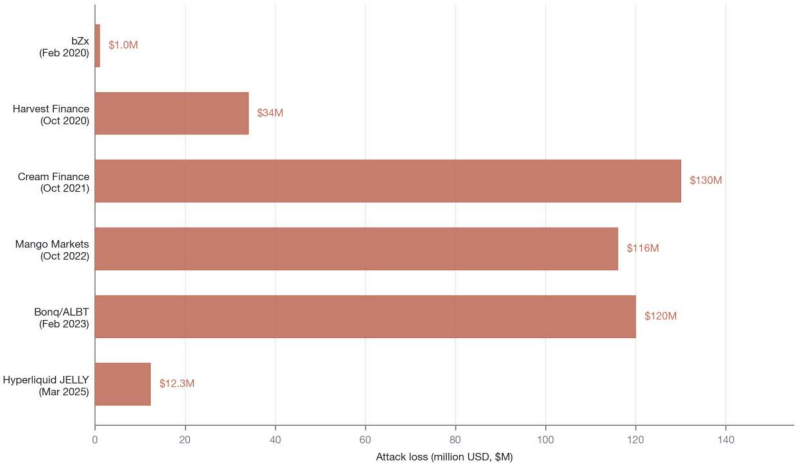

Figure 12-18. The loss scale of major oracle manipulation attacks in DeFi history (Bonq/ALBT's $120 million is the minted notional; constrained by wALBT liquidity, the actual amount extracted was about $1.7 million to $4 million)

Figure 12-18 shows the evolution of the loss scale of oracle manipulation attacks—from the millions to the hundreds of millions since the 2020 bZx incident—reflecting the persistent fragility of DeFi protocols in protecting against external price inputs.

The Mango Markets incident of October 2022 is a paradigmatic case of oracle manipulation. The attacker, Avraham Eisenberg, exploited the weak spot liquidity of the MNGO token to artificially manipulate the oracle price by building positions simultaneously in multiple markets, then used the inflated book profit to borrow various crypto assets worth as much as $116 million from the protocol [25]. Although the protocol's smart contract ran entirely according to its established rules, with no code vulnerability, the false price fed in from outside directly bankrupted the protocol. Eisenberg was charged by the U.S. Department of Justice in January 2023 with commodities fraud, commodities manipulation, and wire fraud, and was convicted by a jury in April 2024; but on May 23, 2025, the U.S. District Court for the Southern District of New York, invoking Rule 29 of the Federal Rules of Criminal Procedure, vacated all criminal convictions on the grounds of improper venue and insufficient elements of wire fraud (Mango Markets had no terms of service, did not prohibit the relevant operations, and had no repayment agreement, so there was no material misrepresentation); the prosecution has appealed, and as of this writing the case remains before the Second Circuit Court of Appeals [26][27].

Oracle risk poses a fundamental problem for insurance-fund governance: how should shortfall losses caused by non-market risk be handled? If the insurance fund pays out according to the established rules, then the attacker is in effect "legally" stealing funds from the insurance fund; if the platform chooses to intervene and refuse to pay, then we return to the discretion-abuse problem discussed earlier. There is no perfect solution to this dilemma; one can only reduce the probability of a successful attack through more refined oracle design (such as time-weighted average price, multi-source aggregation, and outlier filtering) while, through governance mechanisms, standardizing the trigger

conditions and execution process of emergency intervention.

12.4.4 The theory of incomplete contracts

To understand this governance dilemma deeply from a theoretical standpoint, we can invoke the "incomplete contracts" theory from economics. Proposed by Oliver Hart (co-winner of the 2016 Nobel Prize in Economics with Bengt Holmström) and John Moore, this theory holds that because of humans' bounded rationality and the unpredictability of the future, contracting parties cannot foresee, ex ante, all the situations that might arise and write them into the contract [28]. All contracts are therefore "incomplete" in essence.

In the cryptocurrency context, the smart contract is the ultimate embodiment of such an "incomplete contract." Although a smart contract is called a "contract," it is in fact merely a piece of computer code deployed on a blockchain. When writing the code, developers can only set parameters based on their understanding of past market behavior and their predictions of a limited set of future scenarios. They cannot foresee every form of market manipulation, hacker attack, or extreme black-swan event. When these situations not covered by the code occur, the smart contract exhibits a "blank" or "loophole." The developers of Mango Markets could not have foreseen that someone would manipulate the price of a small-cap token in such an extreme way; nor could Hyperliquid's designers have exhaustively enumerated every possible cross-chain attack vector in the code.

The Hart-Moore model further points out that when a contract is incomplete, the key question is who holds the "residual control rights"—the power to make decisions in situations the contract does not specify. On a traditional centralized exchange, the platform holds absolute residual control rights, which gives it great flexibility but also creates the platform moral hazard discussed earlier. In the ideal model of full decentralization, an attempt is made to eliminate residual control rights entirely, leaving everything to code execution. Because of the inherent incompleteness of smart contracts, however, completely eliminating residual control rights is impractical. When unanticipated events such as oracle failure or a market collapse occur, someone or some mechanism must handle the situations not covered by the code, exercising residual control rights to save the system.

This theoretical framework offers a key perspective for understanding the governance dilemma of crypto derivatives: the core of the problem is not "whether discretion is needed" but "how to allocate and constrain discretion." An ideal institutional design should follow a "two-tier architecture": in day-to-day operation, strictly adhere to the code rules to ensure certainty and fairness; and when a systemic crisis occurs, authorize a guarantor of last resort—constrained by strict procedures—to intervene, but with the scope of intervention, the trigger conditions, and the after-the-fact accountability mechanism all clearly specified in advance. This is precisely why even the most hardcore DeFi protocols ultimately tend to retain some form of governance mechanism or emergency pause function. The essence of the governance dilemma is how, under the ideal of decentralization, to appropriately allocate and constrain this unavoidable residual control right.

12.4.5 Information asymmetry and signaling games

Before turning to the governance spectrum, consider the deeper logic of insurance-fund governance from the perspective of information economics. In his seminal paper on the "market for lemons," George Akerlof revealed how information asymmetry leads to market failure: when the seller holds quality information that the buyer cannot observe, high-quality products are driven out of the market by low-quality ones [29]. Mapping this framework onto the governance of crypto derivatives insurance funds, the "lemon problem" appears in a distinctive form: the platform (the seller) holds the fund's true condition (including its actual balance, risk exposure, historical payout record, actuarial adequacy ratio, and other private information), while users and LPs (the buyers) can observe only the public signals the platform chooses to disclose selectively.

Under this information asymmetry, Spence's signaling-game theory [30] provides a key perspective for understanding platform behavior. A high-quality platform (with an adequate insurance fund and transparent governance) has an incentive to distinguish itself from low-quality platforms by sending "costly signals." These signals include publishing on-chain proof of reserves, or PoR (which can be independently verified and is costly to fake), accepting third-party actuarial audits (which require real data to support them), and encoding liquidation rules completely into auditable smart contracts (which, once deployed, cannot be unilaterally tampered with). These signals are effective because the cost for a low-quality platform (one whose fund is inadequate or that engages in misappropriation) to mimic them is extremely high: a platform with a fictitious insurance fund cannot pass the verification of on-chain proof of reserves, and a platform with opaque rules cannot bear the exposure risk of a smart-contract audit. The FTX case is precisely a cautionary counterexample: it sent false signals by fabricating insurance-fund data, and its eventual implosion proved that false signals are unsustainable in the long run.

The logic of signaling games leads directly to the analysis of the governance spectrum. The progression from G0 to G3 is, in essence, a gradual upgrade of the "quality signal" a platform sends to the market, from cheap talk to a verifiable commitment.

12.4.6 The governance spectrum G0–G3

Faced with the tension between rule rigidity and discretion, crypto derivatives platforms have not remained stuck in a black-or-white binary but have explored, in practice, governance models of varying degrees. Taking governance transparency, the degree of decentralization, and the constraints on discretion as yardsticks, one can depict a "governance spectrum" running from a fully centralized black box to fully on-chain autonomy. We can divide it into four main levels: G0 through G3 (Table 12-1). This classification framework echoes the verifiability ladder discussed in Chapter 5 of this book; the governance level of the insurance fund is, in essence, a key dimension of a platform's overall verifiability.

Level	Name	Transparency	Constraint on discretion	Representative platforms
G0	Fully opaque	Size/source/rules all undisclosed	No constraint whatsoever	Early BitMEX, FTX
G1	Size visible	Publishes PoR or on-chain balance	Governance process opaque	Binance, OKX (current)
G2	Size + rules visible	Rules encoded on-chain, auditable	Upgrade authority concentrated in the core team	Hyperliquid
G2–G3	Rules visible + partial on-chain governance	On-chain voting + timelock already running in production	Upgrade authority constrained by DAO governance, but emergency powers retained	dYdX v4
G3	Fully on-chain governance	Upgrades require community vote + timelock	Discretion programmatically constrained	Theoretical standard (none yet fully achieved)

Table 12-1. Definition of the G0–G3 insurance-fund governance spectrum and representative platforms (Data source: constructed by the author)

The G0 level represents fully opaque black-box governance. At this level, the insurance fund's size, funding sources, payout rules, and liquidation logic are all undisclosed. The platform operator holds absolute discretion subject to no oversight whatsoever. Early BitMEX and the later-collapsed FTX are typical representatives of this level. In the G0 model, users can only blindly trust the platform's moral integrity, and history has repeatedly shown that such trust is often betrayed, with serious consequences. The FTX insurance-fund fraud case shows that at the G0 level the insurance fund can even be entirely fictitious, with users utterly unable to detect it.

The G1 level introduces a preliminary degree of transparency and can be described as "size visible, governance opaque." Platforms at this level begin to publish proof of reserves periodically or disclose the on-chain wallet address of the insurance fund, allowing the public to verify that the funds truly exist. How these funds are used, however, along with the specific parameters of the liquidation engine and the decision process in emergencies, still rests in the hands of a centralized team. Most mainstream centralized exchanges on the market today, such as Binance and OKX, sit largely at this level. They build trust by displaying a huge insurance-fund size, but they still retain broad discretion in rule enforcement. The advance of G1 over G0 is that users can at least verify "whether the money is really there," though "how the money will be used" remains unknowable.

The G2 level is a key step toward decentralization, characterized by "both size and rules visible, but upgrade authority concentrated." At this level are mainly the new generation of decentralized derivatives protocols. They encode liquidation logic, penalty collection, and the insurance fund's operating rules completely into smart contracts deployed on-chain for anyone to audit. The system's day-to-day operation achieves "code is law." To cope with the risk brought by incomplete contracts, however, the core

team still retains the power to modify key parameters or upgrade contracts through means such as multi-signature. Hyperliquid's performance in the JELLY incident is a clear depiction of the G2 level: day-to-day operation is fully transparent and automated, but at the moment of crisis the validators (in substance controlled by the core team) can intervene in an emergency. This model represents a qualitative leap in transparency, but it still carries the single-point risk of the team acting unilaterally in bad faith or being coerced by regulators.

The G3 level represents the highest standard the industry is currently exploring: "fully on-chain governance with timelock constraints." At this level, not only are the rules and funds fully transparent, but residual control rights are handed to the decentralized community (usually through token voting). Any modification of system parameters, upgrade of contracts, or use of the insurance fund must go through an on-chain proposal and voting process. More importantly, the system introduces a timelock mechanism: after a vote passes, a change to the code must go through a mandatory waiting period (usually 24 to 72 hours) before taking effect. This gives users who disagree with the decision ample time to withdraw their funds, providing an exit-right guarantee of "voting with one's feet." dYdX v4, through its independent app-chain architecture based on the Cosmos SDK, is actively exploring this direction. The G3 model, through a programmatic democratic process and a time buffer, constrains the abuse of discretion to the greatest extent possible while preserving the system's elasticity.

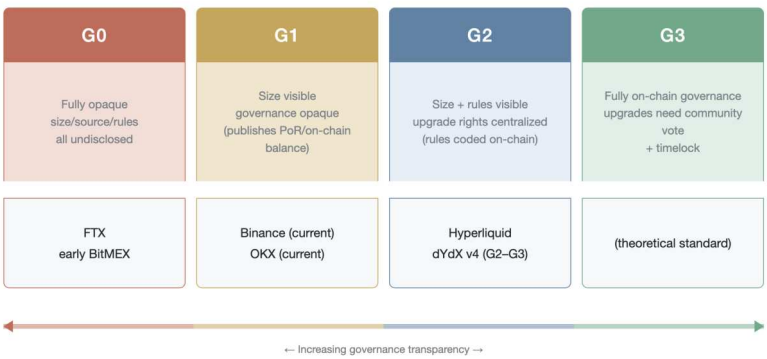

Figure 12-19. The governance spectrum of crypto derivatives platforms and the positioning of major platforms

Figure 12-19 shows the positioning of various platforms on the G0–G3 governance spectrum, with the industry as a whole exhibiting a gradual evolution from low to high transparency.

Even the G3 level, however, is not flawless. Fully on-chain governance faces real-world challenges such as low voter turnout, concentration of governance tokens, and insufficient emergency-response speed. When the system is under attack, waiting for a community vote and the expiry of the timelock may mean a delay of hours or even days, during which the attacker may already have completed the transfer of funds. Some protocols therefore introduce an "emergency multisig" as a safety valve within the G3 frame-

work, allowing intervention that bypasses the normal governance process in extreme situations, subject to after-the-fact community review and ratification. Although this design sacrifices some purity of decentralization, it strikes a pragmatic balance between practicality and safety. In addition, the DAO voting mechanism itself faces the challenge of various behavioral biases: the concentrated holding of governance tokens leads to "whale governance" (plutocratic governance), in which the interests of a few large holders may be systematically inconsistent with those of ordinary LPs (for example, market makers holding large amounts of governance tokens may vote against lowering the leverage cap, because high-leverage trading brings more fee income); chronically low voter turnout allows a few active participants to dominate decisions; and token holders may vote for short-term token-price gains rather than the system's long-term robustness. These behavioral factors mean that G3 may not always be superior in practice to a well-designed G2 mechanism.

Examining insurance-fund governance from a regulatory perspective is likewise important. The Principles for Financial Market Infrastructures, jointly issued by the Bank for International Settlements' Committee on Payments and Market Infrastructures and the International Organization of Securities Commissions, sets an international standard for the default management of central counterparty clearinghouses, requiring CCPs with more complex business risk or systemic importance across multiple jurisdictions to maintain prefunded resources sufficient to cover the "default of the two largest participants and their affiliates" scenario (the industry's "Cover 2" standard), while other CCPs must at least cover the default of the single largest participant ("Cover 1"; the EU's EMIR subsequently raised Cover 2 to a hard minimum for all CCPs within its jurisdiction). This standard provides a reference benchmark for assessing the adequacy of crypto derivatives insurance funds. Although a crypto-market insurance fund is not, in legal nature, a CCP guarantee fund, its functional role is closely analogous. At the regulatory-framework level, the EU's MiCA regulation (Regulation (EU) 2023/1114, in force June 29, 2023, with the core rules for crypto-asset service providers applying from December 30, 2024) imposes capital-adequacy and prudential-operation requirements on crypto-asset service providers, but its specific regulatory standards for derivatives insurance funds remain in the process of detailed rulemaking [31]. Platforms with lower governance transparency on the G0–G3 spectrum (G0–G1) may evade these requirements by registering in loosely regulated jurisdictions, creating a "regulatory arbitrage" in which a platform acquires users in strictly regulated markets while operating its core risk-management mechanism in a regulatory void. This arbitrage not only undermines the consistency of global financial stability but also makes cross-border regulation of insurance funds an urgent issue in crypto-finance regulation. Beyond the applicability of the regulatory framework, the legal characterization of the insurance fund itself carries unresolved uncertainty. Core disputes include: whether the insurance fund constitutes "client assets" and is thereby subject to stricter segregation and fiduciary obligations; the fund's legal position in the priority of claims in a platform's bankruptcy liquidation (as in the FTX case)—whether it is common property belonging to all traders or the platform's own asset; and how liquidation penalties are classified for tax purposes (insurance premium, fee, or fine), with different classifications carrying starkly different compliance obligations for the platform. The unresolved state of these legal

questions constitutes yet another dimension of uncertainty for the sustainability of the insurance-fund institution.

The progression from G0 to G3 is not merely an upgrade of technical architecture but a profound reconstruction of the trust mechanism of crypto derivatives markets. On this spectrum there is no absolutely perfect endpoint, only a process of continually seeking a better balance among transparency, efficiency, safety, and the ideal of decentralization. The governance of the insurance fund, like the weakest link in a chain, determines the ceiling of the entire platform's governance system. A platform that has achieved a high degree of transparency in both trade matching and asset custody will have the credibility of its whole system dragged down by this shortcoming if its insurance-fund management remains stuck at the G0 or G1 level. The political economy of insurance funds ultimately comes down to how, through institutional design, to build a governance consensus—in a market environment full of uncertainty—that can both withstand systemic collapse and defend against human greed.

12.5 An evaluation framework and cross-platform comparison

To comprehensively assess the merits of different derivatives platforms' insurance-fund mechanism designs, we must move beyond a single size metric and establish a multi-dimensional composite evaluation system. As argued in Section 12.1.3, simply comparing "whose insurance fund is larger" is not only superficial but potentially misleading: the platform with the largest absolute size does not necessarily have the greatest buffer thickness per unit of risk exposure. Through a systematic examination of four dimensions—capital adequacy, incentive compatibility, process quality and efficiency, and governance and verifiability—we can more clearly discern each platform's true defensive capacity in responding to extreme risk, and provide investors and protocol designers with a structured analytical tool.

12.5.1 Constructing the four-dimensional evaluation system

Capital adequacy is the primary basis for measuring an insurance fund's defensive capacity, and also the most intuitive but most easily misread dimension. This dimension involves three levels of examination. The basic metric is the ratio of the fund's size to the platform's total open interest; this relative metric reveals the thickness of the capital reserve per unit of risk exposure better than absolute size does. In traditional finance, central counterparty clearinghouses typically maintain strict margin and guarantee-fund ratios and conduct periodic stress tests to ensure solvency under extreme scenarios; in crypto markets, because asset volatility is higher, the market structure is more fragmented, and there is no unified regulatory standard, the reasonable range of this ratio is still being explored dynamically. Above this is stress-test coverage—whether the fund can cover the maximum total loss under historical extreme conditions (such as the "Black Thursday" of March 2020, the liquidation cascade of May 2021, and the "10/10 event" of October 2025) or under simulated future extreme scenarios. This requires combining the liquidation-reflexivity equation (and its divergence-criticality

condition) established in Chapter 11 with the tail-risk-distribution modeling of Section 12.3.5 of this chapter to make a quantitative estimate. Further, there is the reliability of the replenishment mechanism—whether, after the fund is substantially depleted in an extreme event, there is a clear, credible, and rapid recapitalization mechanism. An insurance fund that takes months to recover after a crisis will have its defensive capacity in successive extreme events greatly diminished.

Incentive compatibility examines whether a platform's mechanism can effectively align the interests of various participants with the system's long-term robustness. This dimension covers three key sub-metrics. The reasonableness of the liquidation-penalty structure is the first key point—whether the penalty effectively deters high-risk behavior without excessively punishing normal traders. Too low a penalty cannot constrain high-leverage speculation, while too high a penalty may cause traders to adopt a more aggressive "gamble it all" strategy as they approach the liquidation line, instead aggravating system risk. On this basis, the ability to suppress moral hazard is likewise important, particularly at the platform level—whether the platform aligns its own interests with the system's robustness through "interest-binding." If a platform controls the insurance fund but bears no risk of loss, then the fund may degenerate into a marketing tool or even a fraud tool. Finally, the degree of interest alignment is also a core consideration—whether the distribution of interests across funding sources, use rules, and value appreciation matches the actual risk-bearers. If liquidity providers bear high tail risk without receiving a corresponding risk premium, or if the platform lacks skin-in-the-game constraints when handling shortfall losses, such a mechanism will inevitably face the risk of collapse in extreme conditions.

Process quality and efficiency focuses on the liquidation mechanism's performance in actual operation, especially its response speed and execution accuracy in the face of extreme events such as network congestion, oracle latency, or malicious manipulation. This includes liquidation execution speed and slippage (whether risky positions can be disposed of quickly and effectively in extreme volatility without producing an excessive market impact); the shortfall rate and ADL frequency (as the ultimate outcome metrics of problems in the earlier layers of the liquidation chain, a higher shortfall rate means weaker upstream defenses of the liquidation mechanism); and system performance under extreme conditions (whether problems such as downtime, API latency, or unfillable orders occur). The market-wide liquidation cascade of October 10, 2025 (the "10/10 event") provides empirical data of significant analytical value for this dimension: in that event, several mainstream exchanges suffered varying degrees of system-performance degradation, and some platforms' liquidation engines had insufficient throughput to handle the instantaneous burst of forced-liquidation orders, causing shortfall losses far above normal levels [32].

Beyond the above four dimensions, an increasingly important but often overlooked supplementary dimension is the systemic risk contribution. As the crypto derivatives market grows in scale and cross-platform interconnection deepens, the failure of a single platform's insurance fund may produce spillover effects on the entire ecosystem through multiple transmission channels (including market makers' cross-platform exposure, systemic redemption pressure on stablecoins, and the cross-market spread of panic). Traditional finance has developed mature tools for measuring systemic risk:

among them, the CoVaR (conditional value at risk) proposed by Adrian and Brunnermeier [33] measures the increment in the entire system's value at risk when a single institution falls into distress, while the MES (marginal expected shortfall) proposed by Acharya et al. [34] measures a single institution's expected loss contribution during a systemic crisis. Transplanting these tools to the crypto derivatives domain makes it possible to assess the core question: "if platform X's insurance fund is broken through, how much additional risk will other platforms and the entire market face?" Directly transplanting these traditional tools, however, faces obstacles specific to crypto markets: the extreme insufficiency of transparency in cross-platform position data makes the conditional tail-dependence structure difficult to estimate; the crypto market's volatility-regime switches are more frequent, so conditional-quantile estimates based on historical data may lag severely; and the correlation among exchanges may be transmitted mainly through market makers' cross-platform inventory channel rather than through traditional balance-sheet linkages. Applying CoVaR and MES to the crypto derivatives domain therefore requires modeling adaptations tailored to the above distinctive transmission channels. Although the data availability and transparency of cross-platform positions remain major obstacles, the introduction of the systemic-risk-contribution dimension extends insurance-fund evaluation from "the robustness of a single platform" to "the resilience of the entire ecosystem," connecting with the logical framework of macroprudential regulation.

Governance and verifiability concern the transparency of the insurance fund and the certainty of rule enforcement. This requires not only that the fund balance be verifiable on-chain but also that the liquidation rules, the conditions for using funds, and the emergency-intervention mechanism have a high degree of transparency and predictability. Specifically, this dimension examines rule transparency (whether the inflow, depletion, and replenishment mechanisms of funds are public, clear, and codified), fund auditability (whether the balance and every income-and-expenditure flow can be independently verified in real time by a third party), and the governance mechanism for parameter changes (whether these are decided unilaterally by the platform or through a decentralized checks-and-balances process such as DAO voting). As the G0–G3 governance spectrum established in Section 12.4 of this chapter reveals, a platform's position on this spectrum—from a fully black-box operation (G0) to fully decentralized on-chain governance (G3)—directly determines whether it can maintain user trust at the moment of crisis. An "on-chain visible balance" does not equal "governance transparency"; a visible size with unverifiable use rules is still incomplete transparency. The insurance fund is usually the "weakest link" in a platform's governance chain, because it involves the largest scale of funds, the highest urgency of decisions, and yet transparency requirements that are often lowered in the name of "safety."

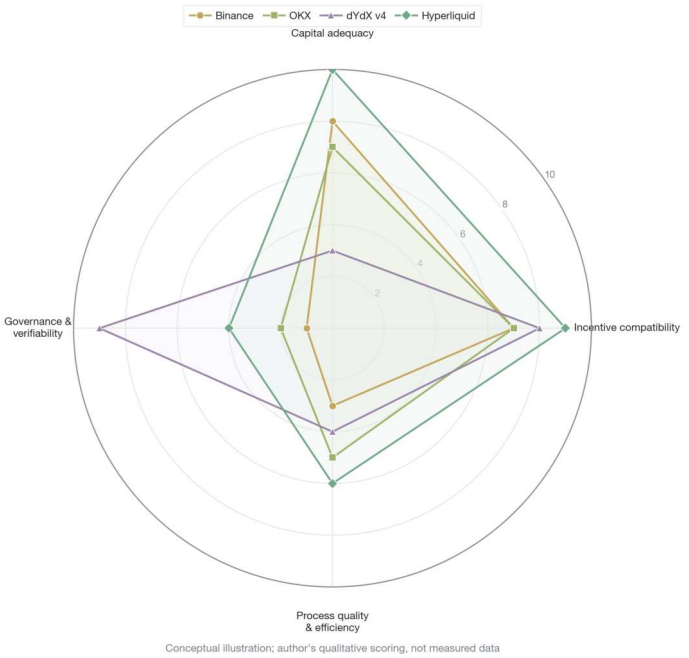

Figure 12-20. A four-dimensional radar chart of major derivatives platforms' insurance-fund mechanisms (conceptual illustration, qualitative scoring by the author, not measured data)

12.5.2 Platform comparison analysis

Figure 12-20 presents, in radar-chart form, the performance profile of each platform across the four dimensions: centralized platforms hold an advantage in capital adequacy but have a clear shortcoming in governance verifiability, while decentralized platforms exhibit the opposite pattern. Applying this four-dimensional evaluation framework to the current market's mainstream platforms, we can observe markedly different mechanism choices and capability emphases. No single platform holds an absolute advantage across all dimensions, and this "no-platform-optimal-on-all" pattern essentially reflects the deep trade-offs in insurance-fund design among capital efficiency, incentive compatibility, process reliability, and governance transparency.

Centralized exchanges, by virtue of their enormous trading volumes and long-term operational accumulation, possess insurance funds of enormous absolute size. According to public data from 2025–2026, Binance's futures insurance fund (an aggregation of segregated funds across contract groups, CoinGlass basis, as of 2025) has remained above $2.3 billion year-round and should be distinguished from its roughly $1 billion Secure Asset Fund for Users (SAFU) user-protection fund; it is the largest single futures insurance fund in the industry [35]. Because of its enormous open-interest base (total OI across all contracts of about $35 billion, fluctuating with market conditions), however, its fund-to-open-interest ratio typically holds around 6.6%. Binance's liquidation penalties adopt a tiered, escalating structure, setting different penalty ratios according to leverage and position size, which deters high-risk behavior to some extent. In terms of process quality, Binance's centralized matching engine performs relatively stably under normal market conditions. But in the 10/10 event, Binance too suffered API latency

and partial functional downtime, exposing its performance bottleneck under extreme load. In terms of governance and verifiability, Binance remains at the G0–G1 level: although some fund addresses have been made public, the rules for using the fund, the adjustment logic of liquidation parameters, and the emergency-intervention mechanism remain a black box to outside observers, and all parameter changes are decided unilaterally by the platform. OKX has not publicly disclosed the size of its futures liquidation insurance fund; the roughly $500 million it discloses (now expanded to over $700 million) is a Security Fund (mainly covering user losses from platform-side hacks and vulnerabilities, comparable to Binance's SAFU) and should not be used directly as a futures insurance fund or in a fund-to-open-interest ratio. OKX has made some improvements in transparency (disclosing more operational data), but its core governance mechanism remains controlled by the platform, and its overall evaluation is similar to Binance's.

Among decentralized derivatives protocols, dYdX v4, by deeply binding its insurance fund to the community treasury, has achieved a high degree of governance verifiability (G2–G3 level). Although its roughly $16 million insurance fund is relatively small in absolute size, with a fund-to-open-interest ratio of only about 2.0%, it is entirely controlled by DAO governance, and the rules for injecting and using funds are transparent and predictable [36]. The liquidation rules are fully codified, parameter changes require a DAO vote, and any community member can put forward a governance proposal and participate in the discussion. This highly transparent governance model puts dYdX v4 far ahead of its centralized competitors on the governance dimension. This community-treasury-based model of socialized risk-bearing, however, still has room for improvement in incentive compatibility: token holders passively bear the system's tail risk without a refined risk-pricing mechanism to compensate for it. In the 10/10 event, dYdX v4 experienced a chain halt, exposing its process-quality shortcoming under extreme load. Moreover, the low fund-to-open-interest ratio means its buffer space is limited in the face of a large-scale liquidation cascade, and the speed of its replenishment mechanism is also constrained by the DAO governance process.

Hyperliquid, for its part, has explored a new direction in market-based risk underwriting. Its HLP vault's total TVL was about $390 million in the second half of 2025 (peaking above $500 million on March 11, 2025, and falling back to about $270 million by mid-2026), and the fund-to-open-interest ratio calculated on this basis was as high as about 18.6% [37]. As noted in Section 12.1.3, however, using total HLP TVL as a whole as the insurance-fund size may overstate the actual risk-buffer thickness. Moreover, the tail risk of long-tail assets (such as low-liquidity meme coins like JELLY and POPCAT) is far greater than that of mainstream assets such as BTC/ETH, and the average ratio of 18.6% masks a coverage that may be severely inadequate for specific asset classes—precisely the "risk-pool commingling" problem revealed by the case studies in Section 12.6. More importantly, by opening its liquidation vault and allowing liquidity providers to participate in risk underwriting autonomously on market-based principles, Hyperliquid makes HLP's annualized return directly reflect the market's dynamic pricing of liquidation risk, creating a marked differentiation from other platforms in incentive compatibility. Its liquidation rules are on-chain verifiable, and the validator consensus mechanism provides a degree of decentralized checks and balances

on parameter governance, so its overall governance level sits at G2. As we see in the case in Section 12.6, however, this complex market-based mechanism still faces severe tests of process quality and efficiency in the face of extreme manipulation of long-tail assets: in the 10/10 event Hyperliquid triggered its ADL mechanism for the first time, and the 2025 JELLY incident further exposed the structural flaw of risk-pool commingling. In addition, although the validator consensus mechanism provides emergency-intervention capability, the degree of centralization and transparency of its decision process still needs improvement.

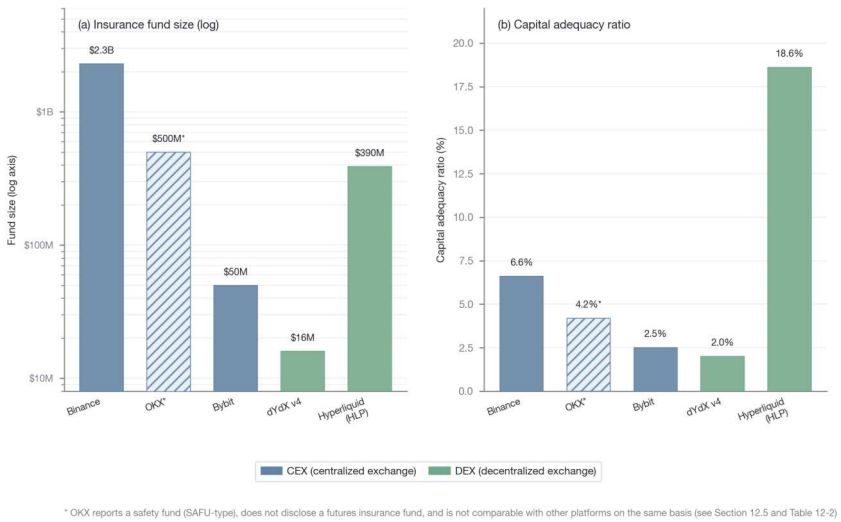

Figure 12-21. Comparison of major derivatives platforms' insurance-fund size and capital adequacy ratio (the capital adequacy ratio is the author's estimate; platforms do not publish this ratio; fund sizes are an as-of-2025 snapshot, and present values have since changed and are highly time-sensitive)

Figure 12-21 translates the above analysis into a visual comparison, intuitively confirming the earlier argument that "absolute size can be misleading" (see Section 12.1.3). Table 12-2 summarizes the systematic comparison of the four major platforms under the four-dimensional evaluation framework, providing readers with a structured frame of reference.

Evaluation dimension	Key metric	Binance	OKX	dYdX v4	Hyperliquid
Capital adequacy	Fund size	About $2.3 billion (futures insurance fund, distinct from the roughly $1 billion SAFU)	Not disclosed‡	About $16 million	HLP total TVL about $390 million (market-making + liquidation)†
	Fund-to-OI ratio	About 6.6%	Not comparable‡	About 2.0%	About 18.6% (upper-bound estimate based on total HLP TVL)†
	Replenishment mechanism	Opaque	Opaque	DAO governance	Market-based replenishment
Incentive compatibility	Penalty structure	Tiered, escalating	Tiered, escalating	On-chain rules	Uniform low fee
	Interest alignment	Low	Low	Medium	High
Process quality	10/10 event performance	Downtime and API latency	Partial latency	Chain halt	ADL triggered
	ADL frequency	Extremely rare	Extremely rare	Chain halt as substitute	First triggered in 10/10
Governance verifiability	Fund transparency	Black box (G0–G1)	Partially transparent (G1)	Fully on-chain (G2–G3)	On-chain verifiable (G2)
	Parameter governance	Platform decides unilaterally	Platform decides unilaterally	DAO vote	Validator consensus

Table 12-2. Four-dimensional evaluation summary of the four major platforms' insurance-fund mechanisms (Data source: compiled by the author from each platform's public documentation)

> Note: † HLP total TVL encompasses a shared capital pool for both the market-making and liquidation strategies, and using it as a whole as the insurance-fund size may overstate the actual risk-buffer thickness; 18.6% should be understood as an upper-bound estimate based on total HLP TVL (see Section 12.1.3). ‡ OKX has not publicly disclosed the size of its futures liquidation insurance fund; the roughly $500 million it discloses is a security fund (comparable to SAFU, covering platform hacks), not comparable on a like-for-like basis with other platforms' futures insurance funds, so the "fund size/ratio" columns are recorded as "not disclosed/not comparable."

Several key insights can be distilled from this cross-platform comparison. Capital adequacy and governance transparency currently exhibit an observable descriptive association in the market: the platforms with the largest capital tend to have the least transparent governance, while the platform with the most transparent governance has the smallest capital. This association, however, may mainly reflect historical path dependence rather than a causal institutional trade-off: centralized platforms were founded earlier and have operated longer, naturally operating in an opaque manner and accumulating a size advantage in the early industry environment that lacked DeFi

infrastructure; decentralized platforms are newer and have not yet experienced enough bull-and-bear cycles to accumulate a large-scale fund. Moreover, opaque and underfunded platforms (such as FTX) have already collapsed and are absent from the current sample, so survivorship bias may also distort the observed association. Whether, as decentralized platforms mature, a platform combining "high transparency plus high capital adequacy" will emerge and break the current association pattern is a proposition worth tracking over the long term. On this basis, a trade-off also exists between incentive compatibility and process reliability: Hyperliquid's market-based mechanism is more refined in incentive design than other platforms, but its complexity also brings a larger attack surface and more edge cases. On balance, no platform has reached an ideal level on all dimensions, and the choice depends on a user's prioritization of the different dimensions: a large institution pursuing capital safety may prefer Binance's absolute size, a DeFi-native user pursuing transparent governance may prefer dYdX v4, and a professional trader pursuing capital efficiency and innovative mechanisms may prefer Hyperliquid.

12.6 Case study: the JELLY incident

The merits of a theoretical framework must ultimately be tested by real market extreme stress. The series of risk events on the Hyperliquid platform in 2025—particularly the JELLY token manipulation case in March—offers us an extremely rare and research-worthy empirical case study. These events not only exposed the hidden fragility of a complex decentralized liquidation architecture but also laid bare the difficult choices decentralized governance faces at the moment of crisis, and further revealed the inherent limitations of a market-based risk-underwriting mechanism in the face of deliberate malicious gaming. The JELLY incident is worth studying in depth not only because of the sophistication of its attack method and the severity of its consequences, but also because it concentrates the technical design, governance mechanism, and political-economy tensions of the insurance fund in a single event, making it the fullest illustration of this chapter's theoretical arguments.

12.6.1 The HLP architecture

To understand the essence of the JELLY incident, we must first dissect the architecture of Hyperliquid Vaults. Hyperliquid's core innovation lies in its HLP vault system—a community-owned protocol vault that executes multiple automated strategies. After a user deposits USDC to become an LP, the capital is allocated across multiple sub-strategies, sharing the overall profit and loss of the strategy portfolio. Among the most critical sub-strategies are the market-making strategy (continuously providing two-sided quotes on the order book to earn the bid-ask spread) and the liquidation vault. The insurance-fund function is executed precisely as a core strategy embedded within HLP—namely, the liquidation vault. This design of integrating the market-making function and the insurance function within the same vault is the key feature distinguishing Hyperliquid from other protocols and the source of its high capital efficiency: the same pool of capital can both earn market-making returns and serve as a liquidation buffer when needed.

The liquidation vault was designed to solve the problem of liquidity evaporation in a decentralized order book under extreme conditions. Its risk-underwriting process follows a strict hierarchical logic: when a leveraged position's equity falls below the maintenance-margin requirement, the system first attempts to close it via a market order on the public order book—an open, competitive process in which any market participant can act as counterparty to absorb the liquidation order. If order-book depth is insufficient, or excessive price slippage drives the position's equity below two-thirds of the maintenance margin, the position is transferred directly to the liquidation vault. After the liquidation vault takes over all of the shortfall account's positions and remaining margin, it uses its enormous capital reserve to absorb the instantaneous shock, then gradually closes out the position in the market via an algorithm to minimize the damage to the market price. The profit or loss is shared by all HLP LPs [38]. The operating model of the HLP liquidation vault differs fundamentally from a centralized exchange's insurance fund. A CEX insurance fund typically uses a "deficit-covering" model: after the liquidation engine executes the closeout at market, the fund makes up the shortfall, and the fund itself bears no directional risk. The HLP liquidation vault, by contrast, uses a "position-takeover" model: it takes over the shortfall account's positions and remaining margin in full, bearing the market risk of holding directional exposure until it can gradually close out in the market. This design difference exposes HLP to an additional risk dimension that a CEX insurance fund does not face—"position-holding risk": in extreme conditions, the taken-over position may deteriorate further during the closeout process, and the JELLY incident is precisely the extreme manifestation of this risk dimension.

The design's strength lies in converting an instantaneous liquidation shock into a gradual release of liquidity, enhancing the system's antifragility. As a final line of defense, Hyperliquid also designed an auto-deleveraging mechanism: when the potential loss facing the liquidation vault exceeds a certain threshold, the system force-closes profitable users' positions to make up the liquidation loss, ensuring the protocol's overall solvency. Above ADL, there is also an ultimate discretion layer—the validator consensus mechanism—in which validators can decide by vote whether to carry out a special intervention. In theoretical reasoning, this four-tier defense system, composed of "order-book market closeout → liquidation-vault absorption → ADL ultimate risk-bearing → validator consensus," seems to construct a complete line of defense.

HLP's three major mechanism advantages earned it a high composite score in the evaluation framework of Section 12.5. First, market-based pricing of risk: HLP's annualized return directly serves as a dynamic risk-price signal—when the system faces higher liquidation risk, the higher return expectation attracts more risk-underwriting capital, and conversely it squeezes out excess capital, achieving a dynamic balance between the insurance fund's size and the actual risk exposure. Second, preliminary risk tiering and segregation: allowing users to create custom vaults focused on specific assets or strategies lays a foundation for more refined risk management in the future. Third, enhanced incentive compatibility: liquidation profits belong to the LPs, incentivizing the community to keep optimizing the liquidation strategy and turning risk management from "the platform's burden" into "the community's opportunity."

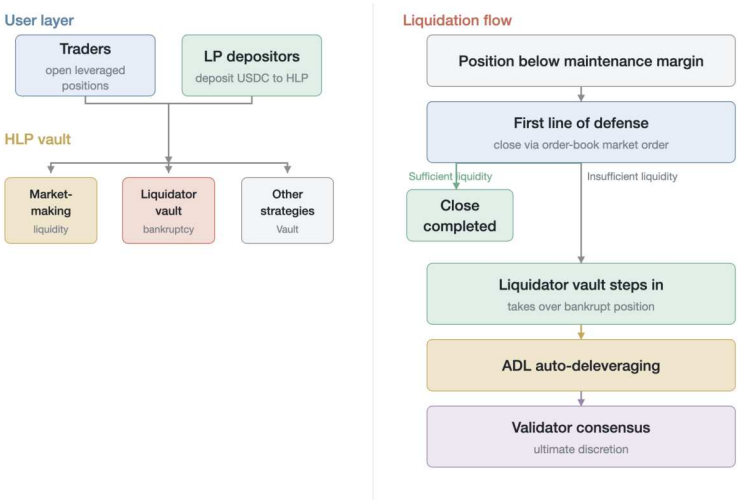

Figure 12-22. The risk-underwriting architecture and liquidation flow of Hyperliquid Vaults

Figure 12-22 presents, with arrows and threshold annotations, the direction of flow and the trigger conditions of this four-tier risk-underwriting architecture. The JELLY incident, however, proved that a significant gap exists between theory and practice.

12.6.2 Timeline of the incident

The JELLY incident of March 26, 2025, however, exposed a structural flaw in this defense system. JELLY was a meme coin issued via Pump.fun on the Solana chain, with a market capitalization of only about $10 million at the time and extremely scarce on-chain liquidity. The attacker precisely exploited a hole in Hyperliquid's risk controls for long-tail assets, carrying out a planned combined attack of cross-chain price manipulation and a liquidation-mechanism loophole [22]. The sophistication of this attack lay in the fact that it did not seek to profit from a directional bet on price but directly targeted the structural flaw of the liquidation mechanism itself.

In the setup phase of the attack, the attacker created three brand-new addresses on-chain and prepared several million dollars in capital. On Hyperliquid, targeting the low-liquidity JELLY, the attacker simultaneously opened a short position with a total value of about $4.5 million (concentrated in one address) and two long positions totaling about $5 million (spread across the other two addresses). This long-short hedged setup left the attacker's net risk exposure to JELLY price movements extremely small. The JELLY incident exposed not only a flaw in the liquidation architecture but, more fundamentally, an absence of basic operational risk controls. In traditional derivatives markets, the pattern of three newly created addresses simultaneously opening opposing enormous positions on the same low-liquidity instrument within a short time would immediately trigger a related-trading surveillance alert; a two-way position of $4.5 million/$5 million against JELLY's market capitalization of only about $10 million means that open interest approached the instrument's entire market capitalization—

an obvious manipulation warning signal; and the pattern of actively and gradually withdrawing margin is itself a clear signal of self-liquidation. The above basic anomaly-detection capabilities are standard equipment on traditional derivatives exchanges, and their absence on Hyperliquid reflects the systematic lag of decentralized platforms in building operational risk-control infrastructure. The real source of the attack's profit was not a directional bet on price but arbitrage against the liquidation mechanism itself—that is, by "injecting" a doomed-to-lose short position into the liquidation vault, then manipulating the price in the external market to make the liquidation vault bear an enormous loss, and finally realizing a net profit through the profit on the long positions.

Next came the liquidation-trigger phase. The attacker began to gradually withdraw margin from the address holding the short position, actively pushing that position toward the liquidation line. The key to this operation was "gradual withdrawal" rather than "one-time withdrawal": by precisely controlling the speed of margin withdrawal, the attacker ensured that the timing of the liquidation was precisely synchronized with the rhythm of the cross-chain manipulation. Because JELLY's depth on the Hyperliquid order book was extremely scarce (for a meme coin with a market capitalization of only $10 million, there was almost no counterparty on the order book capable of absorbing a liquidation order of several million dollars), the liquidation engine could not find sufficient liquidity in the market to complete the closeout. Following the system's design logic, this enormous short position was duly transferred to HLP's liquidation vault. At this point the attacker had successfully "injected" an enormous short risk exposure into HLP, and this was the most critical step in the entire attack chain.

At almost the same moment the short position was taken over by the liquidation vault, the attack entered the cross-chain price-manipulation phase. The attacker deployed enormous capital on a decentralized exchange on the Solana chain (mainly Raydium) to buy up JELLY spot frantically. Because JELLY's on-chain liquidity was extremely thin, this concentrated buying drove the token's price to surge by about 400% in an extremely short time [21]. This violent price swing was rapidly transmitted to the Hyperliquid platform via the oracle. The oracle was designed to ensure consistency between the on-chain price and the off-chain market price, but in this scenario the oracle faithfully relayed an artificially manipulated price signal, instead becoming an indispensable transmission tool in the attack chain. This link reveals a systemic risk in the cross-chain DeFi ecosystem: when a protocol's risk management depends on price signals from an external market, the manipulability of that external market becomes the protocol's security boundary.

As JELLY's price surged, HLP faced severe solvency pressure. The enormous short position the liquidation vault was forced to hold instantly produced about $12 million to $13.5 million in unrealized losses (OAK Research/Halborn put it at about $12 million; CoinDesk and perp.wiki put it at about $13.5 million, equivalent to a temporary drawdown of about 27% of the HLP vault). This figure was nearly enough to exhaust the entire HLP vault's liquidity buffer. At this point, the system should have triggered the ADL mechanism to resolve the crisis—that is, to make up the liquidation loss by force-closing profitable users' positions. A serious architectural flaw, however, caused the ADL mechanism to fail completely.

ADL's trigger logic is based on the ratio of the liquidation vault's unrealized loss to its corresponding capital pool exceeding a preset threshold. In the system design at the time, however, the liquidation vault's capital pool was not fully segregated from the HLP main pool; the liquidation vault was merely a sub-strategy within HLP, not an independent capital entity. This meant that the denominator of the ADL trigger ratio was set to the entire HLP vault's enormous total assets (hundreds of millions of dollars), rather than the liquidation vault's own standalone capital. Against HLP's capital pool of hundreds of millions of dollars, the $12.3 million loss did not reach the ADL trigger threshold. The after-the-fact fix, which segregated the liquidation vault independently, greatly shrank the denominator of the ADL trigger ratio, markedly improving the safety valve's sensitivity. But the specific trigger-threshold value has not been publicly disclosed to the community; Hyperliquid's documentation describes only the general condition that ADL activates when "account value or the value of an isolated position becomes negative," without giving the precise ratio parameter—itself a transparency issue that needs continual improvement in G2-level governance. The system fell into a contradictory deadlock: an enormous shortfall loss was genuinely occurring, yet the final safety valve remained silent because "the pool was too big." This is precisely the fatal manifestation, under extreme conditions, of the "risk-pool commingling" problem analyzed in this section: the capital of the market-making strategy and the capital of the liquidation strategy were mixed in the same pool, weakening the risk signal and lowering the sensitivity of the safety mechanism.

Faced with the imminent systemic solvency crisis, the Hyperliquid team activated the final tier of the four-tier defense system: the validator consensus mechanism. Within just a few minutes of the crisis erupting, the platform's validators unanimously passed an emergency resolution: to disregard the real market price relayed by the oracle and forcibly overwrite JELLY's settlement price to $0.0095, the level before the manipulation occurred. Based on this artificially set price, the system forcibly closed all related positions, instantly eliminating HLP's book loss of over ten million dollars. The essence of this operation was that the validators collectively exercised a "price discretion," replacing the market price and oracle data with human judgment to preserve the system's overall solvency. In the cleanup phase after the crisis was resolved, Hyperliquid gave a full refund to all innocent JELLY long holders at the fair market price before the event, ensuring that ordinary users did not suffer losses because of the platform's mechanism flaw. The attacker's accounts were frozen, with a final net loss of about $910,000 (Arkham basis, an upper-bound estimate under the scenario that the frozen funds cannot be recovered) [21]. Specifically, the attacker's profit-and-loss structure was roughly as follows: the short position lost all of its margin because of the actively triggered liquidation; the two long positions produced a considerable book profit after the price surged, but the validators' price rollback forcibly restored the settlement price to the pre-attack level, wiping out most of the longs' profit; and the buying slippage on Raydium during the cross-chain price manipulation constituted an additional execution cost. The $910,000 net loss was the final result after netting the above items. A counterfactual analysis reveals the economic impact of the intervention: had the validators not intervened, the attacker's net gain—the long profit minus the short loss and manipulation cost—could have been as high as several million dollars, while HLP would

have suffered an actual loss of about $12.3 million. From a purely economic standpoint, the attacker's attack did not succeed in turning a profit; but from the standpoint of system security, the architectural flaw the attack exposed was far more serious than the $910,000 direct loss.

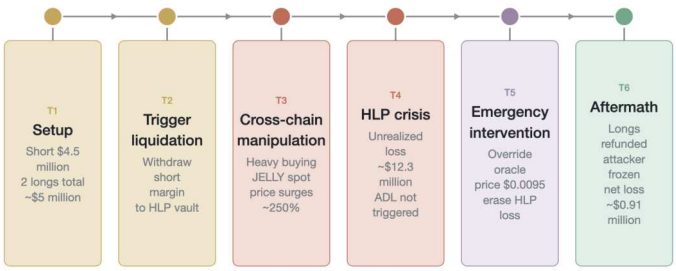

Figure 12-23. Timeline of the JELLY incident's cross-chain manipulation and crisis evolution (the "price surge of about 250%" in the figure is the gain in the initial manipulation window; the cumulative gain to the validator-consensus overwrite point was about 429%, and the "about 400%" in the text lies between the two, reflecting the difference in scope across different time windows of the same event)

Figure 12-23 integrates the time points of each phase, the key operations, and the flow of funds into a complete timeline. The entire attack, from setup to resolution, lasted less than a few hours, showing how fast risk evolves in a cross-chain DeFi environment.

The JELLY incident was not an isolated event but the climax of a series of risk events Hyperliquid experienced in 2025. Earlier, on March 12, 2025, Hyperliquid had already experienced a large whale-manipulation event: a trader used 50x leverage to open a long ETH position of more than $300 million and then triggered liquidation by strategically withdrawing margin, causing HLP to suffer a loss of about $4 million [39]. Although the loss was relatively limited, this event had already exposed HLP's fragility in the face of large directional manipulation and sparked wide community discussion of HLP's safety. And in November 2025, after the JELLY incident, the POPCAT incident further exposed a similar fragility, though its attack vector differed from JELLY's: the attacker withdrew about $3 million in USDC from OKX, split it across 19 wallets, built a POPCAT long with high leverage, placed a fake buy wall of about $20 million on Hyperliquid's own order book to fabricate demand, then abruptly canceled the orders, triggering a liquidation cascade of its own longs and forcing HLP to absorb about $4.9 million in bad debt; the attacker went ahead knowing full well that they would lose all of their roughly $3 million in margin. POPCAT was an on-platform order-book spoofing combined with liquidation-mechanism arbitrage, and did not involve JELLY-style cross-chain spot/oracle manipulation; the two share the common feature of targeting thinly liquid meme coins and being willing to sacrifice their own principal to spill losses onto HLP, and on-chain clustering suggests the two likely came from the same attacker cluster. This "harm yourself to harm others" strategy shows that for premeditated, cost-insensitive directional manipulation, a market-based risk-underwriting mechanism still faces severe challenges: when an attacker's goal is not to profit but to destroy, a defense mechanism based on the assumption of economic rationality will face fundamental

failure.

The POPCAT incident is especially worth analyzing in depth because it occurred after Hyperliquid had implemented a series of fixes in response to the JELLY incident. The three core improvements introduced after the JELLY incident (asset segregation of the liquidation vault from the HLP main pool, dynamic position caps based on market capitalization and order-book depth, and a validator-vote delisting mechanism) all failed to effectively defend against the attack in the POPCAT incident. Asset segregation did allow the ADL mechanism to trigger at an appropriate threshold, avoiding the "pool too big so the safety valve stays silent" problem of the JELLY incident; the dynamic position cap, however, was circumvented by the attacker through dispersing addresses and building positions gradually, and the validators' delisting vote failed to start in time before the loss occurred because of the ambiguity of judging "whether an attack has already happened." This outcome reveals a fundamental limitation of institutional evolution: each round of fixes is essentially a targeted patch against the "last attack vector," while an adaptive attacker actively seeks new attack surfaces. This "attack → patch → new attack" evolutionary dynamic is highly isomorphic to the Red Queen effect in biology: the defender must keep evolving merely to maintain the same relative position against the attacker. From the standpoint of economic theory, this evolutionary dynamic can be understood more precisely as a manifestation of Goodhart's law: when the defense rule (the "measure") is transparently made public, the attacker (the "agent") will adjust its strategy specifically to render that rule ineffective. The logic of the Lucas critique applies equally: a defense strategy formulated on the basis of historical attack patterns will change future attack patterns because of the attacker's expectations about the strategy itself. For a decentralized protocol, this means that risk management cannot rely solely on after-the-fact patching of vulnerabilities but must establish a systematic adversarial mindset: incorporating "how an attacker would exploit this rule" as a core consideration at the mechanism-design stage, and reserving sufficient institutional elasticity for unknown attack vectors.

Event	Whale incident March 12, 2025	JELLY incident March 26, 2025	POPCAT incident November 12, 2025
Trigger asset	ETH	JELLY (memecoin)	POPCAT (memecoin)
HLP loss	~$4 million	peak ~$12.3 million final ~$0 (intervention)	~$4.9 million
Key magnitude	LP withdrawals ~$130 million	final actual loss ~$0	attacker input ~$3 million
Confidence/cost	confidence leverage ~30×	attack cost ~$0.91 million	attacker strategy self-harm to hurt others
Intervention	none (market absorbs)	validators override oracle	manual close + pause bridge
Aftermath	LP confidence shaken	decentralization dispute	mechanism still fragile

Figure 12-24. A comparison of Hyperliquid's three major risk events in 2025

Figure 12-24 provides a structured comparison of the three events across four dimensions: time, attack method, loss scale, and platform response. From it one can observe three progressive trends: the complexity of the attacks escalated from single-platform manipulation (the March 12 whale incident) to more complex attacks on thinly liquid meme coins, with JELLY embodying cross-chain spot/oracle manipulation and POPCAT embodying on-platform order-book spoofing combined with liquidation-mechanism arbitrage; the attackers' risk appetite shifted from arbitrage-for-profit to a cost-insensitive destructive strategy (the POPCAT attacker was willing to sacrifice about $3 million in principal); and the platform's response also evolved from passively absorbing the loss (the whale incident) to actively intervening in the price (the JELLY incident) and after-the-fact architectural reform. This evolutionary path shows that a market-based risk-underwriting mechanism must iterate its defensive capabilities in lockstep when facing continually evolving adversarial attacks.

12.6.3 The boundaries of decentralized governance

The JELLY incident is a textbook "incomplete contracts" case, proving that no rule system designed in advance can exhaust all malicious attack vectors. No matter how sophisticated the code, there always exist edge cases the rule-makers did not foresee. When such an edge case occurs, the system ultimately relies on a "guarantor of last resort" holding discretion. In traditional finance, this role is played by the central bank or the regulator; in Hyperliquid's case, this role is borne collectively by the validators. This fact pushes decentralized derivatives platforms into a fundamental dilemma, which can be stated precisely as follows: should a protocol whose core narrative is "decentralization" and "code is law" possess an emergency centralized "circuit breaker" when facing an attack capable of destroying it? If the answer is yes, then who should hold this circuit breaker? What are the trigger conditions? And how can its abuse be prevented? If the answer is no, then should the protocol accept the possibility of being destroyed by a deliberate attacker in order to preserve the purity of its decentralization?

Hyperliquid's answer is "validator consensus"—a middle path between fully centralized decision-making and fully ungoverned operation. Validators, as stakeholders in the protocol (typically required to stake a large amount of tokens), have an incentive to maintain the protocol's long-term health. By requiring a unanimous or supermajority vote to pass, this mechanism in theory both preserves the capacity for emergency intervention and reduces the risk of single-point abuse through collective decision-making. It must be squarely acknowledged, however, that when the JELLY incident occurred (March 2025, before the permissionless validator set had gone live, when the network still ran a small foundation-bootstrapped validator set), the Hyper Foundation controlled about 81% of the staked HYPE tokens, and the participation of external independent validators was extremely low. It was precisely this highly concentrated validator structure that allowed the emergency resolution to reach "unanimous passage" with zero opposition in about 2 minutes—a speed that in substance is closer to "a unilateral decision by the core team" than to genuine decentralized consensus. This reality means that Hyperliquid's actual position on the governance spectrum may be closer to G1–G2 than to G2. After the incident, the validator set was expanded to 16 nodes, but the foundation still operates five of them and controls the majority of staked tokens, and

the node software remains closed-source. As the validator set decentralizes further, the credibility of this governance mechanism will rise accordingly, but the governance practice at the current stage should be evaluated as it truly is. In the JELLY incident, the validators' decision process was still highly centralized: the decision was made within a few minutes, the community had no time to participate in discussion, and the basis and process of the decision were not adequately recorded or made public. This "act first, explain later" model, though it saved the protocol at the moment of crisis, also posed a severe challenge to the platform's "decentralization" narrative. Critics point out that if validators can overwrite the oracle price and force liquidation within a few minutes, then what is the essential difference between this and the backroom operations of a centralized exchange?

This incident sparked a fierce debate in the community. Supporters argue that in the face of a deliberate malicious attack, protecting the interests of the protocol and users is the highest priority, and the validators' intervention was necessary and justified—just as central banks in traditional finance hold "lender of last resort" discretion during a systemic crisis. Opponents argue that this intervention undermined the fundamental principle of "code is law" and planted the seeds for future selective enforcement and conflicts of interest: if validators can overwrite prices in some situations, then who guarantees they will not abuse this power in other situations for their own benefit?

From a more macro perspective, the JELLY incident reveals an institutional reality of the current stage of DeFi development: absolute decentralization is difficult to achieve fully under current technical conditions. Almost all successful financial systems, whether traditional or crypto, maintain a fragile but necessary balance between rule rigidity and ultimate discretion. Traditional-finance CCPs have "default management committees" to handle extreme situations the rules cannot cover; central banks around the world hold "lender of last resort" discretion to respond to systemic crises; and even Ethereum itself once used a hard fork to "roll back" stolen funds after the 2016 DAO attack. Hyperliquid's validator consensus mechanism is, in essence, a preliminary but necessary practice of this age-old wisdom in a decentralized context. From an operational-security standpoint, the emergency-intervention mechanism itself also constitutes an attack surface: if an attacker could gain control of enough validators' keys or voting power through social engineering or technical means, they could exploit the same emergency-intervention mechanism to carry out a more destructive attack. Moreover, the process of validators completing a unanimous vote "within a few minutes" implies an efficient but possibly insecure communication channel (such as a Telegram group), and whether such channels themselves become a security hazard is worth examining. The design of an emergency-intervention mechanism must solve not only the governance problem of "who has the authority to intervene" but also the operational-security problem of "how the intervention process itself is protected."

After the incident, Hyperliquid quickly implemented a series of systematic fixes, seeking to plug the exposed loopholes without abandoning the market-based risk-underwriting model. It strictly segregated the liquidation vault's assets from the HLP main pool and set an independent ADL trigger threshold for the liquidation vault, thoroughly fixing the mechanism failure caused by risk commingling: this means that even if the liquidation vault's loss is negligible relative to HLP's total assets, ADL will be triggered

as soon as it exceeds the threshold relative to the liquidation vault's own capital. On this basis, it introduced a dynamic position-cap formula based on real market capitalization and order-book depth, curbing the excessive leveraging of long-tail assets at the source: if a token's market capitalization is only $10 million, the system will no longer allow the accumulation of open interest of several million dollars on that instrument, so that an attacker cannot build an enormous position on a low-liquidity asset large enough to threaten the system. Third, it granted validators the power to delist abnormal assets through an on-chain vote, providing an institutionalized tool for responding to similar long-tail-asset manipulation in the future [40].

The POPCAT incident of November 2025, however, showed that although these fixes plugged the specific loopholes exposed in the JELLY incident, they did not fundamentally resolve the fragility of a market-based risk-underwriting mechanism in the face of deliberate manipulation. When an attacker is willing to bear a net loss of several million dollars to create larger-scale systemic destruction, any defense mechanism based on the assumption of economic rationality will face a challenge. This recognition leads us to a deeper proposition: the design of an insurance-fund mechanism is not only a problem of technical optimization but also a political-economy problem concerning risk, power, and trust. As the chapter title reveals, the insurance fund is the node where "technical design" and "political governance" intersect most deeply in the perpetual-futures system; its technical dimension can be optimized with actuarial models, but its governance dimension involves questions of power, trust, and the distribution of interests—questions that cannot be solved by code, but only constrained by institutions.

12.7 Chapter summary

With this, we have completed a systematic analysis of the institutional arrangement that is the insurance fund. As the concluding piece of Part Four, "Design: The Core Mechanisms of Perpetual Futures," this chapter extends the risk management of perpetual futures from the purely technical level to the institutional level of interest gaming, power distribution, and trust-building. The insurance fund and auto-deleveraging together constitute a dual socialization mechanism for responding to extreme risk. Through ex ante pooling, the insurance fund absorbs within the system the negative externalities generated by high-leverage trading, and its core output is not investment return but the irreplaceable settlement credibility and rule predictability—the concrete embodiment, in the crypto derivatives domain, of the core function of financial market infrastructure emphasized in the Bank for International Settlements' Principles for Financial Market Infrastructures. And when this mechanism's funds are exhausted, ADL, as the ultimate means of ex post allocation, is forced to activate, always facing an irreconcilable trilemma among solvency, long-term revenue, and user fairness. The roughly $650 million in excess haircut in the 10/10 event, and the near-zero profit-to-loss symmetry ratio, reveal through empirical data the fundamental inadequacy of static ADL strategies in the face of complex market environments.

The confidence-as-liquidity hypothesis proposed in this chapter reveals the deeper economic significance of the insurance fund. The fund's signaling function is far more important than its mere capacity to absorb capital. The empirical evidence from the

Hyperliquid whale incident—"a $4 million actual loss triggering $130 million in panic withdrawals"—displays a correlational amplification effect of about 32.5 times, far exceeding the amplification of any capital leverage (although this factor may be affected by contemporaneous macro factors, social-media information cascades, and other confounders). The nonlinear "cliff effect" between confidence and the adequacy ratio shows that managing confidence is, in essence, the highest-order form of risk management.

The actuarial adequacy-ratio model transforms the vague qualitative question of "whether the fund is large enough" into a rigorous quantitative analysis based on the tail-risk distribution. The procyclical paradox that the adequacy ratio exhibits, however (accumulating when it is least needed and drying up when it is most needed), directly reveals the structural defect of relying on liquidation penalties as a single revenue source. The maturity mismatch between "the gradual accumulation of revenue" and "the sudden eruption of expenditure" is a fundamental challenge that insurance-fund design must squarely confront.

In addition, the existence of an insurance fund inevitably breeds a dual moral hazard: traders tend to take on greater risk because of implicit risk-bearing, while platform operators face the temptation to misappropriate funds or abuse discretion. The extreme case of FTX fabricating its insurance fund warns us that "being insured" by no means equals "being safer"; insurance itself may create new systemic risk. We therefore introduced the G0-to-G3 governance spectrum, pointing out that the governance of the insurance fund is often the weakest link in a platform's entire verifiability ladder. Visible size does not equal transparent rules; only when the process is open to scrutiny can trust be established.

Based on the above insights, we distill five design principles for building a robust mechanism: risk must be precisely priced to eliminate cross-subsidies; the platform's interests must be deeply bound to the system's robustness to preclude moral hazard; the operating process must have an extremely high degree of verifiability to establish trust; complex risks must be finely tiered and segregated to prevent contagion; and, at the same time, the "guarantor of last resort" holding ultimate discretion must be acknowledged and severely constrained by institutions. Figure 12-25 integrates the causal chain of the three chapters of Part Four into a single complete arc—from the routine regulation of the funding rate, to the eruption of a liquidation cascade, to the absorption by the insurance fund and the final allocation by ADL—intuitively presenting the hierarchical progression among these mechanisms.

Figure 12-25. The complete causal arc of Part Four

With the end of this chapter, the complete arc of Part Four is now closed. We have clearly seen a tight causal chain: from the routine regulatory function of the funding rate in Chapter 10, to the systemic imbalance triggered when the rate mechanism fails under extreme conditions; from the continuous depletion of margin, to the large-scale chain liquidation and cascade reflexivity triggered by the liquidation engine in Chapter 11; and when this series of shocks finally breaks through individual defenses and produces a shortfall gap, this chapter's insurance fund steps in as a risk-absorption layer to fill the loss; and once the fund is exhausted, ADL, as the ultimate risk-allocation mechanism, forcibly apportions the loss to profitable traders. These three chapters are not a parallel enumeration of three independent mechanisms but a complete life-cycle narrative running from normal operation to extreme collapse to crisis cleanup. The design quality of this set of core mechanisms directly determines the safety, capital efficiency, and basic fairness of perpetual futures as a financial product, and it lays a systematic mechanistic foundation for our subsequent discussion of the market's price discovery, arbitrage behavior, liquidity evolution, and volatility characteristics.
